To my two girls, Angela and Stephanie

The first half of the year 2009 was the hardest time in my life — a trip through hell and back. I cannot thank Angela enough for all her love and support she gave to me. Without her I couldn't have made it through that. Stephanie was born shortly after medical treatment and was the biggest motivation during that time.

I love you both!

—Christian Nagel

To Tuija, always.

—Bill Evjen

For donna

—Karli Watson

Dedicated to my parents, Joan & Donald Skinner.

There are many things that I'd like to say to my Mum and Dad, but I'm in the privileged position of not needing to say anything to them. They were both wonderful people, are greatly missed, and the world was made a sweeter place by their being in it. Thanks Mum, thanks Dad, you were brilliant.

—Morgan Skinner

ABOUT THE AUTHORS

CHRISTIAN NAGEL is a Microsoft Regional Director and Microsoft MVP, an associate of thinktecture, and owner of CN innovation. He is a software architect and developer who offers training and consulting on how to develop Microsoft .NET solutions. He looks back on more than 25 years of software development experience. Christian started his computing career with PDP 11 and VAX/VMS systems, covering a variety of languages and platforms. Since 2000, when .NET was just a technology preview, he has been working with various .NET technologies to build numerous .NET solutions. With his profound knowledge of Microsoft technologies, he has written numerous .NET books, and is certified as a Microsoft Certified Trainer and Professional Developer. Christian speaks at international conferences such as TechEd and Tech Days, and started INETA Europe to support .NET user groups. You can contact Christian via his web sites, `www.cninnovation.com` and `www.thinktecture.com`, and follow his tweets on `www.twitter.com/christiannagel`.

BILL EVJEN is an active proponent of .NET technologies and community-based learning initiatives for .NET. He has been actively involved with .NET since the first bits were released in 2000. In the same year, Bill founded the St. Louis .NET User Group (`www.stlnet.org`), one of the world's first such groups. Bill is also the founder and former executive director of the International .NET Association (`www.ineta.org`), which represents more than 500,000 members worldwide.

Based in St. Louis, Missouri, Bill is an acclaimed author and speaker on ASP.NET and Web Services. He has authored or coauthored more than 20 books including *Professional ASP.NET 4*, *Professional VB 2008, ASP.NET Professional Secrets, XML Web Services for ASP.NET*, and *Web Services Enhancements: Understanding the WSE for Enterprise Applications* (all published by Wiley). In addition to writing, Bill is a speaker at numerous conferences, including DevConnections, VSLive, and TechEd. Along with these activities, Bill works closely with Microsoft as a Microsoft Regional Director and an MVP.

Bill is the Global Head of Platform Architecture for Thomson Reuters, Lipper, the international news and financial services company (`www.thomsonreuters.com`). He graduated from Western Washington University in Bellingham, Washington, with a Russian language degree. When he isn't tinkering on the computer, he can usually be found at his summer house in Toivakka, Finland. You can reach Bill on Twitter at @billevjen.

JAY GLYNN is the Principle Architect at PureSafety, a leading provider of results-driven software and information solutions for workforce safety and health. Jay has been developing software for over 25 years and has worked with a variety of languages and technologies including PICK Basic, C, C++, Visual Basic, C# and Java. Jay currently lives in Franklin, Tennessee with his wife and son.

KARLI WATSON is consultant at Infusion Development (www.infusion.com), a technology architect at Boost.net (www.boost.net), and a freelance IT specialist, author, and developer. For the most part, he immerses himself in .NET (in particular C# and lately WPF) and has written numerous books in the field. He specializes in communicating complex ideas in a way that is accessible to anyone with a passion to learn, and spends much of his time playing with new technology to find new things to teach people about.

During those (seemingly few) times where he isn't doing the above, Karli will probably be wishing he was hurtling down a mountain on a snowboard. Or possibly trying to get his novel published. Either way, you'll know him by his brightly colored clothes. You can also find him tweeting online at www.twitter.com/karlequin, and maybe one day he'll get round to making himself a web site.

MORGAN SKINNER began his computing career at a young age on the Sinclair ZX80 at school, where he was underwhelmed by some code a teacher had written and so began programming in assembly language. Since then he's used all sorts of languages and platforms, including VAX Macro Assembler, Pascal, Modula2, Smalltalk, X86 assembly language, PowerBuilder, C/C++, VB, and currently C# (of course). He's been programming in .NET since the PDC release in 2000, and liked it so much he joined Microsoft in 2001. He now works in premier support for developers and spends most of his time assisting customers with C#. You can reach Morgan at www.morganskinner.com.

ABOUT THE TECHNICAL EDITORS

ALEXEI GORKOV is the chief software engineer at EPAM Systems (www.epam.com), a leading software development outsourcing company in Central and Eastern Europe. He has worked with .NET since 2004 and as a front-end developer involved in development of web portals and line-of-business web applications using Microsoft technologies. Over the past four years, he has edited more than a dozen programming books from Wiley Publishing on ASP.NET, Ajax, JavaScript, CSS and XML. He lives in Saratov, Russia.

MITCHEL SELLERS is the CEO of IowaComputerGurus Inc. His extensive experience in software development has lead to a focus on proper architecture, performance, stability, and overall cost effectiveness of delivered solutions. He is the author of *Professional DotNetNuke Module Programming* and many technical articles, and is currently working on his next book, *Visual Studio 2010 and .NET 4 Six-in-One*, scheduled for publication by Wiley in early 2010. He is a regular speaker at user groups and conferences.

Mitchel is a Microsoft C# MVP and a Microsoft Certified Professional, an active participant in the .NET and DotNetNuke development communities, and a DotNetNuke Core Team member. For more information, see his resume at MitchelSellers.com.

ACKNOWLEDGMENTS

THANKS TO ALL AT WILEY for your patience when I started working later on the book than I had expected and planned. Special thanks to Sara Shlaer who was of great support with the time pressure and the change of the Wrox style. Similar to the authors, she worked many weekends to get the book out on time.
Many thanks!

—Christian Nagel

THANKS TO SARA SHLAER, Paul Reese, and Jim Minatel for the opportunity to work on such a great book, and to the technical editors, Alexei Gorkov and Mitchel Sellers, for their excellent work. In addition to my co-authors, I would like to thank my family for putting up with all the writing. Thank you Tuija, Sofia, Henri, and Kalle!

—Bill Evjen

I WOULD LIKE TO THANK Sara Shlaer, Paul Reese, and the rest of the team at Wrox for all the help they provided. I would also like to thank my wife and son for putting up with the nights and weekends lost to the computer. They are my inspiration.

—Jay Glynn

THANKS TO ALL AT WILEY for their support and assistance on this project, as well as their understanding and flexibility in dealing with an author who never seems to have enough time to write. Special thanks to Sara Shlaer — one of the best and friendliest editors I've had the pleasure to work with. Also, thanks to friends, family, and work colleagues for understanding why I haven't had time for much socializing lately, and to donna, as always, for all her support and for putting up with all the late nights.

—Karli Watson

CONTENTS

INTRODUCTION

IF WE WERE TO DESCRIBE THE C# LANGUAGE AND ITS ASSOCIATED ENVIRONMENT, the .NET Framework, as the most significant technology for developers around right now, we would not be exaggerating. .NET is designed to provide an environment within which you can develop almost any application to run on Windows, while C# is a programming language that has been designed specifically to work with the .NET Framework. By using C#, you can, for example, write a dynamic web page, a Windows Presentation Foundation application, an XML Web service, a component of a distributed application, a database access component, a classic Windows desktop application, or even a new smart client application that allows for online/offline capabilities. This book covers the .NET Framework 4. If you are coding using any of the prior versions, there may be sections of the book that will not work for you. We try to notify you of items that are new and specific to the .NET Framework 4.

Don't be fooled by the .NET label in the Framework's name and think that this is a purely Internet-focused framework. The NET bit in the name is there to emphasize Microsoft's belief that *distributed applications*, in which the processing is distributed between client and server, are the way forward. It is also important to understand that C# is not just a language for writing Internet or network-aware applications. It provides a means for you to code up almost any type of software or component that you need to write for the Windows platform. Between them, C# and .NET have revolutionized the way that developers write their programs and have made programming on Windows much easier than it has ever been before.

So what's the big deal about .NET and C#?

THE SIGNIFICANCE OF .NET AND C#

To understand the significance of .NET, it is useful to remind ourselves of the nature of many of the Windows technologies that have appeared in the past 18 years or so. Although they may look quite different on the surface, all of the Windows operating systems from Windows 3.1 (introduced in 1992) through Windows 7 and Windows Server 2008 R2 have the same familiar Windows API at their core. As we have progressed through new versions of Windows, huge numbers of new functions have been added to the API, but this has been a process of evolving and extending the API rather than replacing it.

The same can be said for many of the technologies and frameworks that we have used to develop software for Windows. For example, *COM* (*Component Object Model*) originated as *OLE* (*Object Linking and Embedding*). Originally, it was largely a means by which different types of Office documents could be linked, so that you could place a small Excel spreadsheet in your Word document, for example. From that it evolved into COM, *DCOM* (*Distributed COM*), and eventually *COM+* — a sophisticated technology that formed the basis of the way almost all components communicated, as well as implementing transactions, messaging services, and object pooling.

Microsoft chose this evolutionary approach to software for the obvious reason that it is concerned about backward compatibility. Over the years, a huge base of third-party software has been written for Windows, and Windows would not have enjoyed the success it has had if every time Microsoft introduced a new technology it broke the existing code base!

Although backward compatibility has been a crucial feature of Windows technologies and one of the strengths of the Windows platform, it does have a big disadvantage. Every time some technology evolves and adds new features, it ends up a bit more complicated than it was before.

It was clear that something had to change. Microsoft could not go on forever extending the same development tools and languages, always making them more and more complex in order to satisfy the conflicting demands of keeping up with the newest hardware and maintaining backward compatibility with what was around when Windows first became popular in the early 1990s. There comes a point where you have to start with a clean slate if you want a simple yet sophisticated set of languages, environments, and developer tools, which makes it easy for developers to write state-of-the-art software.

This fresh start is what C# and .NET were all about in the first incarnation. Roughly speaking, .NET is a framework — an API — for programming on the Windows platform. Along with the .NET Framework, C# is a language that has been designed from scratch to work with .NET, as well as to take advantage of all the progress in developer environments and in our understanding of object-oriented programming principles that have taken place over the past 25 years.

Before we continue, we should make it clear that backward compatibility has not been lost in the process. Existing programs will continue to work, and .NET was designed with the capability to work with existing software. Presently, communication between software components on Windows takes place almost entirely using COM. Taking this into account, the .NET Framework does have the capability to provide wrappers around existing COM components so that .NET components can talk to them.

It is true that you don't need to learn C# in order to write code for .NET. Microsoft has extended C++, and made substantial changes to Visual Basic to turn it into a more powerful language, in order to allow code written in either of these languages to target the .NET environment. These other languages, however, are hampered by the legacy of having evolved over the years rather than having been written from the start with today's technology in mind.

This book will equip you to program in C#, while at the same time provide the necessary background in how the .NET architecture works. We not only cover the fundamentals of the C# language but also go on to give examples of applications that use a variety of related technologies, including database access, dynamic web pages, advanced graphics, and directory access.

ADVANTAGES OF .NET

So far, we've talked in general terms about how great .NET is, but we haven't said much about how it helps to make your life as a developer easier. This section briefly identifies some of the improved features of .NET.

- **Object-oriented programming** — Both the .NET Framework and C# are entirely based on object-oriented principles right from the start.
- **Good design** — A base class library, which is designed from the ground up in a highly intuitive way.
- **Language independence** — With .NET, all of the languages — Visual Basic, C#, and managed C++ — compile to a common *Intermediate Language*. This means that languages are interoperable in a way that has not been seen before.
- **Better support for dynamic web pages** — Though Classic ASP offered a lot of flexibility, it was also inefficient because of its use of interpreted scripting languages, and the lack of object-oriented design often resulted in messy ASP code. .NET offers an integrated support for web pages, using ASP.NET. With ASP.NET, code in your pages is compiled and may be written in a .NET-aware high-level language such as C# or Visual Basic 2010. .NET now takes it even further with outstanding support for the latest web technologies such as Ajax and jQuery.
- **Efficient data access** — A set of .NET components, collectively known as ADO.NET, provides efficient access to relational databases and a variety of data sources. Components are also available to allow access to the file system, and to directories. In particular, XML support is built into .NET, allowing you to manipulate data, which may be imported from or exported to non-Windows platforms.

- **Code sharing** — .NET has completely revamped the way that code is shared between applications, introducing the concept of the *assembly*, which replaces the traditional DLL. Assemblies have formal facilities for versioning, and different versions of assemblies can exist side by side.
- **Improved security** — Each assembly can also contain built-in security information that can indicate precisely who or what category of user or process is allowed to call which methods on which classes. This gives you a very fine degree of control over how the assemblies that you deploy can be used.
- **Zero-impact installation** — There are two types of assemblies: shared and private. Shared assemblies are common libraries available to all software, whereas private assemblies are intended only for use with particular software. A private assembly is entirely self-contained, so the process of installing it is simple. There are no registry entries; the appropriate files are simply placed in the appropriate folder in the file system.
- **Support for Web services** — .NET has fully integrated support for developing Web services as easily as you would develop any other type of application.
- **Visual Studio 2010** — .NET comes with a developer environment, Visual Studio 2010, which can cope equally well with C++, C#, and Visual Basic 2010, as well as with ASP.NET or XML code. Visual Studio 2010 integrates all the best features of the respective language-specific environments of all the previous versions of this amazing IDE.
- **C#** — C# is a powerful and popular object-oriented language intended for use with .NET.

We look more closely at the benefits of the .NET architecture in Chapter 1, ".NET Architecture."

WHAT'S NEW IN THE .NET FRAMEWORK 4

The first version of the .NET Framework (1.0) was released in 2002 to much enthusiasm. The.NET Framework 2.0 was introduced in 2005 and was considered a major release of the Framework. The .NET Framework 4 is another major release of the product with many outstanding new features.

With each release of the Framework, Microsoft has always tried to ensure that there were minimal breaking changes to code developed. Thus far, Microsoft has been very successful at this goal.

The following section details some of the changes that are new to C# 2010 and the .NET Framework 4.

Dynamic Typing

The world of programming has seen tremendous growth in dynamic languages such as JavaScript, Python, and Ruby. Because of the growing popularity of this type of programming, Microsoft has released a new dynamic typing capability in C#. It is not always possible to know statically what objects might end up being. Instead of using the `object` keyword and making everything of this type, we can now let the Dynamic Language Runtime (DLR) figure this out at runtime.

Using the new dynamic capabilities of C#, you now have a better interoperability story. You are able to interop with various dynamic languages and work with the DOM more easily. It's even simple to work with the Microsoft Office COM APIs now.

In this release of the .NET Framework 4, Microsoft has included the Dynamic Language Runtime. The DLR has been built upon the Common Language Runtime (CLR) to provide the ability to tie together all the dynamic language interactions.

C# provides access to the new DLR through the use of the new `dynamic` keyword. This is a flag to the compiler; whenever this keyword is encountered, the compiler will realize that it is a dynamic invocation and not the typical static invocation.

Optional and Named Parameters

Optional parameters and named parameters have been in Visual Basic for some time but have not been available to C# until the .NET 4 release. Optional parameters allow you to provide default values for some of the parameters of your methods and allow for a type of overloading by the consumer, even if there is only a single method in place to deal with all the variants. Here's an example:

```
public void CreateUser(string firstname, string lastname,
  bool isAdmin, bool isTrialUser)
{

}
```

If you wanted to overload this and have default values for the two `bool` objects, then you could easily have a few more methods that populate these values for the consumer and then make a call to the master method to actually create the user. Now with optional parameters, you are able to do something like this:

```
public void CreateUser(string firstname, string lastname,
  bool isAdmin = false, bool isTrialUser = true)
{

}
```

Looking over this bit of code, the parameters `firstname` and `lastname` do not have a default value set, while `isAdmin` and `isTrailUser` do have default values set. As a consumer of something like this, you are now able to do some of the following:

```
myClass.CreateUser("Bill", "Evjen");
myClass.CreateUser("Bill", "Evjen", true);
myClass.CreateUser("Bill", "Evjen", true, false);
myClass.CreateUser("Bill", "Evjen", isTrailUser: false);
```

The last example makes use of named parameters, which are also a new feature for C# in this release of the .NET Framework. Named parameters will potentially change the way you write your code. This new feature will allow you to make your code easier to read and understand. As an example of this in action, take a look at the `File.Copy()` method of the `System.IO` namespace. Typically, it would be constructed similarly to this:

```
File.Copy(@"C:\myTestFile.txt", @"C:\myOtherFile.txt", true);
```

In this case, this simple method is working with three parameters, but what are the actual items being passed into the `Copy()` method? Unless you know this method backward and forward, it is hard to tell what is going on by just glancing at this method. Using named parameters, you are able to use the parameter name in the code prior to the value being provided, as in the following example:

```
File.Copy(sourceFileName: @"C:\myTestFile.txt",
   destFileName: @"C:\myOtherFile.txt", overwrite: true);
```

Now with the named parameters in place, you can more easily read and understand what is going on with this line of code. Using named parameters makes no difference to the resulting compilation; they are only used in the coding of the application.

Covariance and Contravariance

Covariance and contravariance were included in prior versions of the .NET Framework, but they have been extended in .NET 4 to perform even better when working with generics, delegates, and more. In the prior versions of .NET, you were able to use contravariance with objects and arrays, but, for instance, you were unable to use contravariance with generic interfaces. In .NET 4, you are able to do this.

ASP.NET MVC

ASP.NET MVC is the latest major addition to ASP.NET and has generated a lot of excitement in the development community. ASP.NET MVC supplies you with the means to create ASP.NET using the model-view-controller model that many developers expect. ASP.NET MVC provides developers with testability, flexibility, and maintainability in the applications they build. It is important to remember that ASP.NET MVC is not meant to be a replacement for the ASP.NET everyone knows and loves, but is simply a different way to construct your applications.

This release of ASP.NET allows you to build using this new model. You will find that it is completely built in to the Framework and Visual Studio.

WHERE C# FITS IN

In one sense, C# can be seen as being the same thing to programming languages that .NET is to the Windows environment. Just as Microsoft has been adding more and more features to Windows and the Windows API over the past decade and a half, Visual Basic 2010 and C++ have undergone expansion. Although Visual Basic and C++ have ended up as hugely powerful languages as a result of this, both languages also suffer from problems because of the legacies left over from the way they evolved.

In the case of Visual Basic 6 and earlier versions, the main strength of the language was the fact that it was simple to understand and made many programming tasks easy, largely hiding the details of the Windows API and the COM component infrastructure from the developer. The downside to this was that Visual Basic was never truly object oriented, so that large applications quickly became disorganized and hard to maintain. As well, because Visual Basic's syntax was inherited from early versions of BASIC (which, in turn, was designed to be intuitively simple for beginning programmers to understand, rather than to write large commercial applications), it didn't really lend itself to well-structured or object-oriented programs.

C++, on the other hand, has its roots in the ANSI C++ language definition. It is not completely ANSI-compliant for the simple reason that Microsoft first wrote its C++ compiler before the ANSI definition had become official, but it comes close. Unfortunately, this has led to two problems. First, ANSI C++ has its roots in a decade-old state of technology, and this shows up in a lack of support for modern concepts (such as Unicode strings and generating XML documentation) and for some archaic syntax structures designed for the compilers of yesteryear (such as the separation of declaration from definition of member functions). Second, Microsoft has been simultaneously trying to evolve C++ into a language that is designed for high-performance tasks on Windows, and in order to achieve that, it has been forced to add a huge number of Microsoft-specific keywords as well as various libraries to the language. The result is that on Windows, the language has become a complete mess. Just ask C++ developers how many definitions for a string they can think of: `char*`, `LPTSTR`, `string`, `CString` (MFC version), `CString` (WTL version), `wchar_t*`, `OLECHAR*`, and so on.

Now enter .NET — a completely revolutionary environment that has brought forth new extensions to both languages. Microsoft has gotten around this by adding yet more Microsoft-specific keywords to C++, and by completely revamping Visual Basic to the current Visual Basic 2010, a language that retains some of the basic VB syntax, but that is so different in design from the original VB that it can be considered, for all practical purposes, a new language.

It is in this context that Microsoft has provided developers an alternative — a language designed specifically for .NET, and designed with a clean slate. C# is the result. Officially, Microsoft describes C# as a "simple, modern, object-oriented, and type-safe programming language derived from C and C++." Most independent observers would probably change that to "derived from C, C++, and Java." Such descriptions are technically accurate but do little to convey the beauty or elegance of the language. Syntactically, C# is very similar to both C++ and Java, to such an extent that many keywords are the same, and C# also shares the same block structure with braces ({}) to mark blocks of code and semicolons to separate statements. The first impression of a piece of C# code is that it looks quite like C++ or Java code. Beyond that initial similarity, however, C# is a lot easier to learn than C++, and of comparable difficulty to Java. Its design is more in tune with modern developer tools than both of those other languages, and it has been designed to provide, simultaneously, the ease of use of Visual Basic and the high-performance, low-level memory access of C++, if required. Some of the features of C# are:

- Full support for classes and object-oriented programming, including both interface and implementation inheritance, virtual functions, and operator overloading.
- A consistent and well-defined set of basic types.
- Built-in support for automatic generation of XML documentation.
- Automatic cleanup of dynamically allocated memory.
- The facility to mark classes or methods with user-defined attributes. This can be useful for documentation and can have some effects on compilation (for example, marking methods to be compiled only in debug builds).
- Full access to the .NET base class library, as well as easy access to the Windows API (if you really need it, which will not be very often).
- Pointers and direct memory access are available if required, but the language has been designed in such a way that you can work without them in almost all cases.
- Support for properties and events in the style of Visual Basic.
- Just by changing the compiler options, you can compile either to an executable or to a library of .NET components that can be called up by other code in the same way as ActiveX controls (COM components).
- C# can be used to write ASP.NET dynamic web pages and XML Web services.

Most of these statements, it should be pointed out, do also apply to Visual Basic 2010 and Managed C++. The fact that C# is designed from the start to work with .NET, however, means that its support for the features of .NET is both more complete and offered within the context of a more suitable syntax than those of other languages. Although the C# language itself is very similar to Java, there are some improvements; in particular, Java is not designed to work with the .NET environment.

Before leaving the subject, it is important to point out a couple of limitations of C#. The one area the language is not designed for is time-critical or extremely high-performance code — the kind where you really are worried about whether a loop takes 1,000 or 1,050 machine cycles to run through, and you need to clean up your resources the millisecond they are no longer needed. C++ is likely to continue to reign supreme among low-level languages in this area. C# lacks certain key facilities needed for extremely high-performance apps, including the ability to specify inline functions and destructors that are guaranteed to run at particular points in the code. However, the proportions of applications that fall into this category are very low.

WHAT YOU NEED TO WRITE AND RUN C# CODE

The .NET Framework 4 will run on Windows XP, 2003, 7, and the latest Windows Server 2008 R2. In order to write code using .NET, you will need to install the .NET 4 SDK.

In addition, unless you are intending to write your C# code using a text editor or some other third-party developer environment, you will almost certainly also want Visual Studio 2010. The full SDK is not needed to run managed code, but the .NET runtime is needed. You may find you need to distribute the .NET runtime with your code for the benefit of those clients who do not have it already installed.

WHAT THIS BOOK COVERS

This book starts by reviewing the overall architecture of .NET in Chapter 1 in order to give you the background you need to be able to write managed code. After that, the book is divided into a number of sections that cover both the C# language and its application in a variety of areas.

Part I: The C# Language

This section gives a good grounding in the C# language itself. This section doesn't presume knowledge of any particular language, although it does assume you are an experienced programmer. You start by looking at C#'s basic syntax and data types, and then explore the object-oriented features of C# before moving on to look at more advanced C# programming topics.

Part II: Visual Studio

This section looks at the main IDE utilized by C# developers worldwide: Visual Studio 2010. The two chapters in this section look at the best way to use the tool to build applications based on the .NET Framework 4. In addition, this section also focuses on the deployment of your projects.

Part III: Foundation

In this section, you look at the principles of programming in the .NET environment. In particular, you look at security, threading, localization, transactions, how to build Windows services, and how to generate your own libraries as assemblies, among other topics.

Part IV: Data

Here, you look at accessing databases with ADO.NET and LINQ, and at interacting with directories and files. This part also extensively covers support in .NET for XML and on the Windows operating system side, and the .NET features of SQL Server 2008.

Part V: Presentation

This section starts with coverage on building classic Windows applications, which are called *Windows Forms* in .NET. Windows Forms are the thick-client version of applications, and using .NET to build these types of applications is a quick and easy way of accomplishing this task. This section also shows how to build applications based upon the Windows Presentation Foundation and Silverlight, and covers writing components that will run on web sites, serving up web pages. Finally, it includes coverage of the tremendous number of features that ASP.NET and ASP.NET MVC provide.

Part VI: Communication

This section is all about communication. It covers services for platform-independent communication using the Windows Communication Foundation (WCF). With Message Queuing, asynchronous disconnected communication is shown. This section looks at utilizing the Windows Workflow Foundation (WF), as well as peer-to-peer networking, and creating syndication feeds.

Appendix

The book closes with an appendix covering Windows 7 and Windows Server 2008 R2 development.

Online Chapters

Even with such a large book, we can't fit in everything we'd like to tell you about C# and using this language with other .NET technologies, so we've made ten additional chapters available online at `www.wrox.com`. These chapters include information on a variety of topics: GDI+, which is a technology that is used for building applications that include advanced graphics; .NET Remoting for communication between .NET clients and servers; Enterprise Services for the services in the background; and the Managed Add-In Framework (MAF). Some other big topics found online include VSTO development and working with LINQ to SQL.

CONVENTIONS

To help you get the most from the text and keep track of what's happening, we've used a number of conventions throughout the book.

> *Boxes with a warning icon like this one hold important, not-to-be forgotten information that is directly relevant to the surrounding text.*

> *The pencil icon indicates notes, tips, hints, tricks, or asides to the current discussion.*

As for styles in the text:

- We *highlight* new terms and important words when we introduce them.
- We show keyboard strokes like this: Ctrl+A.
- We show file names, URLs, and code within the text like so: `persistence.properties`.
- We present code in two different ways:

```
We use a monofont type with no highlighting for most code examples.
We use bold to emphasize code that's particularly important in the present context or to show
changes from a previous code snippet.
```

SOURCE CODE

As you work through the examples in this book, you may choose either to type in all the code manually or to use the source code files that accompany the book. All of the source code used in this book is available for download at `http://www.wrox.com`. Once at the site, simply locate the book's title (either by using the Search box or by using one of the title lists) and click the Download Code link on the book's detail page to obtain all the source code for the book.

Once you download the code, just decompress it with your favorite compression tool. Alternately, you can go to the main Wrox code download page at `http://www.wrox.com/dynamic/books/download.aspx` to see the code available for this book and all other Wrox books.

ERRATA

We make every effort to ensure that there are no errors in the text or in the code. However, no one is perfect, and mistakes do occur. If you find an error in one of our books, like a spelling mistake or faulty piece of code, we would be very grateful for your feedback. By sending in errata you may save another reader hours of frustration and at the same time you will be helping us provide even higher quality information.

To find the errata page for this book, go to `http://www.wrox.com` and locate the title using the Search box or one of the title lists. Then, on the book details page, click the Book Errata link. On this page you can view all errata that has been submitted for this book and posted by Wrox editors. A complete book list including links to each book's errata is also available at `www.wrox.com/misc-pages/booklist.shtml`.

If you don't spot "your" error on the Book Errata page, go to `www.wrox.com/contact/techsupport.shtml` and complete the form there to send us the error you have found. We'll check the information and, if appropriate, post a message to the book's errata page and fix the problem in subsequent editions of the book.

P2P.WROX.COM

For author and peer discussion, join the P2P forums at `p2p.wrox.com`. The forums are a Web-based system for you to post messages relating to Wrox books and related technologies and interact with other readers and technology users. The forums offer a subscription feature to e-mail you topics of interest of your choosing when new posts ar e made to the forums. Wrox authors, editors, other industry experts, and your fellow readers are present on these forums.

At `http://p2p.wrox.com` you will find a number of different forums that will help you not only as you read this book, but also as you develop your own applications. To join the forums, just follow these steps:

1. Go to `p2p.wrox.com` and click the Register link.
2. Read the terms of use and click Agree.
3. Complete the required information to join as well as any optional information you wish to provide and click Submit.
4. You will receive an e-mail with information describing how to verify your account and complete the joining process.

Once you join, you can post new messages and respond to messages other users post. You can read messages at any time on the Web. If you would like to have new messages from a particular forum e-mailed to you, click the Subscribe to this Forum icon by the forum name in the forum listing.

For more information about how to use the Wrox P2P, be sure to read the P2P FAQs for answers to questions about how the forum software works as well as many common questions specific to P2P and Wrox books. To read the FAQs, click the FAQ link on any P2P page.

PART I
The C# Language

1

.NET Architecture

WHAT'S IN THIS CHAPTER?

- Compiling and running code that targets .NET
- Advantages of Microsoft Intermediate Language (MSIL)
- Value and reference types
- Data typing
- Understanding error handling and attributes
- Assemblies, .NET base classes, and namespaces

Throughout this book, we emphasize that the C# language must be considered in parallel with the .NET Framework, rather than viewed in isolation. The C# compiler specifically targets .NET, which means that all code written in C# will always run within the .NET Framework. This has two important consequences for the C# language:

1. The architecture and methodologies of C# reflect the underlying methodologies of .NET.
2. In many cases, specific language features of C# actually depend on features of .NET, or of the .NET base classes.

Because of this dependence, it is important to gain some understanding of the architecture and methodology of .NET before you begin C# programming. That is the purpose of this chapter.

THE RELATIONSHIP OF C# TO .NET

C# is a relatively new programming language and is significant in two respects:

- It is specifically designed and targeted for use with Microsoft's .NET Framework (a feature-rich platform for the development, deployment, and execution of distributed applications).
- It is a language based on the modern object-oriented design methodology, and, when designing it, Microsoft learned from the experience of all the other similar languages that have been around since object-oriented principles came to prominence some 20 years ago.

One important thing to make clear is that C# is a language in its own right. Although it is designed to generate code that targets the .NET environment, it is not itself part of .NET. Some features are supported by .NET but not by C#, and you might be surprised to learn that some features of the C# language are not supported by .NET (for example, some instances of operator overloading)!

However, because the C# language is intended for use with .NET, it is important for you to have an understanding of this Framework if you want to develop applications in C# effectively. Therefore, this chapter takes some time to peek underneath the surface of .NET. Let's get started.

THE COMMON LANGUAGE RUNTIME

Central to the .NET Framework is its runtime execution environment, known as the *Common Language Runtime* (CLR) or the *.NET runtime*. Code running under the control of the CLR is often termed *managed code*.

However, before it can be executed by the CLR, any source code that you develop (in C# or some other language) needs to be compiled. Compilation occurs in two steps in .NET:

1. Compilation of source code to Microsoft Intermediate Language (IL).
2. Compilation of IL to platform-specific code by the CLR.

This two-stage compilation process is very important, because the existence of the Microsoft Intermediate Language is the key to providing many of the benefits of .NET.

IL shares with Java byte code the idea that it is a low-level language with a simple syntax (based on numeric codes rather than text), which can be very quickly translated into native machine code. Having this well-defined universal syntax for code has significant advantages: platform independence, performance improvement, and language interoperability.

Platform Independence

First, platform independence means that the same file containing byte code instructions can be placed on any platform; at runtime, the final stage of compilation can then be easily accomplished so that the code will run on that particular platform. In other words, by compiling to IL you obtain platform independence for .NET, in much the same way as compiling to Java byte code gives Java platform independence.

Note that the platform independence of .NET is only theoretical at present because, at the time of writing, a complete implementation of .NET is available only for Windows. However, a partial implementation is available (see, for example, the Mono project, an effort to create an open source implementation of .NET, at `www.go-mono.com`).

Performance Improvement

Although we previously made comparisons with Java, IL is actually a bit more ambitious than Java byte code. IL is always *Just-in-Time* compiled (known as JIT compilation), whereas Java byte code was often interpreted. One of the disadvantages of Java was that, on execution, the process of translating from Java byte code to native executable resulted in a loss of performance (with the exception of more recent cases, where Java is JIT compiled on certain platforms).

Instead of compiling the entire application in one go (which could lead to a slow startup time), the JIT compiler simply compiles each portion of code as it is called (just in time). When code has been compiled once, the resultant native executable is stored until the application exits so that it does not need to be recompiled the next time that portion of code is run. Microsoft argues that this process is more efficient than compiling the entire application code at the start, because of the likelihood that large portions of any application code will not actually be executed in any given run. Using the JIT compiler, such code will never be compiled.

This explains why we can expect that execution of managed IL code will be almost as fast as executing native machine code. What it does not explain is why Microsoft expects that we will get a performance *improvement*. The reason given for this is that, because the final stage of compilation takes place at runtime, the JIT compiler will know exactly what processor type the program will run on. This means that it can optimize the final executable code to take advantage of any features or particular machine code instructions offered by that particular processor.

Traditional compilers will optimize the code, but they can only perform optimizations that are independent of the particular processor that the code will run on. This is because traditional compilers compile to native executable code before the software is shipped. This means that the compiler does not know what type of processor the code will run on beyond basic generalities, such as that it will be an x86-compatible processor or an Alpha processor.

Language Interoperability

The use of IL not only enables platform independence, it also facilitates *language interoperability*. Simply put, you can compile to IL from one language, and this compiled code should then be interoperable with code that has been compiled to IL from another language.

You are probably now wondering which languages aside from C# are interoperable with .NET; the following sections briefly discuss how some of the other common languages fit into .NET.

Visual Basic 2010

Visual Basic .NET 2002 underwent a complete revamp from Visual Basic 6 to bring it up to date with the first version of the .NET Framework. The Visual Basic language itself had dramatically evolved from VB6, and this meant that VB6 was not a suitable language for running .NET programs. For example, VB6 is heavily integrated into Component Object Model (COM) and works by exposing only event handlers as source code to the developer — most of the background code is not available as source code. Not only that, it does not support implementation inheritance, and the standard data types that Visual Basic 6 uses are incompatible with .NET.

Visual Basic 6 was upgraded to Visual Basic .NET in 2002, and the changes that were made to the language are so extensive you might as well regard Visual Basic as a new language. Existing Visual Basic 6 code does not compile to the present Visual Basic 2010 code (or to Visual Basic .NET 2002, 2003, 2005, and 2008 for that matter). Converting a Visual Basic 6 program to Visual Basic 2010 requires extensive changes to the code. However, Visual Studio 2010 (the upgrade of Visual Studio for use with .NET) can do most of the changes for you. If you attempt to read a Visual Basic 6 project into Visual Studio 2010, it will upgrade the project for you, which means that it will rewrite the Visual Basic 6 source code into Visual Basic 2010 source code. Although this means that the work involved for you is heavily cut down, you will need to check through the new Visual Basic 2010 code to make sure that the project still works as intended because the conversion might not be perfect.

One side effect of this language upgrade is that it is no longer possible to compile Visual Basic 2010 to native executable code. Visual Basic 2010 compiles only to IL, just as C# does. If you need to continue coding in Visual Basic 6, you can do so, but the executable code produced will completely ignore the .NET Framework, and you will need to keep Visual Studio 6 installed if you want to continue to work in this developer environment.

Visual C++ 2010

Visual C++ 6 already had a large number of Microsoft-specific extensions on Windows. With Visual C++ .NET, extensions have been added to support the .NET Framework. This means that existing C++ source code will continue to compile to native executable code without modification. It also means, however, that it will run independently of the .NET runtime. If you want your C++ code to run within the .NET Framework, you can simply add the following line to the beginning of your code:

```
#using <mscorlib.dll>
```

You can also pass the flag `/clr` to the compiler, which then assumes that you want to compile to managed code, and will hence emit IL instead of native machine code. The interesting thing about C++ is that when you compile to managed code, the compiler can emit IL that contains an embedded native executable. This means that you can mix managed types and unmanaged types in your C++ code. Thus the managed C++ code

```
class MyClass
{
```

defines a plain C++ class, whereas the code

```
ref class MyClass
{
```

gives you a managed class, just as if you had written the class in C# or Visual Basic 2010. The advantage of using managed C++ over C# code is that you can call unmanaged C++ classes from managed C++ code without having to resort to COM interop.

The compiler raises an error if you attempt to use features that are not supported by .NET on managed types (for example, templates or multiple inheritances of classes). You will also find that you need to use nonstandard C++ features when using managed classes.

Because of the freedom that C++ allows in terms of low-level pointer manipulation and so on, the C++ compiler is not able to generate code that will pass the CLR's memory type-safety tests. If it is important that your code be recognized by the CLR as memory type-safe, you will need to write your source code in some other language (such as C# or Visual Basic 2010).

COM and COM+

Technically speaking, COM and COM+ are not technologies targeted at .NET — components based on them cannot be compiled into IL (although it is possible to do so to some degree using managed C++, if the original COM component was written in C++). However, COM+ remains an important tool, because its features are not duplicated in .NET. Also, COM components will still work — and .NET incorporates COM interoperability features that make it possible for managed code to call up COM components and vice versa (this is discussed in Chapter 26, "Interop"). In general, however, you will probably find it more convenient for most purposes to code new components as .NET components, so that you can take advantage of the .NET base classes as well as the other benefits of running as managed code.

A CLOSER LOOK AT INTERMEDIATE LANGUAGE

From what you learned in the previous section, Microsoft Intermediate Language obviously plays a fundamental role in the .NET Framework. It makes sense now to take a closer look at the main features of IL, because any language that targets .NET will logically need to support these characteristics too.

Here are the important features of IL:

- Object orientation and the use of interfaces
- Strong distinction between value and reference types
- Strong data typing
- Error handling using exceptions
- Use of attributes

The following sections explore each of these features.

Support for Object Orientation and Interfaces

The language independence of .NET does have some practical limitations. IL is inevitably going to implement some particular programming methodology, which means that languages targeting it need to be compatible with that methodology. The particular route that Microsoft has chosen to follow for IL is that of classic object-oriented programming, with single implementation inheritance of classes.

If you are unfamiliar with the concepts of object orientation, refer to the Web Download Chapter 53, "C#, Visual Basic, C++/CLI, and F#" for more information.

In addition to classic object-oriented programming, IL also brings in the idea of interfaces, which saw their first implementation under Windows with COM. Interfaces built using .NET produce interfaces that are not the same as COM interfaces. They do not need to support any of the COM infrastructure (for example, they are not derived from `IUnknown`, and they do not have associated globally unique identifiers, more commonly know as GUIDs). However, they do share with COM interfaces the idea that they provide a contract, and classes that implement a given interface must provide implementations of the methods and properties specified by that interface.

You have now seen that working with .NET means compiling to IL, and that in turn means that you will need to use traditional object-oriented methodologies. However, that alone is not sufficient to give you language interoperability. After all, C++ and Java both use the same object-oriented paradigms, but they are still not regarded as interoperable. We need to look a little more closely at the concept of language interoperability.

So what exactly do we mean by language interoperability?

After all, COM allowed components written in different languages to work together in the sense of calling each other's methods. What was inadequate about that? COM, by virtue of being a binary standard, did allow components to instantiate other components and call methods or properties against them, without worrying about the language in which the respective components were written. To achieve this, however, each object had to be instantiated through the COM runtime, and accessed through an interface. Depending on the threading models of the relative components, there may have been large performance losses associated with marshaling data between apartments or running components or both on different threads. In the extreme case of components hosted as an executable rather than DLL files, separate processes would need to be created to run them. The emphasis was very much that components could talk to each other but only via the COM runtime. In no way with COM did components written in different languages directly communicate with each other, or instantiate instances of each other — it was always done with COM as an intermediary. Not only that, but the COM architecture did not permit implementation inheritance, which meant that it lost many of the advantages of object-oriented programming.

An associated problem was that, when debugging, you would still need to debug components written in different languages independently. It was not possible to step between languages in the debugger. Therefore, what we *really* mean by language interoperability is that classes written in one language should be able to talk directly to classes written in another language. In particular:

- A class written in one language can inherit from a class written in another language.
- The class can contain an instance of another class, no matter what the languages of the two classes are.
- An object can directly call methods against another object written in another language.
- Objects (or references to objects) can be passed around between methods.
- When calling methods between languages, you can step between the method calls in the debugger, even when this means stepping between source code written in different languages.

This is all quite an ambitious aim, but amazingly, .NET and IL have achieved it. In the case of stepping between methods in the debugger, this facility is really offered by the Visual Studio integrated development environment (IDE) rather than by the CLR itself.

Distinct Value and Reference Types

As with any programming language, IL provides a number of predefined primitive data types. One characteristic of IL, however, is that it makes a strong distinction between value and reference types. *Value types* are those for which a variable directly stores its data, whereas *reference types* are those for which a variable simply stores the address at which the corresponding data can be found.

In C++ terms, using reference types is similar to accessing a variable through a pointer, whereas for Visual Basic, the best analogy for reference types are objects, which in Visual Basic 6 are always accessed through references. IL also lays down specifications about data storage: instances of reference types are always stored in an area of memory known as the *managed heap,* whereas value types are normally stored on the *stack* (although if value types are declared as fields within reference types, they will be stored inline on the heap). Chapter 2, “Core C#,” discusses the stack and the heap and how they work.

Strong Data Typing

One very important aspect of IL is that it is based on exceptionally *strong data typing.* That means that all variables are clearly marked as being of a particular, specific data type (there is no room in IL, for example, for the `Variant` data type recognized by Visual Basic and scripting languages). In particular, IL does not normally permit any operations that result in ambiguous data types.

For instance, Visual Basic 6 developers are used to being able to pass variables around without worrying too much about their types, because Visual Basic 6 automatically performs type conversion. C++ developers are used to routinely casting pointers between different types. Being able to perform this kind of operation can be great for performance, but it breaks type safety. Hence, it is permitted only under certain circumstances in some of the languages that compile to managed code. Indeed, pointers (as opposed to references) are permitted only in marked blocks of code in C#, and not at all in Visual Basic (although they are allowed in managed C++). Using pointers in your code causes it to fail the memory type-safety checks performed by the CLR. You should note that some languages compatible with .NET, such as Visual Basic 2010, still allow some laxity in typing, but that it’s possible only because the compilers behind the scenes ensure that the type safety is enforced in the emitted IL.

Although enforcing type safety might initially appear to hurt performance, in many cases the benefits gained from the services provided by .NET that rely on type safety far outweigh this performance loss. Such services include the following:

- Language interoperability
- Garbage collection
- Security
- Application domains

The following sections take a closer look at why strong data typing is particularly important for these features of .NET.

Strong Data Typing as a Key to Language Interoperability

If a class is to derive from or contains instances of other classes, it needs to know about all the data types used by the other classes. This is why strong data typing is so important. Indeed, it is the absence of any agreed-on system for specifying this information in the past that has always been the real barrier to inheritance and interoperability across languages. This kind of information is simply not present in a standard executable file or DLL.

Suppose that one of the methods of a Visual Basic 2010 class is defined to return an `Integer` — one of the standard data types available in Visual Basic 2010. C# simply does not have any data type of that name. Clearly, you will be able to derive from the class, use this method, and use the return type from C# code, only if the compiler knows how to map Visual Basic 2010s `Integer` type to some known type that is defined in C#. So, how is this problem circumvented in .NET?

Common Type System

This data type problem is solved in .NET using the *Common Type System* (CTS). The CTS defines the predefined data types that are available in IL, so that all languages that target the .NET Framework will produce compiled code that is ultimately based on these types.

For the previous example, Visual Basic 2010s `Integer` is actually a 32-bit signed integer, which maps exactly to the IL type known as `Int32`. Therefore, this will be the data type specified in the IL code. Because the C# compiler is aware of this type, there is no problem. At source code level, C# refers to `Int32` with the keyword `int`, so the compiler will simply treat the Visual Basic 2010 method as if it returned an `int`.

The CTS does not specify merely primitive data types but a rich hierarchy of types, which includes well-defined points in the hierarchy at which code is permitted to define its own types. The hierarchical structure of the CTS reflects the single-inheritance object-oriented methodology of IL, and resembles Figure 1-1.

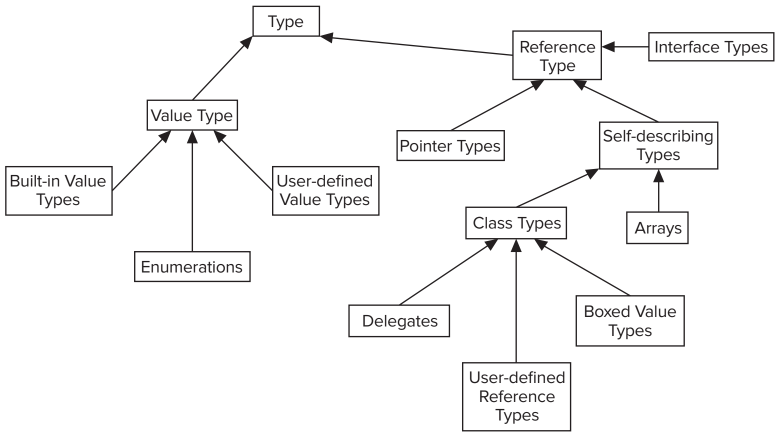

FIGURE 1-1

We will not list all the built-in value types here, because they are covered in detail in Chapter 3, “Objects and Types.” In C#, each predefined type is recognized by the compiler maps onto one of the IL built-in types. The same is true in Visual Basic 2010.

Common Language Specification

The *Common Language Specification* (CLS) works with the CTS to ensure language interoperability. The CLS is a set of minimum standards that all compilers targeting .NET must support. Because IL is a very rich language, writers of most compilers will prefer to restrict the capabilities of a given compiler to support only a subset of the facilities offered by IL and the CTS. That is fine, as long as the compiler supports everything that is defined in the CLS.

For example, take case sensitivity. IL is case-sensitive. Developers who work with case-sensitive languages regularly take advantage of the flexibility that this case sensitivity gives them when selecting variable names. Visual Basic 2010, however, is not case-sensitive. The CLS works around this by indicating that CLS-compliant code should not expose any two names that differ only in their case. Therefore, Visual Basic 2010 code can work with CLS-compliant code.

This example shows that the CLS works in two ways.

1. Individual compilers do not have to be powerful enough to support the full features of .NET — this should encourage the development of compilers for other programming languages that target .NET.
2. If you restrict your classes to exposing only CLS-compliant features, then it guarantees that code written in any other compliant language can use your classes.

The beauty of this idea is that the restriction to using CLS-compliant features applies only to public and protected members of classes and public classes. Within the private implementations of your classes, you can write whatever non-CLS code you want, because code in other assemblies (units of managed code; see later in this chapter) cannot access this part of your code anyway.

We will not go into the details of the CLS specifications here. In general, the CLS will not affect your C# code very much because there are very few non-CLS-compliant features of C# anyway.

It is perfectly acceptable to write non-CLS-compliant code. However, if you do, the compiled IL code is not guaranteed to be fully language interoperable.

Garbage Collection

The *garbage collector* is .NET's answer to memory management and in particular to the question of what to do about reclaiming memory that running applications ask for. Up until now, two techniques have been used on the Windows platform for de-allocating memory that processes have dynamically requested from the system:

➤ Make the application code do it all manually.

➤ Make objects maintain reference counts.

Having the application code responsible for de-allocating memory is the technique used by lower-level, high-performance languages such as C++. It is efficient, and it has the advantage that (in general) resources are never occupied for longer than necessary. The big disadvantage, however, is the frequency of bugs. Code that requests memory also should explicitly inform the system when it no longer requires that memory. However, it is easy to overlook this, resulting in memory leaks.

Although modern developer environments do provide tools to assist in detecting memory leaks, they remain difficult bugs to track down. That's because they have no effect until so much memory has been leaked that Windows refuses to grant any more to the process. By this point, the entire computer may have appreciably slowed down due to the memory demands being made on it.

Maintaining reference counts is favored in COM. The idea is that each COM component maintains a count of how many clients are currently maintaining references to it. When this count falls to zero, the component can destroy itself and free up associated memory and resources. The problem with this is that it still relies on the good behavior of clients to notify the component that they have finished with it. It takes only one client not to do so, and the object sits in memory. In some ways, this is a potentially more serious problem than a simple C++-style memory leak because the COM object may exist in its own process, which means that it will never be removed by the system. (At least with C++ memory leaks, the system can reclaim all memory when the process terminates.)

The .NET runtime relies on the garbage collector instead. The purpose of this program is to clean up memory. The idea is that all dynamically requested memory is allocated on the heap (that is true for all languages, although in the case of .NET, the CLR maintains its own managed heap for .NET applications to use). Every so often, when .NET detects that the managed heap for a given process is becoming full and therefore needs tidying up, it calls the garbage collector. The garbage collector runs through variables currently in scope in your code, examining references to objects stored on the heap to identify which ones are accessible from your code — that is, which objects have references that refer to them. Any objects that are not referred to are deemed to be no longer accessible from your code and can therefore be removed. Java uses a system of garbage collection similar to this.

Garbage collection works in .NET because IL has been designed to facilitate the process. The principle requires that you cannot get references to existing objects other than by copying existing references and that IL be type safe. In this context, what we mean is that if any reference to an object exists, then there is sufficient information in the reference to exactly determine the type of the object.

It would not be possible to use the garbage collection mechanism with a language such as unmanaged C++, for example, because C++ allows pointers to be freely cast between types.

One important aspect of garbage collection is that it is not deterministic. In other words, you cannot guarantee when the garbage collector will be called; it will be called when the CLR decides that it is needed, though it is also possible to override this process and call up the garbage collector in your code.

Look to Chapter 13, "Memory Management and Pointers," for more information on the garbage collection process.

Security

.NET can really excel in terms of complementing the security mechanisms provided by Windows because it can offer code-based security, whereas Windows really offers only role-based security.

Role-based security is based on the identity of the account under which the process is running (that is, who owns and is running the process). *Code-based security,* by contrast, is based on what the code actually does and on how much the code is trusted. Thanks to the strong type safety of IL, the CLR is able to inspect code before running it to determine required security permissions. .NET also offers a mechanism by which code can indicate in advance what security permissions it will require to run.

The importance of code-based security is that it reduces the risks associated with running code of dubious origin (such as code that you have downloaded from the Internet). For example, even if code is running under the administrator account, it is possible to use code-based security to indicate that that code should still not be permitted to perform certain types of operations that the administrator account would normally be allowed to do, such as read or write to environment variables, read or write to the registry, or access the .NET reflection features.

Security issues are covered in more depth in Chapter 21, "Security."

Application Domains

Application domains are an important innovation in .NET and are designed to ease the overhead involved when running applications that need to be isolated from each other but that also need to be able to communicate with each other. The classic example of this is a web server application, which may be simultaneously responding to a number of browser requests. It will, therefore, probably have a number of instances of the component responsible for servicing those requests running simultaneously.

In pre-.NET days, the choice would be between allowing those instances to share a process (with the resultant risk of a problem in one running instance bringing the whole web site down) or isolating those instances in separate processes (with the associated performance overhead).

Up until now, the only means of isolating code has been through processes. When you start a new application, it runs within the context of a process. Windows isolates processes from each other through address spaces. The idea is that each process has available 4GB of virtual memory in which to store its data and executable code (4GB is for 32-bit systems; 64-bit systems use more memory). Windows imposes an extra level of indirection by which this virtual memory maps into a particular area of actual physical memory or disk space. Each process gets a different mapping, with no overlap between the actual physical memories that the blocks of virtual address space map to (see Figure 1-2).

In general, any process is able to access memory only by specifying an address in virtual memory — processes do not have direct access to physical memory. Hence, it is simply impossible for one process to access the memory allocated to another process. This provides an excellent guarantee that any badly behaved code will not be able to damage anything outside of its own address space. (Note that on Windows 95/98, these safeguards are not quite as thorough as they are on Windows NT/2000/XP/2003/Vista/7, so the theoretical possibility exists of applications crashing Windows by writing to inappropriate memory.)

Processes do not just serve as a way to isolate instances of running code from each other. On Windows NT/2000/XP/2003/Vista/7 systems, they also form the unit to which security privileges and permissions are assigned. Each process has its own security token, which indicates to Windows precisely what operations that process is permitted to do.

Although processes are great for security reasons, their big disadvantage is in the area of performance. Often, a number of processes will actually be working together, and therefore need to communicate with each other. The obvious example of this is where a process calls up a COM component, which is an executable and therefore is required to run in its own process. The same thing happens in COM when surrogates are used. Because processes cannot share any memory, a complex marshaling process must be used to copy data between the processes. This results in a very significant performance hit. If you need components to work together and do not want that performance hit, you must use DLL-based components and have everything running in the same address space — with the associated risk that a badly behaved component will bring everything else down.

Application domains are designed as a way of separating components without resulting in the performance problems associated with passing data between processes. The idea is that any one process is divided into a number of application domains. Each application domain roughly corresponds to a single application, and each thread of execution will be running in a particular application domain (see Figure 1-3).

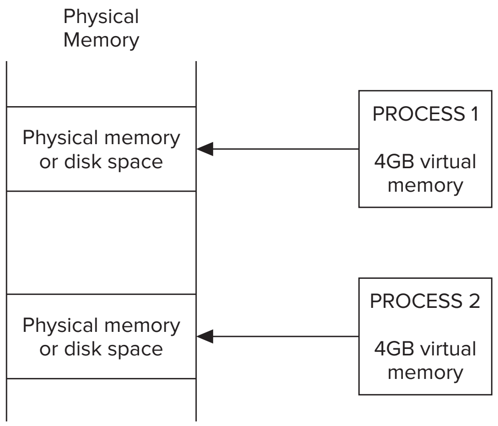

FIGURE 1-2

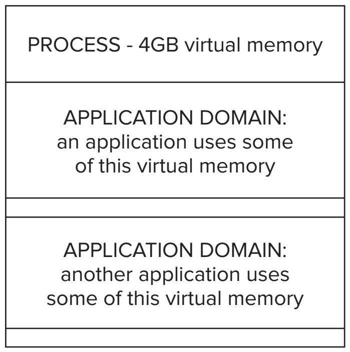

PROCESS - 4GB virtual memory
APPLICATION DOMAIN: an application uses some of this virtual memory
APPLICATION DOMAIN: another application uses some of this virtual memory

FIGURE 1-3

If different executables are running in the same process space, then they are clearly able to easily share data, because, theoretically, they can directly see each other's data. However, although this is possible in principle, the CLR makes sure that this does not happen in practice by inspecting the code for each running application to ensure that the code cannot stray outside of its own data areas. This looks, at first, like an almost impossible task to pull off — after all, how can you tell what the program is going to do without actually running it?

In fact, it is usually possible to do this because of the strong type safety of the IL. In most cases, unless code is using unsafe features such as pointers, the data types it is using will ensure that memory is not accessed inappropriately. For example, .NET array types perform bounds checking to ensure that no out-of-bounds array operations are permitted. If a running application does need to communicate or share data with other applications running in different application domains, it must do so by calling on .NET's remoting services.

Code that has been verified to check that it cannot access data outside its application domain (other than through the explicit remoting mechanism) is said to be *memory type safe*. Such code can safely be run alongside other type-safe code in different application domains within the same process.

Error Handling with Exceptions

The .NET Framework is designed to facilitate handling of error conditions using the same mechanism, based on exceptions, that is employed by Java and C++. C++ developers should note that because of IL's stronger typing system, there is no performance penalty associated with the use of exceptions with IL in the way that there is in C++. Also, the `finally` block, which has long been on many C++ developers' wish lists, is supported by .NET and by C#.

Exceptions are covered in detail in Chapter 15, "Errors and Exceptions." Briefly, the idea is that certain areas of code are designated as exception handler routines, with each one able to deal with a particular error condition (for example, a file not being found, or being denied permission to perform some operation). These conditions can be defined as narrowly or as widely as you want. The exception architecture ensures that when an error condition occurs, execution can immediately jump to the exception handler routine that is most specifically geared to handle the exception condition in question.

The architecture of exception handling also provides a convenient means to pass an object containing precise details of the exception condition to an exception-handling routine. This object might include an appropriate message for the user and details of exactly where in the code the exception was detected.

Most exception-handling architecture, including the control of program flow when an exception occurs, is handled by the high-level languages (C#, Visual Basic 2010, C++), and is not supported by any special IL commands. C#, for example, handles exceptions using `try{}`, `catch{}`, and `finally{}` blocks of code. (For more details, see Chapter 15.)

What .NET does do, however, is provide the infrastructure to allow compilers that target .NET to support exception handling. In particular, it provides a set of .NET classes that can represent the exceptions, and the language interoperability to allow the thrown exception objects to be interpreted by the exception-handling code, regardless of what language the exception-handling code is written in. This language independence is absent from both the C++ and Java implementations of exception handling, although it is present to a limited extent in the COM mechanism for handling errors, which involves returning error codes from methods and passing error objects around. The fact that exceptions are handled consistently in different languages is a crucial aspect of facilitating multi-language development.

Use of Attributes

Attributes are familiar to developers who use C++ to write COM components (through their use in Microsoft's COM Interface Definition Language [IDL]). The initial idea of an attribute was that it provided extra information concerning some item in the program that could be used by the compiler.

Attributes are supported in .NET — and hence now by C++, C#, and Visual Basic 2010. What is, however, particularly innovative about attributes in .NET is that you can define your own custom attributes in your source code. These user-defined attributes will be placed with the metadata for the corresponding data types or methods. This can be useful for documentation purposes, in which they can be used in conjunction with reflection technology to perform programming tasks based on attributes. In addition, in common with the .NET philosophy of language independence, attributes can be defined in source code in one language and read by code that is written in another language.

Attributes are covered in Chapter 14, "Reflection."

ASSEMBLIES

An *assembly* is the logical unit that contains compiled code targeted at the .NET Framework. Assemblies are not covered in detail in this chapter because they are covered thoroughly in Chapter 18, "Assemblies," but we summarize the main points here.

An assembly is completely self-describing and is a logical rather than a physical unit, which means that it can be stored across more than one file (indeed, dynamic assemblies are stored in memory, not on file at all). If an assembly is stored in more than one file, there will be one main file that contains the entry point and describes the other files in the assembly.

Note that the same assembly structure is used for both executable code and library code. The only real difference is that an executable assembly contains a main program entry point, whereas a library assembly does not.

An important characteristic of assemblies is that they contain metadata that describes the types and methods defined in the corresponding code. An assembly, however, also contains assembly metadata that describes the assembly itself. This assembly metadata, contained in an area known as the *manifest,* allows checks to be made on the version of the assembly, and on its integrity.

`ildasm`*, a Windows-based utility, can be used to inspect the contents of an assembly, including the manifest and metadata.* `ildasm` *is discussed in Chapter 18.*

The fact that an assembly contains program metadata means that applications or other assemblies that call up code in a given assembly do not need to refer to the registry, or to any other data source, to find out how to use that assembly. This is a significant break from the old COM way of doing things, in which the GUIDs of the components and interfaces had to be obtained from the registry, and in some cases, the details of the methods and properties exposed would need to be read from a type library.

Having data spread out in up to three different locations meant there was the obvious risk of something getting out of synchronization, which would prevent other software from being able to use the component successfully. With assemblies, there is no risk of this happening, because all the metadata is stored with the program executable instructions. Note that even though assemblies are stored across several files, there are still no problems with data going out of synchronization. This is because the file that contains the assembly entry point also stores details of, and a hash of, the contents of the other files, which means that if one of the files gets replaced, or in any way tampered with, this will almost certainly be detected and the assembly will refuse to load.

Assemblies come in two types: *private* and *shared* assemblies.

Private Assemblies

Private assemblies are the simplest type. They normally ship with software and are intended to be used only with that software. The usual scenario in which you will ship private assemblies is when you are supplying an application in the form of an executable and a number of libraries, where the libraries contain code that should be used only with that application.

The system guarantees that private assemblies will not be used by other software because an application may load only private assemblies that are located in the same folder that the main executable is loaded in, or in a subfolder of it.

Because you would normally expect that commercial software would always be installed in its own directory, there is no risk of one software package overwriting, modifying, or accidentally loading private assemblies intended for another package. And, because private assemblies can be used only by the software package that they are intended for, you have much more control over what software uses them. There is, therefore, less need to take security precautions because there is no risk, for example, of some other commercial software overwriting one of your assemblies with some new version of it (apart from software that is designed specifically to perform malicious damage). There are also no problems with name collisions. If classes in your private assembly happen to have the same name as classes in someone else's private assembly, that does not matter, because any given application will be able to see only the one set of private assemblies.

Because a private assembly is entirely self-contained, the process of deploying it is simple. You simply place the appropriate file(s) in the appropriate folder in the file system (no registry entries need to be made). This process is known as *zero impact (xcopy) installation*.

Shared Assemblies

Shared assemblies are intended to be common libraries that any other application can use. Because any other software can access a shared assembly, more precautions need to be taken against the following risks:

- Name collisions, where another company's shared assembly implements types that have the same names as those in your shared assembly. Because client code can theoretically have access to both assemblies simultaneously, this could be a serious problem.
- The risk of an assembly being overwritten by a different version of the same assembly — the new version is incompatible with some existing client code.

The solution to these problems is placing shared assemblies in a special directory subtree in the file system, known as the *global assembly cache* (GAC). Unlike with private assemblies, this cannot be done by simply copying the assembly into the appropriate folder — it needs to be specifically installed into the cache. This process can be performed by a number of .NET utilities and requires certain checks on the assembly, as well as the set up of a small folder hierarchy within the assembly cache that is used to ensure assembly integrity.

To prevent name collisions, shared assemblies are given a name based on private key cryptography (private assemblies are simply given the same name as their main file name). This name is known as a *strong name*; it is guaranteed to be unique and must be quoted by applications that reference a shared assembly.

Problems associated with the risk of overwriting an assembly are addressed by specifying version information in the assembly manifest and by allowing side-by-side installations.

Reflection

Because assemblies store metadata, including details of all the types and members of these types that are defined in the assembly, it is possible to access this metadata programmatically. Full details of this are given in Chapter 14. This technique, known as reflection, raises interesting possibilities, because it means that managed code can actually examine other managed code, and can even examine itself, to determine information about that code. This is most commonly used to obtain the details of attributes, although you can also use reflection, among other purposes, as an indirect way of instantiating classes or calling methods, given the names of those classes or methods as strings. In this way, you could select classes to instantiate methods to call at runtime, rather than at compile time, based on user input (dynamic binding).

Parallel Programming

The .NET Framework 4 introduces the ability to take advantage of all the dual and quad processors that are out there today. The new parallel computing capabilities provides the means to separate work actions and run these across multiple processors. The new parallel programming APIs that are available now make writing safe multi-threaded code so simple, though it is important to realize that you still need to account for race conditions as well as things such as locks.

The new parallel programming capabilities provide a new Task Parallel Library as well as a PLINQ Execution Engine. Parallel programming is covered in Chapter 20, “Threads, Tasks, and Synchronization.”

.NET FRAMEWORK CLASSES

Perhaps one of the biggest benefits of writing managed code, at least from a developer's point of view, is that you get to use the .NET *base class library*. The .NET base classes are a massive collection of managed code classes that allow you to do almost any of the tasks that were previously available through the Windows API. These classes follow the same object model that IL uses, based on single inheritance. This means that you can either instantiate objects of whichever .NET base class is appropriate or derive your own classes from them.

The great thing about the .NET base classes is that they have been designed to be very intuitive and easy to use. For example, to start a thread, you call the `Start()` method of the `Thread` class. To disable a `TextBox`, you set the `Enabled` property of a `TextBox` object to `false`. This approach — though familiar to Visual Basic and Java developers, whose respective libraries are just as easy to use — will be a welcome relief to C++ developers, who for years have had to cope with such API functions as `GetDIBits()`, `RegisterWndClassEx()`, and `IsEqualIID()`, as well as a whole plethora of functions that require Windows handles to be passed around.

However, C++ developers always had easy access to the entire Windows API, unlike Visual Basic 6 and Java developers who were more restricted in terms of the basic operating system functionality that they have access to from their respective languages. What is new about the .NET base classes is that they combine the ease of use that was typical of the Visual Basic and Java libraries with the relatively comprehensive coverage of the Windows API functions. Many features of Windows still are not available through the base classes, and for those you will need to call into the API functions, but in general, these are now confined to the more exotic features. For everyday use, you will probably find the base classes adequate. Moreover, if you do need to call into an API function, .NET offers a so-called *platform-invoke* that ensures data types are correctly converted, so the task is no harder than calling the function directly from C++ code would have been — regardless of whether you are coding in C#, C++, or Visual Basic 2010.

WinCV, a Windows-based utility, can be used to browse the classes, structs, interfaces, and enums in the base class library. WinCV is discussed in Chapter 16, "Visual Studio 2010."

Although Chapter 3 is nominally dedicated to the subject of base classes, after we have completed our coverage of the syntax of the C# language, most of the rest of this book shows you how to use various classes within the .NET base class library for the .NET Framework 4. That is how comprehensive base classes are. As a rough guide, the areas covered by the .NET 3.5 base classes include the following:

- Core features provided by IL (including the primitive data types in the CTS discussed in Chapter 3)
- Windows GUI support and controls (see Chapters 39, "Windows Forms," and 35, "Core WPF")
- Web Forms (ASP.NET is discussed in Chapters 40, "Core ASP.NET" and 41, "ASP.NET Features")
- Data access (ADO.NET; see Chapters 30, "Core ADO.NET" 34, ".NET Programming with SQL Server," and 33, "Manipulating XML")
- Directory access (see Chapter 52 on the Web, "Directory Services")
- File system and registry access (see Chapter 29, "Manipulating Files and the Registry")
- Networking and web browsing (see Chapter 24, "Networking")
- .NET attributes and reflection (see Chapter 14)
- Access to aspects of the Windows OS (environment variables and so on; see Chapter 21)
- COM interoperability (see Chapter 51 on the Web, "Enterprise Services" and Chapter 26)

Incidentally, according to Microsoft sources, a large proportion of the .NET base classes have actually been written in C#!

NAMESPACES

Namespaces are the way that .NET avoids name clashes between classes. They are designed to prevent situations in which you define a class to represent a customer, name your class `Customer`, and then someone else does the same thing (a likely scenario — the proportion of businesses that have customers seems to be quite high).

A namespace is no more than a grouping of data types, but it has the effect that the names of all data types within a namespace are automatically prefixed with the name of the namespace. It is also possible to nest namespaces within each other. For example, most of the general-purpose .NET base classes are in a namespace called `System`. The base class `Array` is in this namespace, so its full name is `System.Array`.

.NET requires all types to be defined in a namespace; for example, you could place your `Customer` class in a namespace called `YourCompanyName`. This class would have the full name `YourCompanyName.Customer`.

If a namespace is not explicitly supplied, the type will be added to a nameless global namespace.

Microsoft recommends that for most purposes you supply at least two nested namespace names: the first one represents the name of your company, and the second one represents the name of the technology or software package of which the class is a member, such as `YourCompanyName.SalesServices.Customer`. This protects, in most situations, the classes in your application from possible name clashes with classes written by other organizations.

Chapter 2 looks more closely at namespaces.

CREATING .NET APPLICATIONS USING C#

C# can also be used to create console applications: text-only applications that run in a DOS window. You will probably use console applications when unit testing class libraries, and for creating UNIX or Linux daemon processes. More often, however, you will use C# to create applications that use many of the technologies associated with .NET. This section gives you an overview of the different types of applications that you can write in C#.

Creating ASP.NET Applications

The original introduction of ASP.NET 1.0 fundamentally changed the web programming model. ASP.NET 4 is a major release of the product and builds upon its earlier achievements. ASP.NET 4 follows on a series of major revolutionary steps designed to increase your productivity. The primary goal of ASP.NET is to enable you to build powerful, secure, dynamic applications using the least possible amount of code. As this is a C# book, there are many chapters showing you how to use this language to build the latest in web applications.

The following section explores the key features of ASP.NET. For more details, refer to Chapters 40, "Core ASP.NET," 41, "ASP.NET Features," and 42, "ASP.NET MVC."

Features of ASP.NET

First, and perhaps most important, ASP.NET pages are *structured*. That is, each page is effectively a class that inherits from the .NET `System.Web.UI.Page` *class* and can override a set of methods that are evoked during the `Page` object's lifetime. (You can think of these events as page-specific cousins of the `OnApplication_Start` and `OnSession_Start` events that went in the `global.asa` files from the classic

ASP days.) Because you can factor a page's functionality into event handlers with explicit meanings, ASP. NET pages are easier to understand.

Another nice thing about ASP.NET pages is that you can create them in Visual Studio 2010, the same environment in which you create the business logic and data access components that those ASP.NET pages use. A Visual Studio 2010 project, or *solution,* contains all the files associated with an application. Moreover, you can debug your classic ASP pages in the editor as well; in the old days of Visual InterDev, it was often a vexing challenge to configure InterDev and the project's web server to turn debugging on.

For maximum clarity, the ASP.NET code-behind feature lets you take the structured approach even further. ASP.NET allows you to isolate the server-side functionality of a page to a class, compile that class into a DLL with the other pages, and place that DLL into a directory below the HTML portion. A `@Page` directive at the top of the page associates the file with a class. When a browser requests the page, the web server fires the events in the class in the page's class file.

Last, but not least, ASP.NET is remarkable for its increased performance. Whereas classic ASP pages are interpreted with each page request, the web server caches ASP.NET pages after compilation. This means that subsequent requests of an ASP.NET page execute more quickly than the first.

ASP.NET also makes it easy to write pages that cause forms to be displayed by the browser, which you might use in an intranet environment. The traditional wisdom is that form-based applications offer a richer user interface but are harder to maintain because they run on so many different machines. For this reason, people have relied on form-based applications when rich user interfaces were a necessity and extensive support could be provided to the users.

Web Forms

To make web page construction even easier, Visual Studio 2010 supplies *Web Forms*. They allow you to build ASP.NET pages graphically in the same way that Visual Basic 6 or C++ Builder windows are created; in other words, by dragging controls from a toolbox onto a form, then flipping over to the code aspect of that form and writing event handlers for the controls. When you use C# to create a Web Form, you are creating a C# class that inherits from the `Page` base class and an ASP.NET page that designates that class as its code-behind. Of course, you do not have to use C# to create a Web Form; you can use Visual Basic 2010 or another .NET-compliant language just as well.

In the past, the difficulty of web development discouraged some teams from attempting it. To succeed in web development, you needed to know so many different technologies, such as VBScript, ASP, DHTML, JavaScript, and so on. By applying the Form concepts to web pages, Web Forms have made web development considerably easier.

Web Server Controls

The controls used to populate a Web Form are not controls in the same sense as ActiveX controls. Rather, they are XML tags in the ASP.NET namespace that the web browser dynamically transforms into HTML and client-side script when a page is requested. Amazingly, the web server is able to render the same server-side control in different ways, producing a transformation appropriate to the requestor's particular web browser. This means that it is now easy to write fairly sophisticated user interfaces for web pages, without worrying about how to ensure that your page will run on any of the available browsers — because Web Forms will take care of that for you.

You can use C# or Visual Basic 2010 to expand the Web Form toolbox. Creating a new server-side control is simply a matter of implementing .NET's `System.Web.UI.WebControls.WebControl` class.

XML Web Services

Today, HTML pages account for most of the traffic on the World Wide Web. With XML, however, computers have a device-independent format to use for communicating with each other on the Web. In the future, computers may use the Web and XML to communicate information rather than dedicated lines and proprietary formats such as *Electronic Data Interchange* (EDI). XML Web services are designed for a service-oriented Web, in which remote computers provide each other with dynamic information that can be analyzed and reformatted, before final presentation to a user. An XML Web service is an easy way for a computer to expose information to other computers on the Web in the form of XML.

In technical terms, an XML Web service on .NET is an ASP.NET page that returns XML instead of HTML to requesting clients. Such pages have a `code-behind` DLL containing a class that derives from the `WebService` class. The Visual Studio 2010 IDE provides an engine that facilitates web service development.

An organization might choose to use XML Web services for two main reasons. The first reason is that they rely on HTTP; XML Web services can use existing networks (HTTP) as a medium for conveying information. The other is that because XML Web services use XML, the data format is self-describing, nonproprietary, and platform-independent.

Creating Windows Forms

Although C# and .NET are particularly suited to web development, they still offer splendid support for so-called *fat-client* or *thick-client* apps — applications that must be installed on the end user's machine where most of the processing takes place. This support is from *Windows Forms*.

A Windows Form is the .NET answer to a Visual Basic 6 Form. To design a graphical window interface, you just drag controls from a toolbox onto a Windows Form. To determine the window's behavior, you write event-handling routines for the form's controls. A Windows Form project compiles to an executable that must be installed alongside the .NET runtime on the end user's computer. As with other .NET project types, Windows Form projects are supported by both Visual Basic 2010 and C#. Chapter 39, "Windows Forms," examines Windows Forms more closely.

Using the Windows Presentation Foundation (WPF)

One of the newest technologies to hit the block is the *Windows Presentation Foundation* (WPF). WPF makes use of XAML in building applications. XAML stands for Extensible Application Markup Language. This new way of creating applications within a Microsoft environment is something that was introduced in 2006 and is part of the .NET Framework 3.0, 3.5, and 4. This means that to run any WPF application, you need to make sure that the .NET Framework 3.0, 3.5, or 4 is installed on the client machine. WPF applications are available for Windows 7, Windows Vista, Windows XP, Windows Server 2003, and Windows Server 2008 (the only operating systems that allow for the installation of the .NET Framework 3.0, 3.5, or 4).

XAML is the XML declaration that is used to create a form that represents all the visual aspects and behaviors of the WPF application. Though it is possible to work with a WPF application programmatically, WPF is a step in the direction of declarative programming, which the industry is moving to. Declarative programming means that instead of creating objects through programming in a compiled language such as C#, VB, or Java, you declare everything through XML-type programming. Chapter 35, "Core WPF" details how to build these new types of applications using XAML and C#.

Windows Controls

Although Web Forms and Windows Forms are developed in much the same way, you use different kinds of controls to populate them. Web Forms use web server controls, and Windows Forms use *Windows Controls*.

A Windows Control is a lot like an ActiveX control. After a Windows Control is implemented, it compiles to a DLL that must be installed on the client's machine. In fact, the .NET SDK provides a utility that creates a wrapper for ActiveX controls, so that they can be placed on Windows Forms. As is the case with Web Controls, Windows Control creation involves deriving from a particular class: `System.Windows.Forms.Control`.

Windows Services

A Windows Service (originally called an NT Service) is a program designed to run in the background in Windows NT/2000/XP/2003/Vista/7 (but not Windows 9*x*). Services are useful when you want a program to be running continuously and ready to respond to events without having been explicitly started by the user. A good example is the World Wide Web Service on web servers, which listens for web requests from clients.

It is very easy to write services in C#. .NET Framework base classes are available in the `System.ServiceProcess` namespace that handles many of the boilerplate tasks associated with services. In addition, Visual Studio .NET allows you to create a C# Windows Service project, which uses C# source code for a basic Windows Service. Chapter 25, "Windows Services," explores how to write C# Windows Services.

Windows Communication Foundation

Looking at how you move data and services from one point to another using Microsoft-based technologies, you will find that there are a lot of choices at your disposal. For instance, you can use ASP.NET Web services, .NET Remoting, Enterprise Services, and MSMQ for starters. What technology should you use? Well, it really comes down to what you are trying to achieve, because each technology is better used in a particular situation.

With that in mind, Microsoft brought all these technologies together, and with the release of the .NET Framework 3.0 as well as its inclusion in the .NET Framework 3.5 and 4, you now have a single way to move data — the Windows Communication Foundation (WCF). WCF provides you with the ability to build your service one time and then expose this service in a multitude of ways (under different protocols even) by just making changes within a configuration file. You will find that WCF is a powerful new way of connecting disparate systems. Chapter 43, "Windows Communication Foundation," covers this in detail.

Windows Workflow Foundation

The Windows Workflow Foundation (WF) was really introduced back with the release of the .NET Framework 3.0, but has had a good overhaul that many will find more approachable now. You will find that Visual Studio 2010 has greatly improved as far as working with WF and makes it easier to construct your workflows. You will also find a new flow control, the `Flowchart` class, as well as new activities such as `DoWhile`, `ForEach`, and `ParallelForEach`.

WF is covered in Chapter 44, "Windows Workflow Foundation 4."

THE ROLE OF C# IN THE .NET ENTERPRISE ARCHITECTURE

C# requires the presence of the .NET runtime, and it will probably be a few years before most clients — particularly most home computers — have .NET installed. In the meantime, installing a C# application is likely to mean also installing the .NET redistributable components. Because of that, it is likely that we will see many C# applications first in the enterprise environment. Indeed, C# arguably presents an outstanding opportunity for organizations that are interested in building robust, *n*-tiered client-server applications.

When combined with ADO.NET, C# has the ability to quickly and generically access data stores such as SQL Server and Oracle databases. The returned datasets can easily be manipulated using the ADO.NET object model or LINQ, and automatically render as XML for transport across an office intranet.

After a database schema has been established for a new project, C# presents an excellent medium for implementing a layer of data access objects, each of which could provide insertion, updates, and deletion access to a different database table.

Because it's the first component-based C language, C# is a great language for implementing a business object tier, too. It encapsulates the messy plumbing for intercomponent communication, leaving developers free to focus on gluing their data access objects together in methods that accurately enforce their organizations' business rules. Moreover, with attributes, C# business objects can be outfitted for method-level security checks, object pooling, and JIT activation supplied by COM+ Services. Furthermore, .NET ships with utility programs that allow your new .NET business objects to interface with legacy COM components.

To create an enterprise application with C#, you create a class library project for the data access objects and another for the business objects. While developing, you can use Console projects to test the methods on your classes. Fans of extreme programming can build Console projects that can be executed automatically from batch files to unit test that working code has not been broken.

On a related note, C# and .NET will probably influence the way you physically package your reusable classes. In the past, many developers crammed a multitude of classes into a single physical component because this arrangement made deployment a lot easier; if there was a versioning problem, you knew just where to look. Because deploying .NET enterprise components involves simply copying files into directories, developers can now package their classes into more logical, discrete components without encountering "DLL Hell."

Last, but not least, ASP.NET pages coded in C# constitute an excellent medium for user interfaces. Because ASP.NET pages compile, they execute quickly. Because they can be debugged in the Visual Studio 2010 IDE, they are robust. Because they support full-scale language features such as early binding, inheritance, and modularization, ASP.NET pages coded in C# are tidy and easily maintained.

Seasoned developers acquire a healthy skepticism about strongly hyped new technologies and languages and are reluctant to use new platforms simply because they are urged to. If you are an enterprise developer in an IT department, though, or if you provide application services across the World Wide Web, let us assure you that C# and .NET offer at least four solid benefits, even if some of the more exotic features such as XML Web services and server-side controls don't pan out:

- ➤ Component conflicts will become infrequent and deployment is easier because different versions of the same component can run side by side on the same machine without conflicting.
- ➤ Your ASP.NET code will not look like spaghetti code.
- ➤ You can leverage a lot of the functionality in the .NET base classes.
- ➤ For applications requiring a Windows Forms user interface, C# makes it very easy to write this kind of application.

Windows Forms have, to some extent, been downplayed due to the advent of Web Forms and Internet-based applications. However, if you or your colleagues lack expertise in JavaScript, ASP, or related technologies, Windows Forms are still a viable option for creating a user interface with speed and ease. Just remember to factor your code so that the user interface logic is separate from the business logic and the data access code. Doing so will allow you to migrate your application to the browser at some point in the future if you need to. In addition, it is likely that Windows Forms will remain the dominant user interface for applications for use in homes and small businesses for a long time to come. In addition to this, the new smart client features of Windows Forms (the ability to easily work in an online/offline mode) will bring a new round of exciting applications.

SUMMARY

This chapter has covered a lot of ground, briefly reviewing important aspects of the .NET Framework and C#'s relationship to it. It started by discussing how all languages that target .NET are compiled into Microsoft Intermediate Language (IL) before this is compiled and executed by the Common Language Runtime (CLR). This chapter also discussed the roles of the following features of .NET in the compilation and execution process:

- ➤ Assemblies and .NET base classes
- ➤ COM components

- JIT compilation
- Application domains
- Garbage collection

Figure 1-4 provides an overview of how these features come into play during compilation and execution.

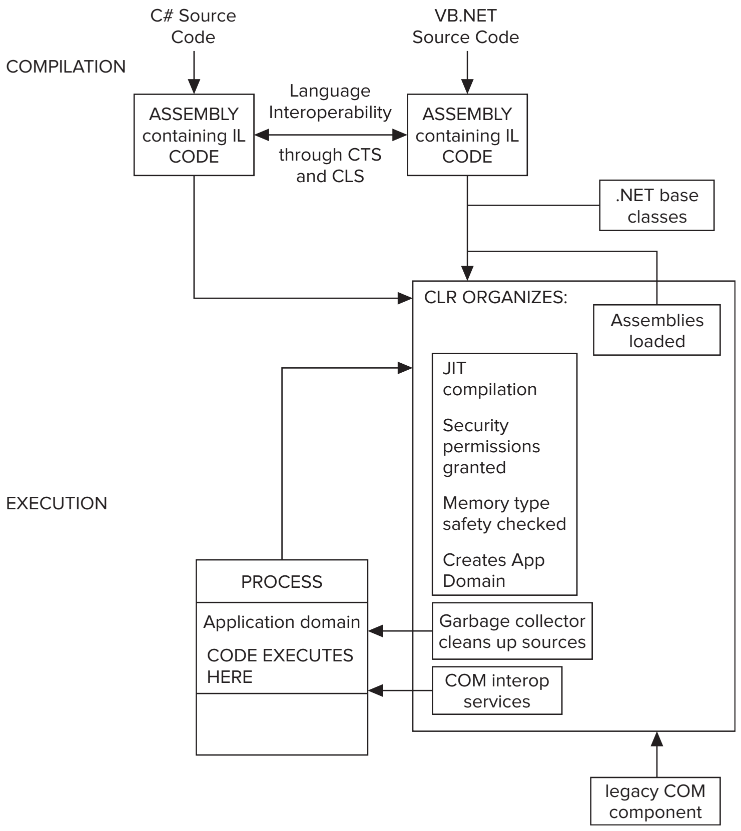

FIGURE 1-4

You learned about the characteristics of IL, particularly its strong data typing and object orientation, and how these characteristics influence the languages that target .NET, including C#. You also learned how the strongly typed nature of IL enables language interoperability, as well as CLR services such as garbage collection and security. There was also a focus on the Common Language Specification (CLS) and the Common Type System (CTS) to help deal with language interoperability.

Finally, you learned how C# could be used as the basis for applications that are built on several .NET technologies, including ASP.NET.

Chapter 2 discusses how to write code in C#.

2 Core C#

WHAT'S IN THIS CHAPTER?

- Declaring variables
- Initialization and scope of variables
- Predefined C# data types
- Dictating the flow of execution within a C# program using conditional statements, loops, and jump statements
- Enumerations
- Namespaces
- The `Main()` method
- Basic command-line C# compiler options
- Using `System.Console` to perform console I/O
- Using internal comments and documentation features
- Preprocessor directives
- Guidelines and conventions for good programming in C#

Now that you understand more about what C# can do, you will want to learn how to use it. This chapter gives you a good start in that direction by providing you with a basic knowledge of the fundamentals of C# programming, which is built on in subsequent chapters. By the end of this chapter, you will know enough C# to write simple programs (though without using inheritance or other object-oriented features, which are covered in later chapters).

YOUR FIRST C# PROGRAM

Let's start by compiling and running the simplest possible C# program — a simple console app consisting of a class that writes a message to the screen.

The Code

Type the following into a text editor (such as Notepad), and save it with a `.cs` extension (for example, `First.cs`). The `Main()` method is shown here (for more information, see "The Main Method" section later in this chapter):

```
using System;

namespace Wrox
{
   public class MyFirstClass
   {
      static void Main()
      {
         Console.WriteLine("Hello from Wrox.");
         Console.ReadLine();
         return;
      }
   }
}
```

code snippet First.cs

Compiling and Running the Program

You can compile this program by simply running the C# command-line compiler (`csc.exe`) against the source file, like this:

```
csc First.cs
```

If you want to compile code from the command line using the `csc` command, you should be aware that the .NET command-line tools, including `csc`, are available only if certain environment variables have been set up. Depending on how you installed .NET (and Visual Studio 2010), this may or may not be the case on your machine.

If you do not have the environment variables set up, you have the following two options: The first is to run the batch file `%Microsoft Visual Studio 2010%\Common7\Tools\vsvars32.bat` *from the command prompt before running* `csc`*, where* `%Microsoft Visual Studio 2010%` *is the folder to which Visual Studio 2010 has been installed. The second, and easier, way is to use the Visual Studio 2010 command prompt instead of the usual command prompt window. You will find the Visual Studio 2010 command prompt in the Start menu, under Programs, Microsoft Visual Studio 2010, Visual Studio Tools. It is simply a command prompt window that automatically runs* `vsvars32.bat` *when it opens.*

Compiling the code produces an executable file named `First.exe`, which you can run from the command line or from Windows Explorer like any other executable. Give it a try:

```
csc First.cs
Microsoft (R) Visual C# 2010 Compiler version 4.0.20506.1
Copyright (C) Microsoft Corporation. All rights reserved.

First.exe
Hello from Wrox.
```

A Closer Look

First, a few general comments about C# syntax. In C#, as in other C-style languages, most statements end in a semicolon (`;`) and can continue over multiple lines without needing a continuation character. Statements can be joined into blocks using curly braces (`{}`). Single-line comments begin with two forward slash characters (`//`), and multiline comments begin with a slash and an asterisk (`/*`) and end with the same combination reversed (`*/`). In these aspects, C# is identical to C++ and Java but different from Visual Basic. It is the semicolons and curly braces that give C# code such a different visual appearance from Visual Basic code. If your background is predominantly Visual Basic, take extra care to remember the semicolon at the end of every statement. Omitting this is usually the biggest single cause of compilation errors among developers new to C-style languages. Another thing to remember is that C# is case-sensitive. That means that variables named `myVar` and `MyVar` are two different variables.

The first few lines in the previous code example have to do with *namespaces* (mentioned later in this chapter), which is a way to group together associated classes. The `namespace` keyword declares the namespace your class should be associated with. All code within the braces that follow it is regarded as being within that namespace. The `using` statement specifies a namespace that the compiler should look at to find any classes that are referenced in your code but that aren't defined in the current namespace. This serves the same purpose as the `import` statement in Java and the `using namespace` statement in C++.

```
using System;

namespace Wrox
{
```

The reason for the presence of the `using` statement in the `First.cs` file is that you are going to use a library class, `System.Console`. The `using System` statement allows you to refer to this class simply as `Console` (and similarly for any other classes in the `System` namespace). Without the `using`, we would have to fully qualify the call to the `Console.WriteLine` method like this:

```
System.Console.WriteLine("Hello from Wrox.");
```

The standard `System` namespace is where the most commonly used .NET types reside. It is important to realize that everything you do in C# depends on the .NET base classes. In this case, you are using the `Console` class within the `System` namespace to write to the console window. C# has no built-in keywords of its own for input or output; it is completely reliant on the .NET classes.

Next, you declare a class called `MyFirstClass`. However, because it has been placed in a namespace called `Wrox`, the fully qualified name of this class is `Wrox.MyFirstCSharpClass`:

```
    class MyFirstCSharpClass
    {
```

All C# code must be contained within a class. The class declaration consists of the `class` keyword, followed by the class name and a pair of curly braces. All code associated with the class should be placed between these braces.

Next, you declare a method called `Main()`. Every C# executable (such as console applications, Windows applications, and Windows services) must have an entry point — the `Main()` method (note the capital `M`):

```
        public static void Main()
        {
```

The method is called when the program is started. This method must return either nothing (`void`) or an integer (`int`). Note the format of method definitions in C#:

```
 [modifiers] return_type MethodName([parameters])
{
   // Method body. NB. This code block is pseudo-code.
}
```

Here, the first square brackets represent certain optional keywords. Modifiers are used to specify certain features of the method you are defining, such as where the method can be called from. In this case, you have two modifiers: `public` and `static`. The `public` modifier means that the method can be accessed from anywhere, so it can be called from outside your class. The `static` modifier indicates that the method does not operate on a specific instance of your class and therefore is called without first instantiating the class. This is important because you are creating an executable rather than a class library. You set the return type to `void`, and in the example, you don't include any parameters.

Finally, we come to the code statements themselves:

```
           Console.WriteLine("Hello from Wrox.");
           Console.ReadLine();
           return;
```

In this case, you simply call the `WriteLine()` method of the `System.Console` class to write a line of text to the console window. `WriteLine()` is a `static` method, so you don't need to instantiate a `Console` object before calling it.

`Console.ReadLine()` reads user input. Adding this line forces the application to wait for the carriage return key to be pressed before the application exits, and, in the case of Visual Studio 2010, the console window disappears.

You then call `return` to exit from the method (also, because this is the `Main()` method, you exit the program as well). You specified `void` in your method header, so you don't return any values.

Now that you have had a taste of basic C# syntax, you are ready for more detail. Because it is virtually impossible to write any nontrivial program without *variables*, we will start by looking at variables in C#.

VARIABLES

You declare variables in C# using the following syntax:

```
datatype identifier;
```

For example:

```
int i;
```

This statement declares an `int` named `i`. The compiler won't actually let you use this variable in an expression until you have initialized it with a value.

After it has been declared, you can assign a value to the variable using the assignment operator, =:

```
i = 10;
```

You can also declare the variable and initialize its value at the same time:

```
int i = 10;
```

If you declare and initialize more than one variable in a single statement, all of the variables will be of the same data type:

```
int x = 10, y =20;   // x and y are both ints
```

To declare variables of different types, you need to use separate statements. You cannot assign different data types within a multiple variable declaration:

```
int x = 10;
bool y = true;              // Creates a variable that stores true or false
int x = 10, bool y = true;  // This won't compile!
```

Notice the `//` and the text after it in the preceding examples. These are comments. The `//` character sequence tells the compiler to ignore the text that follows on this line because it is for a human to better understand the program and not part of the program itself. We further explain comments in code later in this chapter.

Initialization of Variables

Variable initialization demonstrates an example of C#'s emphasis on safety. Briefly, the C# compiler requires that any variable be initialized with some starting value before you refer to that variable in an operation. Most modern compilers will flag violations of this as a warning, but the ever-vigilant C# compiler treats such violations as errors. This prevents you from unintentionally retrieving junk values from memory that is left over from other programs.

C# has two methods for ensuring that variables are initialized before use:

- ➤ Variables that are fields in a class or struct, if not initialized explicitly, are by default zeroed out when they are created (classes and structs are discussed later).
- ➤ Variables that are local to a method must be explicitly initialized in your code prior to any statements in which their values are used. In this case, the initialization doesn't have to happen when the variable is declared, but the compiler will check all possible paths through the method and will flag an error if it detects any possibility of the value of a local variable being used before it is initialized.

For example, you can't do the following in C#:

```
public static int Main()
{
   int d;
   Console.WriteLine(d);   // Can't do this! Need to initialize d before use
   return 0;
}
```

Notice that this code snippet demonstrates defining `Main()` so that it returns an `int` instead of `void`.

When you attempt to compile these lines, you will receive this error message:

```
Use of unassigned local variable 'd'
```

Consider the following statement:

```
Something objSomething;
```

In C#, this line of code would create only a *reference* for a `Something` object, but this reference would not yet actually refer to any object. Any attempt to call a method or property against this variable would result in an error.

Instantiating a reference object in C# requires use of the `new` keyword. You create a reference as shown in the previous example and then point the reference at an object allocated on the heap using the `new` keyword:

```
objSomething = new Something();   // This creates a Something on the heap
```

Type Inference

Type inference makes use of the var keyword. The syntax for declaring the variable changes somewhat. The compiler "infers" what type the variable is by what the variable is initialized to. For example,

```
int someNumber = 0;
```

becomes

```
var someNumber = 0;
```

Even though someNumber is never declared as being an int, the compiler figures this out and someNumber is an int for as long as it is in scope. Once compiled, the two preceding statements are equal.

Here is a short program to demonstrate:

```
using System;

namespace Wrox
{
  class Program
  {
    static void Main(string[] args)
    {
      var name = "Bugs Bunny";
      var age = 25;
      var isRabbit = true;

      Type nameType = name.GetType();
      Type ageType = age.GetType();
      Type isRabbitType = isRabbit.GetType();

      Console.WriteLine("name is type " + nameType.ToString());
      Console.WriteLine("age is type " + ageType.ToString());
      Console.WriteLine("isRabbit is type " + isRabbitType.ToString());
    }
  }
}
```

code snippet Var.cs

The output from this program is:

```
name is type System.String
age is type System.Int32
isRabbit is type System.Bool
```

There are a few rules that you need to follow:

- The variable must be initialized. Otherwise, the compiler doesn't have anything to infer the type from.
- The initializer cannot be null.
- The initializer must be an expression.
- You can't set the initializer to an object unless you create a new object in the initializer.

We examine this more closely in the discussion of anonymous types in Chapter 3, "Objects and Types."

After the variable has been declared and the type inferred, the variable's type cannot be changed. When established, the variable's type follows all the strong typing rules that any other variable type must follow.

Variable Scope

The *scope* of a variable is the region of code from which the variable can be accessed. In general, the scope is determined by the following rules:

- A *field* (also known as a member variable) of a class is in scope for as long as its containing class is in scope.
- A *local variable* is in scope until a closing brace indicates the end of the block statement or method in which it was declared.
- A local variable that is declared in a `for`, `while`, or similar statement is in scope in the body of that loop.

Scope Clashes for Local Variables

It's common in a large program to use the same variable name for different variables in different parts of the program. This is fine as long as the variables are scoped to completely different parts of the program so that there is no possibility for ambiguity. However, bear in mind that local variables with the same name can't be declared twice in the same scope. For example, you can't do this:

```
int x = 20;
// some more code
int x = 30;
```

Consider the following code sample:

```
using System;

namespace Wrox.ProCSharp.Basics
{
   public class ScopeTest
   {
      public static int Main()
      {
         for (int i = 0; i < 10; i++)
         {
            Console.WriteLine(i);
         }   // i goes out of scope here

         // We can declare a variable named i again, because
         // there's no other variable with that name in scope

         for (int i = 9; i >= 0; i--)
         {
            Console.WriteLine(i);
         }   // i goes out of scope here.
         return 0;
      }
   }
}
```

code snippet Scope.cs

This code simply prints out the numbers from 0 to 9, and then back again from 9 to 0, using two `for` loops. The important thing to note is that you declare the variable `i` twice in this code, within the same method. You can do this because `i` is declared in two separate loops, so each `i` variable is local to its own loop.

Here's another example:

```
public static int Main()
{
   int j = 20;
   for (int i = 0; i < 10; i++)
   {
      int j = 30;   // Can't do this—j is still in scope
      Console.WriteLine(j + i);
   }
   return 0;
}
```

code snippet ScopeBad.cs

If you try to compile this, you'll get an error like the following:

```
ScopeTest.cs(12,15): error CS0136: A local variable named 'j' cannot be declared in
this scope because it would give a different meaning to 'j', which is already used
in a 'parent or current' scope to denote something else.
```

This occurs because the variable `j`, which is defined before the start of the `for` loop, is still in scope within the `for` loop, and won't go out of scope until the `Main()` method has finished executing. Although the second `j` (the illegal one) is in the loop's scope, that scope is nested within the `Main()` method's scope. The compiler has no way to distinguish between these two variables, so it won't allow the second one to be declared.

Scope Clashes for Fields and Local Variables

In certain circumstances, however, you can distinguish between two identifiers with the same name (although not the same fully qualified name) and the same scope, and in this case the compiler allows you to declare the second variable. The reason is that C# makes a fundamental distinction between variables that are declared at the type level (fields) and variables that are declared within methods (local variables).

Consider the following code snippet:

```
using System;

namespace Wrox
{
   class ScopeTest2
   {
       static int j = 20;
       public static void Main()
       {
           int j = 30;
           Console.WriteLine(j);
           return;
       }
    }
}
```

code snippet ScopeTest2.cs

This code will compile, even though you have two variables named `j` in scope within the `Main()` method: the `j` that was defined at the class level, and doesn't go out of scope until the class is destroyed (when the `Main()` method terminates, and the program ends); and the `j` defined in `Main()`. In this case, the new variable named `j` that you declare in the `Main()` method *hides* the class-level variable with the same name, so when you run this code, the number `30` will be displayed.

However, what if you want to refer to the class-level variable? You can actually refer to fields of a class or struct from outside the object, using the syntax `object.fieldname`. In the previous example, you are accessing a static field (you look at what this means in the next section) from a static method, so you can't use an instance of the class; you just use the name of the class itself:

```
...
public static void Main()
{
   int j = 30;
   Console.WriteLine(j);
   Console.WriteLine(ScopeTest2.j);
}
...
```

If you were accessing an instance field (a field that belongs to a specific instance of the class), you would need to use the `this` keyword instead.

Constants

As the name implies, a constant is a variable whose value cannot be changed throughout its lifetime. Prefixing a variable with the `const` keyword when it is declared and initialized designates that variable as a constant:

```
const int a = 100;   // This value cannot be changed.
```

Constants have the following characteristics:

- They must be initialized when they are declared, and after a value has been assigned, it can never be overwritten.
- The value of a constant must be computable at compile time. Therefore, you can't initialize a constant with a value taken from a variable. If you need to do this, you will need to use a read-only field (this is explained in Chapter 3).
- Constants are always implicitly static. However, notice that you don't have to (and, in fact, are not permitted to) include the `static` modifier in the constant declaration.

At least three advantages exist for using constants in your programs:

- Constants make your programs easier to read by replacing magic numbers and strings with readable names whose values are easy to understand.
- Constants make your programs easier to modify. For example, assume that you have a `SalesTax` constant in one of your C# programs, and that constant is assigned a value of 6 percent. If the sales tax rate changes at a later point in time, you can modify the behavior of all tax calculations simply by assigning a new value to the constant; you don't have to hunt through your code for the value `.06` and change each one, hoping that you will find all of them.
- Constants help prevent mistakes in your programs. If you attempt to assign another value to a constant somewhere in your program other than at the point where the constant is declared, the compiler will flag the error.

PREDEFINED DATA TYPES

Now that you have seen how to declare variables and constants, let's take a closer look at the data types available in C#. As you will see, C# is much stricter about the types available and their definitions than some other languages are.

Value Types and Reference Types

Before examining the data types in C#, it is important to understand that C# distinguishes between two categories of data type:

- Value types
- Reference types

The next few sections look in detail at the syntax for value and reference types. Conceptually, the difference is that a *value type* stores its value directly, whereas a *reference type* stores a reference to the value.

These types are stored in different places in memory; value types are stored in an area known as the *stack*, and reference types are stored in an area known as the *managed heap*. It is important to be aware of whether a type is a value type or a reference type because of the different effect each assignment has. For example, `int` is a value type, which means that the following statement will result in two locations in memory storing the value 20:

```
// i and j are both of type int
i = 20;
j = i;
```

However, consider the following code. For this code, assume that you have defined a class called `Vector`. Assume that `Vector` is a reference type and has an `int` member variable called `Value`:

```
Vector x, y;
x = new Vector();
x.Value = 30;   // Value is a field defined in Vector class
y = x;
Console.WriteLine(y.Value);
y.Value = 50;
Console.WriteLine(x.Value);
```

The crucial point to understand is that after executing this code, there is only one `Vector` object around. `x` and `y` both point to the memory location that contains this object. Because `x` and `y` are variables of a reference type, declaring each variable simply reserves a reference — it doesn't instantiate an object of the given type. In neither case is an object actually created. To create an object, you have to use the `new` keyword, as shown. Because `x` and `y` refer to the same object, changes made to `x` will affect `y` and vice versa. Hence the code will display `30` and then `50`.

C++ developers should note that this syntax is like a reference, not a pointer. You use the . notation, not ->, to access object members. Syntactically, C# references look more like C++ reference variables. However, behind the superficial syntax, the real similarity is with C++ pointers.

If a variable is a reference, it is possible to indicate that it does not refer to any object by setting its value to `null`:

```
y = null;
```

If a reference is set to `null`, then clearly it is not possible to call any nonstatic member functions or fields against it; doing so would cause an exception to be thrown at runtime.

In C#, basic data types such as `bool` and `long` are value types. This means that if you declare a `bool` variable and assign it the value of another `bool` variable, you will have two separate `bool` values in memory. Later, if you change the value of the original `bool` variable, the value of the second `bool` variable does not change. These types are copied by value.

In contrast, most of the more complex C# data types, including classes that you yourself declare, are reference types. They are allocated upon the heap, have lifetimes that can span multiple function calls, and can be accessed through one or several aliases. The Common Language Runtime (CLR) implements an elaborate algorithm to track which reference variables are still reachable and which have been orphaned. Periodically, the CLR will destroy orphaned objects and return the memory that they once occupied back to the operating system. This is done by the garbage collector.

C# has been designed this way because high performance is best served by keeping primitive types (such as `int` and `bool`) as value types and larger types that contain many fields (as is usually the case with classes) as reference types. If you want to define your own type as a value type, you should declare it as a struct.

CTS Types

As mentioned in Chapter 1, ".NET Architecture," the basic predefined types recognized by C# are not intrinsic to the language but are part of the .NET Framework. For example, when you declare an `int` in C#, what you are actually declaring is an instance of a .NET struct, `System.Int32`. This may sound like a small point, but it has a profound significance: it means that you are able to treat all the primitive data types syntactically as if they were classes that supported certain methods. For example, to convert an `int i` to a `string`, you can write:

```
string s = i.ToString();
```

It should be emphasized that, behind this syntactical convenience, the types really are stored as primitive types, so there is absolutely no performance cost associated with the idea that the primitive types are notionally represented by .NET structs.

The following sections review the types that are recognized as built-in types in C#. Each type is listed, along with its definition and the name of the corresponding .NET type (CTS type). C# has 15 predefined types, 13 value types, and 2 (`string` and `object`) reference types.

Predefined Value Types

The built-in CTS value types represent primitives, such as integer and floating-point numbers, character, and Boolean types.

Integer Types

C# supports eight predefined integer types, shown in the following table.

NAME	CTS TYPE	DESCRIPTION	RANGE (MIN:MAX)
`sbyte`	`System.SByte`	8-bit signed integer	-128:127 ($-2^7:2^7–1$)
`short`	`System.Int16`	16-bit signed integer	-32,768:32,767 ($-2^{15}:2^{15}–1$)
`int`	`System.Int32`	32-bit signed integer	-2,147,483,648:2,147,483,647 ($-2^{31}:2^{31}–1$)
`long`	`System.Int64`	64-bit signed integer	-9,223,372,036,854,775,808: 9,223,372,036,854 ,775,807 ($-2^{63}:2^{63}–1$)
`byte`	`System.Byte`	8-bit unsigned integer	0:255 ($0:2^8–1$)
`ushort`	`System.UInt16`	16-bit unsigned integer	0:65,535 ($0:2^{16}–1$)
`uint`	`System.UInt32`	32-bit unsigned integer	0:4,294,967,295 ($0:2^{32}–1$)
`ulong`	`System.UInt64`	64-bit unsigned integer	0:18,446,744,073,709,551,615 ($0:2^{64}–1$)

Some C# types have the same names as C++ and Java types but have different definitions. For example, in C#, an `int` is always a 32-bit signed integer. In C++ an `int` is a signed integer, but the number of bits is platform-dependent (32 bits on Windows). In C#, all data types have been defined in a platform-independent manner to allow for the possible future porting of C# and .NET to other platforms.

A `byte` is the standard 8-bit type for values in the range 0 to 255 inclusive. Be aware that, in keeping with its emphasis on type safety, C# regards the `byte` type and the `char` type as completely distinct, and any programmatic conversions between the two must be explicitly requested. Also be aware that unlike the other types in the integer family, a `byte` type is by default unsigned. Its signed version bears the special name `sbyte`.

With .NET, a `short` is no longer quite so short; it is now 16 bits long. The `int` type is 32 bits long. The `long` type reserves 64 bits for values. All integer-type variables can be assigned values in decimal or in hex notation. The latter requires the `0x` prefix:

```
long x = 0x12ab;
```

If there is any ambiguity about whether an integer is `int`, `uint`, `long`, or `ulong`, it will default to an `int`. To specify which of the other integer types the value should take, you can append one of the following characters to the number:

```
uint ui = 1234U;
long l = 1234L;
ulong ul = 1234UL;
```

You can also use lowercase `u` and `l`, although the latter could be confused with the integer `1` (one).

Floating-Point Types

Although C# provides a plethora of integer data types, it supports floating-point types as well.

NAME	CTS TYPE	DESCRIPTION	SIGNIFICANT FIGURES	RANGE (APPROXIMATE)
`float`	`System.Single`	32-bit single-precision floating point	7	$\pm 1.5 \times 10^{245}$ to $\pm 3.4 \times 10^{38}$
`double`	`System.Double`	64-bit double-precision floating point	15/16	$\pm 5.0 \times 10^{2324}$ to $\pm 1.7 \times 10^{308}$

The `float` data type is for smaller floating-point values, for which less precision is required. The `double` data type is bulkier than the `float` data type but offers twice the precision (15 digits).

If you hard-code a non-integer number (such as 12.3) in your code, the compiler will normally assume that you want the number interpreted as a `double`. If you want to specify that the value is a `float`, you append the character `F` (or `f`) to it:

```
float f = 12.3F;
```

The Decimal Type

The `decimal` type represents higher-precision floating-point numbers, as shown in the following table.

NAME	CTS TYPE	DESCRIPTION	SIGNIFICANT FIGURES	RANGE (APPROXIMATE)
`decimal`	`System.Decimal`	128-bit high-precision decimal notation	28	$\pm 1.0 \times 10^{228}$ to $\pm 7.9 \times 10^{28}$

One of the great things about the CTS and C# is the provision of a dedicated `decimal` type for financial calculations. How you use the 28 digits that the decimal type provides is up to you. In other words, you can track smaller dollar amounts with greater accuracy for cents or larger dollar amounts with more rounding in the fractional area. Bear in mind, however, that `decimal` is not implemented under the hood as a primitive type, so using `decimal` will have a performance effect on your calculations.

To specify that your number is a `decimal` type rather than a `double`, `float`, or an integer, you can append the `M` (or `m`) character to the value, as shown in the following example:

```
decimal d = 12.30M;
```

The Boolean Type

The C# `bool` type is used to contain Boolean values of either `true` or `false`.

NAME	CTS TYPE	DESCRIPTION	SIGNIFICANT FIGURES	RANGE (APPROXIMATE)
`bool`	`System.Boolean`	Represents true or false	NA	true false

You cannot implicitly convert `bool` values to and from integer values. If a variable (or a function return type) is declared as a `bool`, you can only use values of `true` and `false`. You will get an error if you try to use zero for `false` and a non-zero value for `true`.

The Character Type

For storing the value of a single character, C# supports the `char` data type.

NAME	CTS TYPE	VALUES
`char`	`System.Char`	Represents a single 16-bit (Unicode) character

Literals of type `char` are signified by being enclosed in single quotation marks, for example `'A'`. If you try to enclose a character in double quotation marks, the compiler will treat this as a string and throw an error.

As well as representing `chars` as character literals, you can represent them with four-digit hex Unicode values (for example `'\u0041'`), as integer values with a cast (for example, `(char)65`), or as hexadecimal values (`'\x0041'`). You can also represent them with an escape sequence, as shown in the following table.

ESCAPE SEQUENCE	CHARACTER
`\'`	Single quotation mark
`\"`	Double quotation mark
`\\`	Backslash
`\0`	Null
`\a`	Alert
`\b`	Backspace
`\f`	Form feed
`\n`	Newline
`\r`	Carriage return
`\t`	Tab character
`\v`	Vertical tab

Predefined Reference Types

C# supports two predefined reference types, `object` and `string`, described in the following table.

NAME	CTS TYPE	DESCRIPTION
`object`	`System.Object`	The root type. All other types in the CTS are derived (including value types) from `object`.
`string`	`System.String`	Unicode character string

The object Type

Many programming languages and class hierarchies provide a root type, from which all other objects in the hierarchy are derived. C# and .NET are no exception. In C#, the `object` type is the ultimate parent type from which all other intrinsic and user-defined types are derived. This means that you can use the `object` type for two purposes:

- You can use an `object` reference to bind to an object of any particular subtype. For example, in Chapter 7, "Operators and Casts," you will see how you can use the `object` type to box a value object on the stack to move it to the heap. `object` references are also useful in reflection, when code must manipulate objects whose specific types are unknown.
- The `object` type implements a number of basic, general-purpose methods, which include `Equals()`, `GetHashCode()`, `GetType()`, and `ToString()`. Responsible user-defined classes may need to provide replacement implementations of some of these methods using an object-oriented technique known as *overriding*, which is discussed in Chapter 4, "Inheritance." When you override `ToString()`, for example, you equip your class with a method for intelligently providing a string representation of itself. If you don't provide your own implementations for these methods in your classes, the compiler will pick up the implementations in `object`, which may or may not be correct or sensible in the context of your classes.

We examine the `object` type in more detail in subsequent chapters.

The string Type

C# recognizes the `string` keyword, which under the hood is translated to the .NET class, `System.String`. With it, operations like string concatenation and string copying are a snap:

```
string str1 = "Hello ";
string str2 = "World";
string str3 = str1 + str2; // string concatenation
```

Despite this style of assignment, `string` is a reference type. Behind the scenes, a `string` object is allocated on the heap, not the stack, and when you assign one string variable to another string, you get two references to the same string in memory. However, with `string` there are some differences from the usual behavior for reference types. For example, strings are immutable. Should you make changes to one of these strings, this will create an entirely new `string` object, leaving the other string unchanged. Consider the following code:

```
using System;

class StringExample
{
   public static int Main()
   {
      string s1 = "a string";
      string s2 = s1;
      Console.WriteLine("s1 is " + s1);
      Console.WriteLine("s2 is " + s2);
      s1 = "another string";
      Console.WriteLine("s1 is now " + s1);
      Console.WriteLine("s2 is now " + s2);
      return 0;
   }
}
```

code snippet StringExample.cs

The output from this is:

```
s1 is a string
s2 is a string
s1 is now another string
s2 is now a string
```

Changing the value of `s1` has no effect on `s2`, contrary to what you'd expect with a reference type! What's happening here is that when `s1` is initialized with the value `a string`, a new string object is allocated on the heap. When `s2` is initialized, the reference points to this same object, so `s2` also has the value `a string`. However, when you now change the value of `s1`, instead of replacing the original value, a new object will be allocated on the heap for the new value. The `s2` variable will still point to the original object, so its value is unchanged. Under the hood, this happens as a result of operator overloading, a topic that is explored in Chapter 7. In general, the `string` class has been implemented so that its semantics follow what you would normally intuitively expect for a string.

String literals are enclosed in double quotation marks (`"."`); if you attempt to enclose a string in single quotation marks, the compiler will take the value as a `char`, and throw an error. C# strings can contain the same Unicode and hexadecimal escape sequences as `char`s. Because these escape sequences start with a backslash, you can't use this character unescaped in a string. Instead, you need to escape it with two backslashes (`\\`):

```
string filepath = "C:\\ProCSharp\\First.cs";
```

Even if you are confident that you can remember to do this all the time, typing all those double backslashes can prove annoying. Fortunately, C# gives you an alternative. You can prefix a string literal with the at character (`@`) and all the characters in it will be treated at face value; they won't be interpreted as escape sequences:

```
string filepath = @"C:\ProCSharp\First.cs";
```

This even allows you to include line breaks in your string literals:

```
string jabberwocky = @"'Twas brillig and the slithy toves
Did gyre and gimble in the wabe.";
```

Then the value of `jabberwocky` would be this:

```
'Twas brillig and the slithy toves
Did gyre and gimble in the wabe.
```

FLOW CONTROL

This section looks at the real nuts and bolts of the language: the statements that allow you to control the *flow* of your program rather than executing every line of code in the order it appears in the program.

Conditional Statements

Conditional statements allow you to branch your code depending on whether certain conditions are met or on the value of an expression. C# has two constructs for branching code — the `if` statement, which allows you to test whether a specific condition is met, and the `switch` statement, which allows you to compare an expression with a number of different values.

The if Statement

For conditional branching, C# inherits the C and C++ `if.else` construct. The syntax should be fairly intuitive for anyone who has done any programming with a procedural language:

```
if (condition)
   statement(s)
else
   statement(s)
```

If more than one statement is to be executed as part of either condition, these statements need to be joined together into a block using curly braces ({.}). (This also applies to other C# constructs where statements can be joined into a block, such as the for and while loops):

```
bool isZero;
if (i == 0)
{
   isZero = true;
   Console.WriteLine("i is Zero");
}
else
{
   isZero = false;
   Console.WriteLine("i is Non-zero");
}
```

If you want to, you can use an if statement without a final else statement. You can also combine else if clauses to test for multiple conditions:

```
using System;

namespace Wrox
{
   class MainEntryPoint
   {
      static void Main(string[] args)
      {
         Console.WriteLine("Type in a string");
         string input;
         input = Console.ReadLine();
         if (input == "")
         {
            Console.WriteLine("You typed in an empty string.");
         }
         else if (input.Length < 5)
         {
            Console.WriteLine("The string had less than 5 characters.");
         }
         else if (input.Length < 10)
         {
            Console.WriteLine("The string had at least 5 but less than 10
               Characters.");
         }
         Console.WriteLine("The string was " + input);
      }
   }
```

code snippet ElseIf.cs

There is no limit to how many else ifs you can add to an if clause.

You'll notice that the previous example declares a string variable called input, gets the user to enter text at the command line, feeds this into input, and then tests the length of this string variable. The code also shows how easy string manipulation can be in C#. To find the length of input, for example, use input.Length.

One point to note about if is that you don't need to use the braces if there's only one statement in the conditional branch:

```
if (i == 0) Let's add some brackets here.
   Console.WriteLine("i is Zero");       // This will only execute if i == 0
Console.WriteLine("i can be anything");  // Will execute whatever the
                                         // value of i
```

However, for consistency, many programmers prefer to use curly braces whenever they use an `if` statement.

The `if` statements presented also illustrate some of the C# operators that compare values. Note in particular that C# uses == to compare variables for equality. Do not use = for this purpose. A single = is used to assign values.

In C#, the expression in the `if` clause must evaluate to a Boolean. It is not possible to test an integer (returned from a function, say) directly. You have to convert the integer that is returned to a Boolean `true` or `false`, for example, by comparing the value with zero or with `null`:

```
if (DoSomething() != 0)
{
   // Non-zero value returned
}
else
{
   // Returned zero
}
```

The switch Statement

The `switch.case` statement is good for selecting one branch of execution from a set of mutually exclusive ones. It takes the form of a `switch` argument followed by a series of `case` clauses. When the expression in the `switch` argument evaluates to one of the values beside a `case` clause, the code immediately following the `case` clause executes. This is one example where you don't need to use curly braces to join statements into blocks; instead, you mark the end of the code for each case using the `break` statement. You can also include a `default` case in the `switch` statement, which will execute if the expression evaluates to none of the other cases. The following `switch` statement tests the value of the `integerA` variable:

```
switch (integerA)
{
   case 1:
      Console.WriteLine("integerA =1");
      break;
   case 2:
      Console.WriteLine("integerA =2");
      break;
   case 3:
      Console.WriteLine("integerA =3");
      break;
   default:
      Console.WriteLine("integerA is not 1,2, or 3");
      break;
}
```

Note that the case values must be constant expressions; variables are not permitted.

Though the `switch.case` statement should be familiar to C and C++ programmers, C#'s `switch.case` is a bit safer than its C++ equivalent. Specifically, it prohibits fall-through conditions in almost all cases. This means that if a `case` clause is fired early on in the block, later clauses cannot be fired unless you use a `goto` statement to mark that you want them fired, too. The compiler enforces this restriction by flagging every `case` clause that is not equipped with a `break` statement as an error similar to this:

```
Control cannot fall through from one case label ('case 2:') to another
```

Although it is true that fall-through behavior is desirable in a limited number of situations, in the vast majority of cases, it is unintended and results in a logical error that's hard to spot. Isn't it better to code for the norm rather than for the exception?

By getting creative with `goto` statements, however, you can duplicate fall-through functionality in your `switch.cases`. But, if you find yourself really wanting to, you probably should reconsider your approach.

The following code illustrates both how to use `goto` to simulate fall-through, and how messy the resultant code can get:

```
// assume country and language are of type string
switch(country)
{
   case "America":
      CallAmericanOnlyMethod();
      goto case "Britain";
   case "France":
      language = "French";
      break;
   case "Britain":
      language = "English";
      break;
}
```

There is one exception to the no-fall-through rule, however, in that you can fall through from one case to the next if that case is empty. This allows you to treat two or more cases in an identical way (without the need for `goto` statements):

```
switch(country)
{
   case "au":
   case "uk":
   case "us":
      language = "English";
      break;
   case "at":
   case "de":
      language = "German";
      break;
}
```

One intriguing point about the `switch` statement in C# is that the order of the cases doesn't matter — you can even put the `default` case first! As a result, no two cases can be the same. This includes different constants that have the same value, so you can't, for example, do this:

```
// assume country is of type string
const string england = "uk";
const string britain = "uk";
switch(country)
{
   case england:
   case britain:    // This will cause a compilation error.
      language = "English";
      break;
}
```

The previous code also shows another way in which the `switch` statement is different in C# compared to C++: In C#, you are allowed to use a string as the variable being tested.

Loops

C# provides four different loops (`for`, `while`, do . . . while, and `foreach`) that allow you to execute a block of code repeatedly until a certain condition is met.

The for Loop

C# `for` loops provide a mechanism for iterating through a loop where you test whether a particular condition holds before you perform another iteration. The syntax is:

```
for (initializer; condition; iterator)
   statement(s)
```

where:

- ➤ The initializer is the expression evaluated before the first loop is executed (usually initializing a local variable as a loop counter).
- ➤ The condition is the expression checked before each new iteration of the loop (this must evaluate to `true` for another iteration to be performed).
- ➤ The iterator is an expression evaluated after each iteration (usually incrementing the loop counter).

The iterations end when the condition evaluates to `false`.

The `for` loop is a so-called pretest loop because the loop condition is evaluated before the loop statements are executed, and so the contents of the loop won't be executed at all if the loop condition is `false`.

The `for` loop is excellent for repeating a statement or a block of statements for a predetermined number of times. The following example is typical of the use of a `for` loop. The following code will write out all the integers from 0 to 99:

```
for (int i = 0; i < 100; i=i+1)   // This is equivalent to
                                        // For i = 0 To 99 in VB.
{
   Console.WriteLine(i);
}
```

Here, you declare an `int` called `i` and initialize it to zero. This will be used as the loop counter. You then immediately test whether it is less than 100. Because this condition evaluates to `true`, you execute the code in the loop, displaying the value 0. You then increment the counter by one, and walk through the process again. Looping ends when `i` reaches 100.

Actually, the way the preceding loop is written isn't quite how you would normally write it. C# has a shorthand for adding 1 to a variable, so instead of `i = i + 1`, you can simply write `i++`:

```
for (int i = 0; i < 100; i++)
{
    // etc.
       }
```

You can also make use of type inference for the iteration variable `i` in the preceding example. Using type inference the loop construct would be:

```
for (var i = 0; i < 100; i++)
...
```

It's not unusual to nest `for` loops so that an inner loop executes once completely for each iteration of an outer loop. This scheme is typically employed to loop through every element in a rectangular multidimensional array. The outermost loop loops through every row, and the inner loop loops through every column in a particular row. The following code displays rows of numbers. It also uses another `Console` method, `Console.Write()`, which does the same as `Console.WriteLine()` but doesn't send a carriage return to the output.

```
using System;

namespace Wrox
{
   class MainEntryPoint
   {
      static void Main(string[] args)
      {
         // This loop iterates through rows
         for (int i = 0; i < 100; i+=10)
         {
            // This loop iterates through columns
            for (int j = i; j < i + 10; j++)
```

```
                {
                   Console.Write(" " + j);
                }
                Console.WriteLine();
             }
          }
       }
    }
```

code snippet NestedFor.cs

Although `j` is an integer, it will be automatically converted to a string so that the concatenation can take place.

The preceding sample results in this output:

```
 0  1  2  3  4  5  6  7  8  9
 10  11  12  13  14  15  16  17  18  19
 20  21  22  23  24  25  26  27  28  29
 30  31  32  33  34  35  36  37  38  39
 40  41  42  43  44  45  46  47  48  49
 50  51  52  53  54  55  56  57  58  59
 60  61  62  63  64  65  66  67  68  69
 70  71  72  73  74  75  76  77  78  79
 80  81  82  83  84  85  86  87  88  89
 90  91  92  93  94  95  96  97  98  99
```

Although it is technically possible to evaluate something other than a counter variable in a `for` loop's test condition, it is certainly not typical. It is also possible to omit one (or even all) of the expressions in the `for` loop. In such situations, however, you should consider using the `while` loop.

The while Loop

Like the `for` loop, `while` is a pretest loop. The syntax is similar, but `while` loops take only one expression:

```
while(condition)
   statement(s);
```

Unlike the `for` loop, the `while` loop is most often used to repeat a statement or a block of statements for a number of times that is not known before the loop begins. Usually, a statement inside the `while` loop's body will set a Boolean flag to `false` on a certain iteration, triggering the end of the loop, as in the following example:

```
bool condition = false;
while (!condition)
{
   // This loop spins until the condition is true.
   DoSomeWork();
   condition = CheckCondition();   // assume CheckCondition() returns a bool
}
```

The do . . . while Loop

The `do...while` loop is the post-test version of the `while` loop. This means that the loop's test condition is evaluated after the body of the loop has been executed. Consequently, `do...while` loops are useful for situations in which a block of statements must be executed at least one time, as in this example:

```
bool condition;
do
{
   // This loop will at least execute once, even if Condition is false.
   MustBeCalledAtLeastOnce();
   condition = CheckCondition();
} while (condition);
```

The foreach Loop

The foreach loop allows you to iterate through each item in a collection. For now, we won't worry about exactly what a collection is (it is explained fully in Chapter 10, "Collections"); we will just say that it is an object that represents a list of objects. Technically, to count as a collection, it must support an interface called IEnumerable. Examples of collections include C# arrays, the collection classes in the System .Collection namespaces, and user-defined collection classes. You can get an idea of the syntax of foreach from the following code, if you assume that arrayOfInts is (unsurprisingly) an array of ints:

```
foreach (int temp in arrayOfInts)
{
   Console.WriteLine(temp);
}
```

Here, foreach steps through the array one element at a time. With each element, it places the value of the element in the int variable called temp and then performs an iteration of the loop.

Here is another situation where type inference can be used. The foreach loop would become:

```
foreach (var temp in arrayOfInts)
...
```

temp would be inferred to int because that is what the collection item type is.

An important point to note with foreach is that you can't change the value of the item in the collection (temp in the preceding code), so code such as the following will not compile:

```
foreach (int temp in arrayOfInts)
{
   temp++;
   Console.WriteLine(temp);
}
```

If you need to iterate through the items in a collection and change their values, you will need to use a for loop instead.

Jump Statements

C# provides a number of statements that allow you to jump immediately to another line in the program. The first of these is, of course, the notorious goto statement.

The goto Statement

The goto statement allows you to jump directly to another specified line in the program, indicated by a *label* (this is just an identifier followed by a colon):

```
goto Label1;
   Console.WriteLine("This won't be executed");
Label1:
   Console.WriteLine("Continuing execution from here");
```

A couple of restrictions are involved with goto. You can't jump into a block of code such as a for loop, you can't jump out of a class, and you can't exit a finally block after try.catch blocks (Chapter 15, "Errors and Exceptions," looks at exception handling with try.catch.finally).

The reputation of the goto statement probably precedes it, and in most circumstances, its use is sternly frowned upon. In general, it certainly doesn't conform to good object-oriented programming practice.

The break Statement

You have already met the break statement briefly — when you used it to exit from a case in a switch statement. In fact, break can also be used to exit from for, foreach, while, or do...while loops. Control will switch to the statement immediately after the end of the loop.

If the statement occurs in a nested loop, control will switch to the end of the innermost loop. If the break occurs outside of a switch statement or a loop, a compile-time error will occur.

The continue Statement

The continue statement is similar to break, and must also be used within a for, foreach, while, or do...while loop. However, it exits only from the current iteration of the loop, meaning that execution will restart at the beginning of the next iteration of the loop, rather than outside the loop altogether.

The return Statement

The return statement is used to exit a method of a class, returning control to the caller of the method. If the method has a return type, return must return a value of this type; otherwise if the method returns void, you should use return without an expression.

ENUMERATIONS

An *enumeration* is a user-defined integer type. When you declare an enumeration, you specify a set of acceptable values that instances of that enumeration can contain. Not only that, but you can give the values user-friendly names. If, somewhere in your code, you attempt to assign a value that is not in the acceptable set of values to an instance of that enumeration, the compiler will flag an error.

Creating an enumeration can save you a lot of time and headaches in the long run. At least three benefits exist to using enumerations instead of plain integers:

- As mentioned, enumerations make your code easier to maintain by helping to ensure that your variables are assigned only legitimate, anticipated values.
- Enumerations make your code clearer by allowing you to refer to integer values by descriptive names rather than by obscure "magic" numbers.
- Enumerations make your code easier to type, too. When you go to assign a value to an instance of an enumerated type, the Visual Studio .NET IDE will, through IntelliSense, pop up a list box of acceptable values to save you some keystrokes and to remind you of what the possible options are.

You can define an enumeration as follows:

```
public enum TimeOfDay
{
   Morning = 0,
   Afternoon = 1,
   Evening = 2
}
```

In this case, you use an integer value to represent each period of the day in the enumeration. You can now access these values as members of the enumeration. For example, TimeOfDay.Morning will return the value 0. You will typically use this enumeration to pass an appropriate value into a method and iterate through the possible values in a switch statement:

```
class EnumExample
{
   public static int Main()
   {
      WriteGreeting(TimeOfDay.Morning);
      return 0;
   }

   static void WriteGreeting(TimeOfDay timeOfDay)
   {
      switch(timeOfDay)
```

```
         {
            case TimeOfDay.Morning:
               Console.WriteLine("Good morning!");
               break;
            case TimeOfDay.Afternoon:
               Console.WriteLine("Good afternoon!");
               break;
            case TimeOfDay.Evening:
               Console.WriteLine("Good evening!");
               break;
            default:
               Console.WriteLine("Hello!");
               break;
         }
      }
   }
```

The real power of enums in C# is that behind the scenes they are instantiated as structs derived from the base class, `System.Enum`. This means it is possible to call methods against them to perform some useful tasks. Note that because of the way the .NET Framework is implemented there is no performance loss associated with treating the enums syntactically as structs. In practice, after your code is compiled, enums will exist as primitive types, just like `int` and `float`.

You can retrieve the string representation of an enum as in the following example, using the earlier `TimeOfDay` enum:

```
TimeOfDay time = TimeOfDay.Afternoon;
Console.WriteLine(time.ToString());
```

This will return the string `Afternoon`.

Alternatively, you can obtain an enum value from a string:

```
TimeOfDay time2 = (TimeOfDay) Enum.Parse(typeof(TimeOfDay), "afternoon", true);
Console.WriteLine((int)time2);
```

This code snippet illustrates both obtaining an enum value from a string and converting to an integer. To convert from a string, you need to use the static `Enum.Parse()` method, which, as shown, takes three parameters. The first is the type of enum you want to consider. The syntax is the keyword `typeof` followed by the name of the enum class in brackets. (Chapter 7 explores the `typeof` operator in more detail.) The second parameter is the string to be converted, and the third parameter is a `bool` indicating whether you should ignore case when doing the conversion. Finally, note that `Enum.Parse()` actually returns an object reference — you need to explicitly convert this to the required enum type (this is an example of an unboxing operation). For the preceding code, this returns the value `1` as an object, corresponding to the enum value of `TimeOfDay.Afternoon`. On converting explicitly to an `int`, this produces the value `1` again.

Other methods on `System.Enum` do things such as return the number of values in an enum definition or list the names of the values. Full details are in the MSDN documentation.

NAMESPACES

As you saw earlier in this chapter, namespaces provide a way of organizing related classes and other types. Unlike a file or a component, a namespace is a logical rather than physical grouping. When you define a class in a C# file, you can include it within a namespace definition. Later, when you define another class that performs related work in another file, you can include it within the same namespace, creating a logical grouping that gives an indication to other developers using the classes how they are related and used:

```
namespace CustomerPhoneBookApp
{
   using System;

   public struct Subscriber
```

```
        {
            // Code for struct here...
        }
    }
```

Placing a type in a namespace effectively gives that type a long name, consisting of the type's namespace as a series of names separated with periods (`.`), terminating with the name of the class. In the preceding example, the full name of the `Subscriber` struct is `CustomerPhoneBookApp.Subscriber`. This allows distinct classes with the same short name to be used within the same program without ambiguity. This full name is often called the fully qualified name.

You can also nest namespaces within other namespaces, creating a hierarchical structure for your types:

```
namespace Wrox
{
    namespace ProCSharp
    {
        namespace Basics
        {
            class NamespaceExample
            {
                // Code for the class here...
            }
        }
    }
}
```

Each namespace name is composed of the names of the namespaces it resides within, separated with periods, starting with the outermost namespace and ending with its own short name. So the full name for the `ProCSharp` namespace is `Wrox.ProCSharp`, and the full name of `NamespaceExample` class is `Wrox.ProCSharp.Basics.NamespaceExample`.

You can use this syntax to organize the namespaces in your namespace definitions too, so the previous code could also be written as follows:

```
namespace Wrox.ProCSharp.Basics
{
    class NamespaceExample
    {
        // Code for the class here...
    }
}
```

Note that you are not permitted to declare a multipart namespace nested within another namespace.

Namespaces are not related to assemblies. It is perfectly acceptable to have different namespaces in the same assembly or to define types in the same namespace in different assemblies.

Defining the namespace hierarchy should be planned out prior to the start of a project. Generally the accepted format is `CompanyName.ProjectName.SystemSection`. So in the previous example, Wrox is the company name, ProCSharp is the project, and in the case of this chapter, Basics is the section.

The using Directive

Obviously, namespaces can grow rather long and tiresome to type, and the ability to indicate a particular class with such specificity may not always be necessary. Fortunately, as noted at the beginning of this chapter, C# allows you to abbreviate a class's full name. To do this, list the class's namespace at the top of the file, prefixed with the `using` keyword. Throughout the rest of the file, you can refer to the types in the namespace simply by their type names:

```
using System;
using Wrox.ProCSharp;
```

As remarked earlier, virtually all C# source code will have the statement `using System;` simply because so many useful classes supplied by Microsoft are contained in the `System` namespace.

If two namespaces referenced by `using` statements contain a type of the same name, you will need to use the full (or at least a longer) form of the name to ensure that the compiler knows which type is to be accessed. For example, say classes called `NamespaceExample` exist in both the `Wrox.ProCSharp.Basics` and `Wrox.ProCSharp.OOP` namespaces. If you then create a class called `Test` in the `Wrox.ProCSharp` namespace, and instantiate one of the `NamespaceExample` classes in this class, you need to specify which of these two classes you're talking about:

```
using Wrox.ProCSharp.OOP;
using Wrox.ProCSharp.Basics;
namespace Wrox.ProCSharp
{
  class Test
  {
    public static int Main()
    {
      Basics.NamespaceExample nSEx = new Basics.NamespaceExample();
     // do something with the nSEx variable.
      return 0;
    }
  }
}
```

Your organization will probably want to spend some time developing a namespace schema so that its developers can quickly locate functionality that they need and so that the names of the organization's homegrown classes won't conflict with those in off-the-shelf class libraries. Guidelines on establishing your own namespace scheme along with other naming recommendations are discussed later in this chapter.

Namespace Aliases

Another use of the `using` keyword is to assign aliases to classes and namespaces. If you have a very long namespace name that you want to refer to several times in your code but don't want to include in a simple `using` statement (for example, to avoid type name conflicts), you can assign an alias to the namespace. The syntax for this is as follows:

```
using alias = NamespaceName;
```

The following example (a modified version of the previous example) assigns the alias `Introduction` to the `Wrox.ProCSharp.Basics` namespace and uses this to instantiate a `NamespaceExample` object, which is defined in this namespace. Notice the use of the namespace alias qualifier (`::`). This forces the search to start with the `Introduction` namespace alias. If a class called `Introduction` had been introduced in the same scope, a conflict would happen. The :: operator allows the alias to be referenced even if the conflict exists. The `NamespaceExample` class has one method, `GetNamespace()`, which uses the `GetType()` method exposed by every class to access a `Type` object representing the class's type. You use this object to return a name of the class's namespace:

```
using System;
using Introduction =  Wrox.ProCSharp.Basics;
```

```
class Test
{
   public static int Main()
   {
      Introduction::NamespaceExample NSEx =
         new Introduction::NamespaceExample();
      Console.WriteLine(NSEx.GetNamespace());
      return 0;
   }
}

namespace Wrox.ProCSharp.Basics
{
   class NamespaceExample
   {
      public string GetNamespace()
      {
         return this.GetType().Namespace;
      }
   }
}
```

THE MAIN() METHOD

As you saw at the start of this chapter, C# programs start execution at a method named `Main()`. This must be a static method of a class (or struct), and must have a return type of either `int` or `void`.

Although it is common to specify the `public` modifier explicitly, because by definition the method must be called from outside the program, it doesn't actually matter what accessibility level you assign to the entry-point method — it will run even if you mark the method as `private`.

Multiple Main() Methods

When a C# console or Windows application is compiled, by default the compiler looks for exactly one `Main()` method in any class matching the signature that was just described and makes that class method the entry point for the program. If there is more than one `Main()` method, the compiler will return an error message. For example, consider the following code called `DoubleMain.cs`:

```
using System;

namespace Wrox
{
   class Client
   {
      public static int Main()
      {
         MathExample.Main();
         return 0;
      }
   }

   class MathExample
   {
      static int Add(int x, int y)
      {
         return x + y;
      }

      public static int Main()
```

```
         {
            int i = Add(5,10);
            Console.WriteLine(i);
            return 0;
         }
      }
   }
```

code snippet DoubleMain.cs

This contains two classes, both of which have a `Main()` method. If you try to compile this code in the usual way, you will get the following errors:

```
csc DoubleMain.cs
Microsoft (R) Visual C# 2010 Compiler version 4.0.20506.1
Copyright (C) Microsoft Corporation. All rights reserved.

DoubleMain.cs(7,25): error CS0017: Program
        'DoubleMain.exe' has more than one entry point defined:
        'Wrox.Client.Main()'.  Compile with /main to specify the type that
        contains the entry point.
DoubleMain.cs(21,25): error CS0017: Program
        'DoubleMain.exe' has more than one entry point defined:
        'Wrox.MathExample.Main()'.  Compile with /main to specify the type that
        contains the entry point.
```

However, you can explicitly tell the compiler which of these methods to use as the entry point for the program by using the `/main` switch, together with the full name (including namespace) of the class to which the `Main()` method belongs:

```
csc DoubleMain.cs /main:Wrox.MathExample
```

Passing Arguments to Main()

The examples so far have shown only the `Main()` method without any parameters. However, when the program is invoked, you can get the CLR to pass any command-line arguments to the program by including a parameter. This parameter is a string array, traditionally called `args` (although C# will accept any name). The program can use this array to access any options passed through the command line when the program is started.

The following sample, `ArgsExample.cs`, loops through the string array passed in to the `Main()` method and writes the value of each option to the console window:

```
using System;

namespace Wrox
{
   class ArgsExample
   {
      public static int Main(string[] args)
      {
         for (int i = 0; i < args.Length; i++)
         {
            Console.WriteLine(args[i]);
         }
         return 0;
      }
   }
}
```

code snippet ArgsExample.cs

You can compile this as usual using the command line. When you run the compiled executable, you can pass in arguments after the name of the program, as shown in this example:

```
ArgsExample /a /b /c
/a
/b
/c
```

MORE ON COMPILING C# FILES

You have seen how to compile console applications using `csc.exe`, but what about other types of applications? What if you want to reference a class library? The full set of compilation options for the C# compiler is of course detailed in the MSDN documentation, but we list here the most important options.

To answer the first question, you can specify what type of file you want to create using the `/target` switch, often abbreviated as `/t`. This can be one of those shown in the following table.

OPTION	OUTPUT
`/t:exe`	A console application (the default)
`/t:library`	A class library with a manifest
`/t:module`	A component without a manifest
`/t:winexe`	A Windows application (without a console window)

If you want a nonexecutable file (such as a DLL) to be loadable by the .NET runtime, you must compile it as a library. If you compile a C# file as a module, no assembly will be created. Although modules cannot be loaded by the runtime, they can be compiled into another manifest using the `/addmodule` switch.

Another option we need to mention is `/out`. This allows you to specify the name of the output file produced by the compiler. If the `/out` option isn't specified, the compiler will base the name of the output file on the name of the input C# file, adding an extension according to the target type (for example, `exe` for a Windows or console application or `dll` for a class library). Note that the `/out` and `/t`, or `/target`, options must precede the name of the file you want to compile.

If you want to reference types in assemblies that aren't referenced by default, you can use the `/reference` or `/r` switch, together with the path and filename of the assembly. The following example demonstrates how you can compile a class library and then reference that library in another assembly. It consists of two files:

- The class library
- A console application, which will call a class in the library

The first file is called `MathLibrary.cs` and contains the code for your DLL. To keep things simple, it contains just one (public) class, `MathLib`, with a single method that adds two `int`s:

```
namespace Wrox
{
   public class MathLib
   {
      public int Add(int x, int y)
      {
         return x + y;
      }
   }
}
```

code snippet MathLibrary.cs

You can compile this C# file into a .NET DLL using the following command:

```
csc /t:library MathLibrary.cs
```

The console application, `MathClient.cs`, will simply instantiate this object and call its `Add()` method, displaying the result in the console window:

```
using System;

namespace Wrox
{
   class Client
   {
      public static void Main()
      {
         MathLib mathObj = new MathLib();
         Console.WriteLine(mathObj.Add(7,8));
      }
   }
}
```

code snippet MathClient.cs

You can compile this code using the `/r` switch to point at or reference the newly compiled DLL:

```
csc MathClient.cs /r:MathLibrary.dll
```

You can then run it as normal just by entering `MathClient` at the command prompt. This displays the number `15` — the result of your addition.

CONSOLE I/O

By this point, you should have a basic familiarity with C#'s data types, as well as some knowledge of how the thread-of-control moves through a program that manipulates those data types. In this chapter, you have also used several of the `Console` class's static methods used for reading and writing data. Because these methods are so useful when writing basic C# programs, this section quickly reviews them in more detail.

To read a line of text from the console window, you use the `Console.ReadLine()` method. This will read an input stream (terminated when the user presses the `Return` key) from the console window and return the input string. There are also two corresponding methods for writing to the console, which you have already used extensively:

- `Console.Write()` — Writes the specified value to the console window.
- `Console.WriteLine()` — This does the same, but adds a newline character at the end of the output.

Various forms (overloads) of these methods exist for all the predefined types (including `object`), so in most cases you don't have to convert values to strings before you display them.

For example, the following code lets the user input a line of text and displays that text:

```
string s = Console.ReadLine();
Console.WriteLine(s);
```

`Console.WriteLine()` also allows you to display formatted output in a way comparable to C's `printf()` function. To use `WriteLine()` in this way, you pass in a number of parameters. The first is a string containing markers in curly braces where the subsequent parameters will be inserted into the text. Each marker contains a zero-based index for the number of the parameter in the following list. For example, `{0}` represents the first parameter in the list. Consider the following code:

```
int i = 10;
int j = 20;
Console.WriteLine("{0} plus {1} equals {2}", i, j, i + j);
```

This code displays:

```
10 plus 20 equals 30
```

You can also specify a width for the value, and justify the text within that width, using positive values for right-justification and negative values for left-justification. To do this, use the format {n,w}, where n is the parameter index and w is the width value:

```
int i = 940;
int j = 73;
Console.WriteLine(" {0,4}\n+{1,4}\n —— \n {2,4}", i, j, i + j);
```

The result of this is:

```
  940
+  73
 ————
 1013
```

Finally, you can also add a format string, together with an optional precision value. It is not possible to give a complete list of potential format strings because, as you will see in Chapter 9, "Strings and Regular Expressions," you can define your own format strings. However, the main ones in use for the predefined types are shown in the following table.

STRING	DESCRIPTION
C	Local currency format.
D	Decimal format. Converts an integer to base 10, and pads with leading zeros if a precision specifier is given.
E	Scientific (exponential) format. The precision specifier sets the number of decimal places (6 by default). The case of the format string (e or E) determines the case of the exponential symbol.
F	Fixed-point format; the precision specifier controls the number of decimal places. Zero is acceptable.
G	General format. Uses E or F formatting, depending on which is more compact.
N	Number format. Formats the number with commas as the thousands separators, for example 32,767.44.
P	Percent format.
X	Hexadecimal format. The precision specifier can be used to pad with leading zeros.

Note that the format strings are normally case insensitive, except for e/E.

If you want to use a format string, you should place it immediately after the marker that gives the parameter number and field width, and separate it with a colon. For example, to format a `decimal` value as currency for the computer's locale, with precision to two decimal places, you would use `C2`:

```
decimal i = 940.23m;
decimal j = 73.7m;
Console.WriteLine(" {0,9:C2}\n+{1,9:C2}\n —— \n {2,9:C2}", i, j, i + j);
```

The output of this in U.S. currency is:

```
   $940.23
+   $73.70
 —————————
 $1,013.93
```

As a final trick, you can also use placeholder characters instead of these format strings to map out formatting. For example:

```
double d = 0.234;
Console.WriteLine("{0:#.00}", d);
```

This displays as `.23`, because the `#` symbol is ignored if there is no character in that place, and zeros will either be replaced by the character in that position if there is one or be printed as a zero.

USING COMMENTS

The next topic — adding comments to your code — looks very simple on the surface, but can be complex.

Internal Comments within the Source Files

As noted earlier in this chapter, C# uses the traditional C-type single-line (`//...`) and multiline (`/* ... */`) comments:

```
// This is a singleline comment
/* This comment
   spans multiple lines. */
```

Everything in a single-line comment, from the `//` to the end of the line, will be ignored by the compiler, and everything from an opening `/*` to the next `*/` in a multiline comment combination will be ignored. Obviously, you can't include the combination `*/` in any multiline comments, because this will be treated as the end of the comment.

It is actually possible to put multiline comments within a line of code:

```
Console.WriteLine(/* Here's a comment! */ "This will compile.");
```

Use inline comments with care because they can make code hard to read. However, they can be useful when debugging if, say, you temporarily want to try running the code with a different value somewhere:

```
DoSomething(Width, /*Height*/ 100);
```

Comment characters included in string literals are, of course, treated like normal characters:

```
string s = "/* This is just a normal string .*/";
```

XML Documentation

In addition to the C-type comments, illustrated in the preceding section, C# has a very neat feature that we want to highlight: the ability to produce documentation in XML format automatically from special comments. These comments are single-line comments but begin with three slashes (`///`) instead of the usual two. Within these comments, you can place XML tags containing documentation of the types and type members in your code.

The tags in the following table are recognized by the compiler.

TAG	DESCRIPTION
`<c>`	Marks up text within a line as code, for example `<c>int i = 10;</c>`.
`<code>`	Marks multiple lines as code.
`<example>`	Marks up a code example.
`<exception>`	Documents an exception class. (Syntax is verified by the compiler.)
`<include>`	Includes comments from another documentation file. (Syntax is verified by the compiler.)
`<list>`	Inserts a list into the documentation.
`<param>`	Marks up a method parameter. (Syntax is verified by the compiler.)
`<paramref>`	Indicates that a word is a method parameter. (Syntax is verified by the compiler.)
`<permission>`	Documents access to a member. (Syntax is verified by the compiler.)

continues

(continued)

TAG	DESCRIPTION
`<remarks>`	Adds a description for a member.
`<returns>`	Documents the return value for a method.
`<see>`	Provides a cross-reference to another parameter. (Syntax is verified by the compiler.)
`<seealso>`	Provides a "see also" section in a description. (Syntax is verified by the compiler.)
`<summary>`	Provides a short summary of a type or member.
`<value>`	Describes a property.

To see how this works, add some XML comments to the `MathLibrary.cs` file from the previous "More on Compiling C# Files" section. You will add a `<summary>` element for the class and for its `Add()` method, and also a `<returns>` element and two `<param>` elements for the `Add()` method:

```
// MathLib.cs
namespace Wrox
{

   ///<summary>
   ///   Wrox.Math class.
   ///   Provides a method to add two integers.
   ///</summary>
   public class MathLib
   {
      ///<summary>
      ///   The Add method allows us to add two integers.
      ///</summary>
      ///<returns>Result of the addition (int)</returns>
      ///<param name="x">First number to add</param>
      ///<param name="y">Second number to add</param>
      public int Add(int x, int y)
      {
         return x + y;
      }
   }
}
```

The C# compiler can extract the XML elements from the special comments and use them to generate an XML file. To get the compiler to generate the XML documentation for an assembly, you specify the `/doc` option when you compile, together with the name of the file you want to be created:

```
csc /t:library /doc:MathLibrary.xml MathLibrary.cs
```

The compiler will throw an error if the XML comments do not result in a well-formed XML document.

This will generate an XML file named `Math.xml`, which looks like this:

```
<?xml version="1.0"?>
<doc>
   <assembly>
      <name>MathLibrary</name>
   </assembly>
   <members>
      <member name="T:Wrox.MathLibrary">
         <summary>
            Wrox.MathLibrary class.
            Provides a method to add two integers.
         </summary>
      </member>
      <member name=
            "M:Wrox.MathLibrary.Add(System.Int32,System.Int32)">
            <summary>
               The Add method allows us to add two integers.
            </summary>
            <returns>Result of the addition (int)</returns>
            <param name="x">First number to add</param>
            <param name="y">Second number to add</param>
         </member>
      </members>
   </doc>
```

code snippet MathLibrary.xml

Notice how the compiler has actually done some work for you; it has created an `<assembly>` element and also added a `<member>` element for each type or member of a type in the file. Each `<member>` element has a `name` attribute with the full name of the member as its value, prefixed by a letter that indicates whether this is a type (`T:`), field (`F:`), or member (`M:`).

THE C# PREPROCESSOR DIRECTIVES

Besides the usual keywords, most of which you have now encountered, C# also includes a number of commands that are known as *preprocessor directives*. These commands never actually get translated to any commands in your executable code, but instead they affect aspects of the compilation process. For example, you can use preprocessor directives to prevent the compiler from compiling certain portions of your code. You might do this if you are planning to release two versions of the code — a basic version and an enterprise version that will have more features. You could use preprocessor directives to prevent the compiler from compiling code related to the additional features when you are compiling the basic version of the software. Another scenario is that you might have written bits of code that are intended to provide you with debugging information. You probably don't want those portions of code compiled when you actually ship the software.

The preprocessor directives are all distinguished by beginning with the `#` symbol.

C++ developers will recognize the preprocessor directives as something that plays an important part in C and C++. However, there aren't as many preprocessor directives in C#, and they are not used as often. C# provides other mechanisms, such as custom attributes, that achieve some of the same effects as C++ directives. Also, note that C# doesn't actually have a separate preprocessor in the way that C++ does. The so-called preprocessor directives are actually handled by the compiler. Nevertheless, C# retains the name preprocessor directive because these commands give the impression of a preprocessor.

The next sections briefly cover the purposes of the preprocessor directives.

#define and #undef

`#define` is used like this:

```
#define DEBUG
```

What this does is tell the compiler that a symbol with the given name (in this case `DEBUG`) exists. It is a little bit like declaring a variable, except that this variable doesn't really have a value — it just exists. And this symbol isn't part of your actual code; it exists only for the benefit of the compiler, while the compiler is compiling the code, and has no meaning within the C# code itself.

#undef does the opposite, and removes the definition of a symbol:

```
#undef DEBUG
```

If the symbol doesn't exist in the first place, then #undef has no effect. Similarly, #define has no effect if a symbol already exists.

You need to place any #define and #undef directives at the beginning of the C# source file, before any code that declares any objects to be compiled.

#define isn't much use on its own, but when combined with other preprocessor directives, especially #if, it becomes very powerful.

Incidentally, you might notice some changes from the usual C# syntax. Preprocessor directives are not terminated by semicolons and normally constitute the only command on a line. That's because for the preprocessor directives, C# abandons its usual practice of requiring commands to be separated by semicolons. If it sees a preprocessor directive, it assumes that the next command is on the next line.

#if, #elif, #else, and #endif

These directives inform the compiler whether to compile a block of code. Consider this method:

```
int DoSomeWork(double x)
{
   // do something
   #if DEBUG
      Console.WriteLine("x is " + x);
   #endif
}
```

This code will compile as normal, except for the Console.WriteLine() method call that is contained inside the #if clause. This line will be executed only if the symbol DEBUG has been defined by a previous #define directive. When the compiler finds the #if directive, it checks to see if the symbol concerned exists and compiles the code inside the #if clause only if the symbol does exist. Otherwise, the compiler simply ignores all the code until it reaches the matching #endif directive. Typical practice is to define the symbol DEBUG while you are debugging and have various bits of debugging-related code inside #if clauses. Then, when you are close to shipping, you simply comment out the #define directive, and all the debugging code miraculously disappears, the size of the executable file gets smaller, and your end users don't get confused by being shown debugging information. (Obviously, you would do more testing to make sure your code still works without DEBUG defined.) This technique is very common in C and C++ programming and is known as *conditional compilation*.

The #elif (=else if) and #else directives can be used in #if blocks and have intuitively obvious meanings. It is also possible to nest #if blocks:

```
#define ENTERPRISE
#define W2K

// further on in the file

#if ENTERPRISE
   // do something
   #if W2K
      // some code that is only relevant to enterprise
      // edition running on W2K
   #endif
#elif PROFESSIONAL
```

```
   // do something else
#else
   // code for the leaner version
#endif
```

Note that, unlike the situation in C++, using `#if` is not the only way to compile code conditionally. C# provides an alternative mechanism through the `Conditional` attribute, which is explored in Chapter 14, "Reflection."

`#if` and `#elif` support a limited range of logical operators too, using the operators `!`, `==`, `!=`, and `||`. A symbol is considered to be `true` if it exists and `false` if it doesn't. For example:

```
#if W2K && (ENTERPRISE==false)   // if W2K is defined but ENTERPRISE isn't
```

#warning and #error

Two other very useful preprocessor directives are `#warning` and `#error`. These will respectively cause a warning or an error to be raised when the compiler encounters them. If the compiler sees a `#warning` directive, it will display whatever text appears after the `#warning` to the user, after which compilation continues. If it encounters a `#error` directive, it will display the subsequent text to the user as if it were a compilation error message and then immediately abandon the compilation, so no IL code will be generated.

You can use these directives as checks that you haven't done anything silly with your `#define` statements; you can also use the `#warning` statements to remind yourself to do something:

```
#if DEBUG && RELEASE
   #error "You've defined DEBUG and RELEASE simultaneously!"
#endif

#warning "Don't forget to remove this line before the boss tests the code!"
   Console.WriteLine("*I hate this job.*");
```

#region and #endregion

The `#region` and `#endregion` directives are used to indicate that a certain block of code is to be treated as a single block with a given name, like this:

```
#region Member Field Declarations
   int x;
   double d;
   Currency balance;
#endregion
```

This doesn't look that useful by itself; it doesn't affect the compilation process in any way. However, the real advantage is that these directives are recognized by some editors, including the Visual Studio .NET editor. These editors can use these directives to lay out your code better on the screen. You will see how this works in Chapter 16.

#line

The `#line` directive can be used to alter the filename and line number information that is output by the compiler in warnings and error messages. You probably won't want to use this directive that often. It's most useful when you are coding in conjunction with some other package that alters the code you are typing in before sending it to the compiler. In this situation, line numbers, or perhaps the filenames reported by the compiler, won't match up to the line numbers in the files or the filenames you are editing. The `#line` directive can be used to restore the match. You can also use the syntax `#line default` to restore the line to the default line numbering:

```
#line 164 "Core.cs" // We happen to know this is line 164 in the file
                    // Core.cs, before the intermediate
                    // package mangles it.

// later on

#line default      // restores default line numbering
```

#pragma

The `#pragma` directive can either suppress or restore specific compiler warnings. Unlike command-line options, the `#pragma` directive can be implemented on a class or method level, allowing fine-grained control of what warnings are suppressed and when. The following example disables the "field not used" warning and then restores it after the `MyClass` class compiles:

```
#pragma warning disable 169
public class MyClass
{
  int neverUsedField;
}
#pragma warning restore 169
```

C# PROGRAMMING GUIDELINES

The final section of this chapter supplies the guidelines you need to bear in mind when writing C# programs.

Rules for Identifiers

This section examines the rules governing what names you can use for variables, classes, methods, and so on. Note that the rules presented in this section are not merely guidelines: they are enforced by the C# compiler.

Identifiers are the names you give to variables, to user-defined types such as classes and structs, and to members of these types. Identifiers are case-sensitive, so, for example, variables named `interestRate` and `InterestRate` would be recognized as different variables. Following are a few rules determining what identifiers you can use in C#:

- They must begin with a letter or underscore, although they can contain numeric characters.
- You can't use C# keywords as identifiers.

The following table lists the C# reserved keywords.

abstract	event	new	struct
as	explicit	null	switch
base	extern	object	this
bool	false	operator	throw
break	finally	out	true
byte	fixed	override	try
case	float	params	typeof
catch	for	private	uint

`char`	`foreach`	`protected`	`ulong`
`checked`	`goto`	`public`	`unchecked`
`class`	`if`	`readonly`	`unsafe`
`const`	`implicit`	`ref`	`ushort`
`continue`	`in`	`return`	`using`
`decimal`	`int`	`sbyte`	`virtual`
`default`	`interface`	`sealed`	`volatile`
`delegate`	`internal`	`short`	`void`
`do`	`is`	`sizeof`	`while`
`double`	`lock`	`stackalloc`	
`else`	`long`	`static`	
`enum`	`namespace`	`string`	

If you need to use one of these words as an identifier (for example, if you are accessing a class written in a different language), you can prefix the identifier with the `@` symbol to indicate to the compiler that what follows is to be treated as an identifier, not as a C# keyword (so `abstract` is not a valid identifier, but `@abstract` is).

Finally, identifiers can also contain Unicode characters, specified using the syntax `\uXXXX`, where `XXXX` is the four-digit hex code for the Unicode character. The following are some examples of valid identifiers:

- `Name`
- `Überfluß`
- `_Identifier`
- `\u005fIdentifier`

The last two items in this list are identical and interchangeable (because `005f` is the Unicode code for the underscore character), so obviously these identifiers couldn't both be declared in the same scope. Note that although syntactically you are allowed to use the underscore character in identifiers, this isn't recommended in most situations. That's because it doesn't follow the guidelines for naming variables that Microsoft has written to ensure that developers use the same conventions, making it easier to read each other's code.

Usage Conventions

In any development language, there usually arise certain traditional programming styles. The styles are not part of the language itself but are conventions concerning, for example, how variables are named or how certain classes, methods, or functions are used. If most developers using that language follow the same conventions, it makes it easier for different developers to understand each other's code — which in turn generally helps program maintainability. Conventions do, however, depend on the language and the environment. For example, C++ developers programming on the Windows platform have traditionally used the prefixes `psz` or `lpsz` to indicate strings — `char *pszResult; char *lpszMessage;` — but on Unix machines it's more common not to use any such prefixes: `char *Result; char *Message;`.

You'll notice from the sample code in this book that the convention in C# is to name variables without prefixes: `string Result; string Message;`.

Whereas, with many languages, usage conventions simply evolved as the language was used, with C# and the whole of the .NET Framework, Microsoft has written very comprehensive usage guidelines, which are detailed in the .NET/C# MSDN documentation. This should mean that, right from the start, .NET programs will have a high degree of interoperability in terms of developers being able to understand code. The guidelines have also been developed with the benefit of some 20 years' hindsight in object-oriented programming. Judging by the relevant newsgroups, the guidelines have been carefully thought out and are well received in the developer community. Hence the guidelines are well worth following.

It should be noted, however, that the guidelines are not the same as language specifications. You should try to follow the guidelines when you can. Nevertheless, you won't run into problems if you have a good reason for not doing so — for example, you won't get a compilation error because you don't follow these guidelines. The general rule is that if you don't follow the usage guidelines you must have a convincing reason. Departing from the guidelines should be a positive decision rather than simply not bothering. Also, if you compare the guidelines with the samples in the remainder of this book, you'll notice that in numerous examples we have chosen not to follow the conventions. That's usually because the conventions are designed for much larger programs than our samples, and although they are great if you are writing a complete software package, they are not really suitable for small 20-line standalone programs. In many cases, following the conventions would have made our samples harder, rather than easier, to follow.

The full guidelines for good programming style are quite extensive. This section is confined to describing some of the more important guidelines, as well as the ones most likely to surprise you. If you want to make absolutely certain that your code follows the usage guidelines completely, you will need to refer to the MSDN documentation.

Naming Conventions

One important aspect to making your programs understandable is how you choose to name your items — and that includes naming variables, methods, classes, enumerations, and namespaces.

It is intuitively obvious that your names should reflect the purpose of the item and should not clash with other names. The general philosophy in the .NET Framework is also that the name of a variable should reflect the purpose of that variable instance and not the data type. For example, `height` is a good name for a variable, whereas `integerValue` isn't. However, you will probably feel that that principle is an ideal that is hard to achieve. Particularly when you are dealing with controls, in most cases, you'll probably be happier sticking with variable names such as `confirmationDialog` and `chooseEmployeeListBox`, which do indicate the data type in the name.

The following sections look at some of the things you need to think about when choosing names.

Casing of Names

In many cases you should use *Pascal casing* for names. Pascal casing means that the first letter of each word in a name is capitalized: `EmployeeSalary`, `ConfirmationDialog`, `PlainTextEncoding`. You will notice that essentially all of the names of namespaces, classes, and members in the base classes follow Pascal casing. In particular, the convention of joining words using the underscore character is discouraged. So, you should try not to use names such as `employee_salary`. It has also been common in other languages to use all capitals for names of constants. This is not advised in C# because such names are harder to read — the convention is to use Pascal casing throughout:

```
const int MaximumLength;
```

The only other casing scheme that you are advised to use is *camel casing*. Camel casing is similar to Pascal casing, except that the first letter of the first word in the name is not capitalized: `employeeSalary`, `confirmationDialog`, `plainTextEncoding`. Following are three situations in which you are advised to use camel casing:

- For names of all private member fields in types:

  ```
  public int subscriberId;
  ```

  Note, however, that often it is conventional to prefix names of member fields with an underscore:

  ```
  public int _subscriberId;
  ```

- For names of all parameters passed to methods:

  ```
  public void RecordSale(string salesmanName, int quantity);
  ```

- To distinguish items that would otherwise have the same name. A common example is when a property wraps around a field:

  ```
  private string employeeName;

  public string EmployeeName
  {
     get
     {
        return employeeName;

     }

  }
  ```

If you are doing this, you should always use camel casing for the private member and Pascal casing for the public or protected member, so that other classes that use your code see only names in Pascal case (except for parameter names).

You should also be wary about case sensitivity. C# is case-sensitive, so it is syntactically correct for names in C# to differ only by the case, as in the previous examples. However, you should bear in mind that your assemblies might at some point be called from Visual Basic .NET applications — and *Visual Basic .NET is not case-sensitive*. Hence, if you do use names that differ only by case, it is important to do so only in situations in which both names will never be seen outside your assembly. (The previous example qualifies as okay because camel case is used with the name that is attached to a `private` variable.) Otherwise, you may prevent other code written in Visual Basic .NET from being able to use your assembly correctly.

Name Styles

You should be consistent about your style of names. For example, if one of the methods in a class is called `ShowConfirmationDialog()`, then you should not give another method a name such as `ShowDialogWarning()` or `WarningDialogShow()`. The other method should be called `ShowWarningDialog()`.

Namespace Names

Namespace names are particularly important to design carefully to avoid risk of ending up with the same name for one of your namespaces as someone else's. Remember, namespace names are the *only* way that .NET distinguishes names of objects in shared assemblies. So, if you use the same namespace name for your software package as another package, and both packages get installed on the same computer, there are going to be problems. Because of this, it's almost always a good idea to create a top-level namespace with the name of your company and then nest successive namespaces that narrow down the technology, group, or department you are working in or the name of the package your classes are intended for. Microsoft recommends namespace names that begin with `<CompanyName>.<TechnologyName>` as in these two examples:

```
WeaponsOfDestructionCorp.RayGunControllers
WeaponsOfDestructionCorp.Viruses
```

Names and Keywords

It is important that the names do not clash with any keywords. In fact, if you attempt to name an item in your code with a word that happens to be a C# keyword, you'll almost certainly get a syntax error because the compiler will assume that the name refers to a statement. However, because of the possibility that your classes will be accessed by code written in other languages, it is also important that you don't use names that are keywords in other .NET languages. Generally speaking, C++ keywords are similar to C# keywords, so confusion with C++ is unlikely, and those commonly encountered keywords that are unique to Visual C++ tend to start with two underscore characters. As with C#, C++ keywords are spelled in lowercase, so if you hold to the convention of naming your public classes and members with Pascal-style names, they will always have at least one uppercase letter in their names, and there will be no risk of clashes with C++ keywords. However, you are more likely to have problems with Visual Basic .NET, which has many more keywords than C# does, and being non-case–sensitive means that you cannot rely on Pascal-style names for your classes and methods.

The following table lists the keywords and standard function calls in Visual Basic .NET, which you should avoid, if possible, in whatever case combination, for your public C# classes.

`Abs`	`Do`	`Loc`	`RGB`
`Add`	`Double`	`Local`	`Right`
`AddHandler`	`Each`	`Lock`	`RmDir`
`AddressOf`	`Else`	`LOF`	`Rnd`
`Alias`	`ElseIf`	`Log`	`RTrim`
`And`	`Empty`	`Long`	`SaveSettings`
`Ansi`	`End`	`Loop`	`Second`
`AppActivate`	`Enum`	`LTrim`	`Seek`
`Append`	`EOF`	`Me`	`Select`
`As`	`Erase`	`Mid`	`SetAttr`
`Asc`	`Err`	`Minute`	`SetException`
`Assembly`	`Error`	`MIRR`	`Shared`
`Atan`	`Event`	`MkDir`	`Shell`
`Auto`	`Exit`	`Module`	`Short`
`Beep`	`Exp`	`Month`	`Sign`
`Binary`	`Explicit`	`MustInherit`	`Sin`
`BitAnd`	`ExternalSource`	`MustOverride`	`Single`
`BitNot`	`False`	`MyBase`	`SLN`
`BitOr`	`FileAttr`	`MyClass`	`Space`
`BitXor`	`FileCopy`	`Namespace`	`Spc`
`Boolean`	`FileDateTime`	`New`	`Split`
`ByRef`	`FileLen`	`Next`	`Sqrt`
`Byte`	`Filter`	`Not`	`Static`
`ByVal`	`Finally`	`Nothing`	`Step`
`Call`	`Fix`	`NotInheritable`	`Stop`
`Case`	`For`	`NotOverridable`	`Str`
`Catch`	`Format`	`Now`	`StrComp`

CBool	FreeFile	NPer	StrConv

Delegate	Lcase	Replace	WriteOnly
DeleteSetting	Left	Reset	Xor
Dim	Lib	Resume	Year

Use of Properties and Methods

One area that can cause confusion in a class is whether a particular quantity should be represented by a property or a method. The rules here are not hard and fast, but in general, you ought to use a property if something really should look and feel like a variable. (If you're not sure what a property is, see Chapter 3.) This means, among other things, that:

- Client code should be able to read its value. Write-only properties are not recommended, so, for example, use a `SetPassword()` method, not a write-only `Password` property.
- Reading the value should not take too long. The fact that something is a property usually suggests that reading it will be relatively quick.
- Reading the value should not have any observable and unexpected side effect. Further, setting the value of a property should not have any side effect that is not directly related to the property. Setting the width of a dialog box has the obvious effect of changing the appearance of the dialog box on the screen. That's fine, because that's obviously related to the property in question.
- It should be possible to set properties in any order. In particular, it is not good practice when setting a property to throw an exception because another related property has not yet been set. For example, to use a class that accesses a database, you need to set `ConnectionString`, `UserName`, and `Password`, then the author of the class should make sure the class is implemented so that the user really can set them in any order.
- Successive reads of a property should give the same result. If the value of a property is likely to change unpredictably, you should code it as a method instead. `Speed`, in a class that monitors the motion of an automobile, is not a good candidate for a property. Use a `GetSpeed()` method here; but, `Weight` and `EngineSize` are good candidates for properties because they will not change for a given object.

If the item you are coding satisfies all the preceding criteria, it is probably a good candidate for a property. Otherwise, you should use a method.

Use of Fields

The guidelines are pretty simple here. Fields should almost always be private, except that in some cases it may be acceptable for constant or read-only fields to be public. The reason is that if you make a field public, you may hinder your ability to extend or modify the class in the future.

The previous guidelines should give you a foundation of good practices, and you should also use them in conjunction with a good object-oriented programming style.

A final helpful note to keep in mind is that Microsoft has been fairly careful about being consistent and has followed its own guidelines when writing the .NET base classes. So a very good way to get an intuitive feel for the conventions to follow when writing .NET code is to simply look at the base classes — see how classes, members, and namespaces are named, and how the class hierarchy works. Consistency between the base classes and your classes will help in readability and maintainability.

SUMMARY

This chapter examined some of the basic syntax of C#, covering the areas needed to write simple C# programs. We covered a lot of ground, but much of it will be instantly recognizable to developers who are familiar with any C-style language (or even JavaScript).

You have seen that although C# syntax is similar to C++ and Java syntax, there are many minor differences. You have also seen that in many areas this syntax is combined with facilities to write code very quickly, for example high-quality string handling facilities. C# also has a strongly defined type system, based on a distinction between value and reference types. Chapters 3 and 4 cover the C# object-oriented programming features.

3

Objects and Types

WHAT'S IN THIS CHAPTER?

- The differences between classes and structs
- Class members
- Passing values by value and by reference
- Method overloading
- Constructors and static constructors
- Read-only fields
- Partial classes
- Static classes
- The `Object` class, from which all other types are derived

So far, you've been introduced to some of the building blocks of the C# language, including variables, data types, and program flow statements, and you have seen a few very short complete programs containing little more than the `Main()` method. What you haven't really seen yet is how to put all these together to form a longer, complete program. The key to this lies in working with classes — the subject of this chapter. Note that we cover inheritance and features related to inheritance in Chapter 4, "Inheritance."

This chapter introduces the basic syntax associated with classes. However, we assume that you are already familiar with the underlying principles of using classes — for example, that you know what a constructor or a property is. This chapter is largely confined to applying those principles in C# code.

CLASSES AND STRUCTS

Classes and structs are essentially templates from which you can create objects. Each object contains data and has methods to manipulate and access that data. The class defines what data and functionality each particular object (called an *instance*) of that class can contain. For example, if you have a class that represents a customer, it might define fields such as `CustomerID`, `FirstName`, `LastName`, and `Address`, which you will use to hold information about a particular customer. It might also define functionality that acts upon the data stored in these fields. You can then instantiate an object of this class to represent one specific customer, set the field values for that instance, and use its functionality.

```
class PhoneCustomer
{
   public const string DayOfSendingBill = "Monday";
   public int CustomerID;
   public string FirstName;
   public string LastName;
}
```

Structs differ from classes in the way that they are stored in memory and accessed (classes are reference types stored in the heap; structs are value types stored on the stack), and in some of their features (for example, structs don't support inheritance). You will tend to use structs for smaller data types for performance reasons. In terms of syntax, however, structs look very similar to classes; the main difference is that you use the keyword `struct` instead of `class` to declare them. For example, if you wanted all `PhoneCustomer` instances to be allocated on the stack instead of the managed heap, you could write:

```
struct PhoneCustomerStruct
{
   public const string DayOfSendingBill = "Monday";
   public int CustomerID;
   public string FirstName;
   public string LastName;
}
```

For both classes and structs, you use the keyword `new` to declare an instance. This keyword creates the object and initializes it; in the following example, the default behavior is to zero out its fields:

```
PhoneCustomer myCustomer = new PhoneCustomer();      // works for a class
PhoneCustomerStruct myCustomer2 = new PhoneCustomerStruct();// works for a struct
```

In most cases, you'll use classes much more often than structs. Therefore, we discuss classes first and then the differences between classes and structs and the specific reasons why you might choose to use a struct instead of a class. Unless otherwise stated, however, you can assume that code presented for a class will work equally well for a struct.

CLASSES

The data and functions within a class are known as the class's *members*. Microsoft's official terminology distinguishes between data members and function members. In addition to these members, classes can contain nested types (such as other classes). Accessibility to the members can be `public, protected`, `internal protected`, `private`, or `internal`. These are described in detail in Chapter 5, "Generics."

Data Members

Data members are those members that contain the data for the class — fields, constants, and events. Data members can be `static`. A class member is always an instance member unless it is explicitly declared as `static`.

Fields are any variables associated with the class. You have already seen fields in use in the `PhoneCustomer` class in the previous example.

After you have instantiated a `PhoneCustomer` object, you can then access these fields using the `Object.FieldName` syntax, as shown in this example:

```
PhoneCustomer Customer1 = new PhoneCustomer();
Customer1.FirstName = "Simon";
```

Constants can be associated with classes in the same way as variables. You declare a constant using the `const` keyword. If it is declared as `public`, then it will be accessible from outside the class.

```
class PhoneCustomer
{
   public const string DayOfSendingBill = "Monday";
   public int CustomerID;
   public string FirstName;
   public string LastName;
}
```

Events are class members that allow an object to notify a caller whenever something noteworthy happens, such as a field or property of the class changing, or some form of user interaction occurring. The client can have code, known as an event handler, which reacts to the event. Chapter 8, "Delegates, Lambdas, and Events," looks at events in detail.

Function Members

- Function members are those members that provide some functionality for manipulating the data in the class. They include methods, properties, constructors, finalizers, operators, and indexers.
- *Methods* are functions that are associated with a particular class. Just as with data members, function members are instance members by default. They can be made static by using the `static` modifier.
- *Properties* are sets of functions that can be accessed from the client in a similar way to the public fields of the class. C# provides a specific syntax for implementing read and write properties on your classes, so you don't have use method names that have the words `Get` or `Set` embedded in them. Because there's a dedicated syntax for properties that is distinct from that for normal functions, the illusion of objects as actual things is strengthened for client code.
- *Constructors* are special functions that are called automatically when an object is instantiated. They must have the same name as the class to which they belong and cannot have a return type. Constructors are useful for initialization.
- *Finalizers* are similar to constructors but are called when the CLR detects that an object is no longer needed. They have the same name as the class, preceded by a tilde (~). It is impossible to predict precisely when a finalizer will be called. Finalizers are discussed in Chapter 13, "Memory Management and Pointers."
- *Operators,* at their simplest, are actions such as + or –. When you add two integers, you are, strictly speaking, using the + operator for integers. However, C# also allows you to specify how existing operators will work with your own classes (*operator overloading*). Chapter 7, "Operators and Casts," looks at operators in detail.
- *Indexers* allow your objects to be indexed in the same way as an array or collection.

Methods

Note that official C# terminology makes a distinction between functions and methods. In C# terminology, the term "function member" includes not only methods, but also other nondata members of a class or struct. This includes indexers, operators, constructors, destructors, and also — perhaps somewhat surprisingly — properties. These are contrasted with data members: fields, constants, and events.

Declaring Methods

In C#, the definition of a method consists of any method modifiers (such as the method's accessibility), the type of the return value, followed by the name of the method, followed by a list of input arguments enclosed in parentheses, followed by the body of the method enclosed in curly braces:

```
[modifiers] return_type MethodName([parameters])
{
   // Method body
}
```

Each parameter consists of the name of the type of the parameter, and the name by which it can be referenced in the body of the method. Also, if the method returns a value, a return statement must be used with the return value to indicate each exit point. For example:

```
public bool IsSquare(Rectangle rect)
{
   return (rect.Height == rect.Width);
}
```

This code uses one of the .NET base classes, `System.Drawing.Rectangle`, which represents a rectangle.

If the method doesn't return anything, you specify a return type of `void` because you can't omit the return type altogether, and if it takes no arguments, you still need to include an empty set of parentheses after the method name. In this case, including a return statement is optional — the method returns automatically when the closing curly brace is reached. You should note that a method can contain as many return statements as required:

```
public bool IsPositive(int value)
{
   if (value < 0)
      return false;
   return true;
}
```

Invoking Methods

The following example, `MathTest`, illustrates the syntax for definition and instantiation of classes, and definition and invocation of methods. Besides the class that contains the `Main()` method, it defines a class named `MathTest`, which contains a couple of methods and a field.

```
using System;

namespace Wrox
{
   class MainEntryPoint
   {
      static void Main()
      {
         // Try calling some static functions.
         Console.WriteLine("Pi is " + MathTest.GetPi());
         int x = MathTest.GetSquareOf(5);
         Console.WriteLine("Square of 5 is " + x);

         // Instantiate at MathTest object
         MathTest math = new MathTest();   // this is C#'s way of
                                           // instantiating a reference type

         // Call nonstatic methods
         math.value = 30;
         Console.WriteLine(
             "Value field of math variable contains " + math.value);
         Console.WriteLine("Square of 30 is " + math.GetSquare());
      }
   }

   // Define a class named MathTest on which we will call a method
   class MathTest
   {
      public int value;

      public int GetSquare()
      {
         return value*value;
         }

         public static int GetSquareOf(int x)
         {
            return x*x;
         }

         public static double GetPi()
         {
            return 3.14159;
         }
      }
   }
```

code snippet MathTest.cs

Running the `MathTest` example produces these results:

```
Pi is 3.14159
Square of 5 is 25
Value field of math variable contains 30
Square of 30 is 900
```

As you can see from the code, the `MathTest` class contains a field that contains a number, as well as a method to find the square of this number. It also contains two static methods, one to return the value of pi and one to find the square of the number passed in as a parameter.

Some features of this class are not really good examples of C# program design. For example, `GetPi()` would usually be implemented as a `const` field, but following good design here would mean using some concepts that we have not yet introduced.

Passing Parameters to Methods

In general, parameters can be passed into methods by reference or by value. When a variable is passed by reference, the called method gets the actual variable — so any changes made to the variable inside the method persist when the method exits. But, when a variable is passed by value, the called method gets an identical copy of the variable — which means any changes made are lost when the method exits. For complex data types, passing by reference is more efficient because of the large amount of data that must be copied when passing by value.

In C#, all parameters are passed by value unless you specifically say otherwise. However, you need to be careful in understanding the implications of this for reference types. Because reference type variables hold only a reference to an object, it is this reference that will be copied, not the object itself. Hence, changes made to the underlying object will persist. Value type variables, in contrast, hold the actual data, so a copy of the data itself will be passed into the method. An `int`, for instance, is passed by value to a method, and any changes that the method makes to the value of that `int` do not change the value of the original `int` object. Conversely, if an array or any other reference type, such as a class, is passed into a method, and the method uses the reference to change a value in that array, the new value is reflected in the original array object.

Here is an example, `ParameterTest.cs`, which demonstrates the following:

```
using System;

namespace Wrox
{
   class ParameterTest
   {
      static void SomeFunction(int[] ints, int i)
      {
         ints[0] = 100;
         i = 100;
         }

         public static int Main()
         {
            int i = 0;
            int[] ints = { 0, 1, 2, 4, 8 };
            // Display the original values.
            Console.WriteLine("i = " + i);
            Console.WriteLine("ints[0] = " + ints[0]);
            Console.WriteLine("Calling SomeFunction.");

            // After this method returns, ints will be changed,
            // but i will not.
            SomeFunction(ints, i);
            Console.WriteLine("i = " + i);
            Console.WriteLine("ints[0] = " + ints[0]);
            return 0;
         }
      }
   }
```

code snippet ParameterTest.cs

The output of this is:

```
ParameterTest.exe
i = 0
ints[0] = 0
Calling SomeFunction...
i = 0
ints[0] = 100
```

Notice how the value of `i` remains unchanged, but the value changed in `ints` is also changed in the original array.

The behavior of strings is different again. This is because strings are immutable (if you alter a string's value, you create an entirely new string), so strings don't display the typical reference-type behavior. Any changes made to a string within a method call won't affect the original string. This point is discussed in more detail in Chapter 9, "Strings and Regular Expressions."

ref Parameters

As mentioned, passing variables by value is the default, but you can force value parameters to be passed by reference. To do so, use the `ref` keyword. If a parameter is passed to a method, and if the input argument for that method is prefixed with the `ref` keyword, any changes that the method makes to the variable will affect the value of the original object:

```
static void SomeFunction(int[] ints, ref int i)
{
   ints[0] = 100;
   i = 100;     // The change to i will persist after SomeFunction() exits.
}
```

You will also need to add the `ref` keyword when you invoke the method:

```
SomeFunction(ints, ref i);.
```

Finally, it is also important to understand that C# continues to apply initialization requirements to parameters passed to methods. Any variable must be initialized before it is passed into a method, whether it is passed in by value or by reference.

out Parameters

In C-style languages, it is common for functions to be able to output more than one value from a single routine. This is accomplished using output parameters, by assigning the output values to variables that have been passed to the method by reference. Often, the starting values of the variables that are passed by reference are unimportant. Those values will be overwritten by the function, which may never even look at any previous value.

It would be convenient if you could use the same convention in C#. However, C# requires that variables be initialized with a starting value before they are referenced. Although you could initialize your input variables with meaningless values before passing them into a function that will fill them with real, meaningful ones, this practice seems at best needless and at worst confusing. However, there is a way to short-circuit the C# compiler's insistence on initial values for input arguments.

You do this with the `out` keyword. When a method's input argument is prefixed with `out`, that method can be passed a variable that has not been initialized. The variable is passed by reference, so any changes that the method makes to the variable will persist when control returns from the called method. Again, you also need to use the `out` keyword when you call the method, as well as when you define it:

```
static void SomeFunction(out int i)
{
   i = 100;
}

public static int Main()
{
   int i; // note how i is declared but not initialized.
   SomeFunction(out i);
   Console.WriteLine(i);
   return 0;
}
```

Named Arguments

Typically, parameters need to be passed into a method in the same order that they are defined. Named arguments allow you to pass in parameters in any order. So for the following method:

```
string FullName(string firstName, string lastName)
{
    return firstName + " " + lastName;
}
```

The following method calls will return the same full name:

```
FullName("John", "Doe");
FullName(lastName: "Doe", firstName: "John");
```

If the method has several parameters, you can mix positional and named arguments in the same call.

Optional Arguments

Parameters can also be optional. You must supply a default value for parameters that are optional. The optional parameter(s) must be the last ones defined as well. So the following method declaration would be incorrect:

```
void TestMethod(int optionalNumber = 10, int notOptionalNumber)
{
    System.Console.Write(optionalNumber + notOptionalNumber);
}
```

For this method to work, the `optionalNumber` parameter would have to be defined last.

Method Overloading

C# supports method overloading — several versions of the method that have different signatures (that is, the same name, but a different number of parameters and/or different parameter data types). To overload methods, you simply declare the methods with the same name but different numbers or types of parameters:

```
class ResultDisplayer
{
   void DisplayResult(string result)
   {
      // implementation
   }

   void DisplayResult(int result)
   {
      // implementation
   }
}
```

If optional parameters won't work for you, then you need to use method overloading to achieve the same effect:

```
class MyClass
{
   int DoSomething(int x)   // want 2nd parameter with default value 10
   {
      DoSomething(x, 10);
   }

   int DoSomething(int x, int y)
   {
      // implementation
   }
}
```

As in any language, method overloading carries with it the potential for subtle runtime bugs if the wrong overload is called. Chapter 4 discusses how to code defensively against these problems. For now, you should know that C# does place some minimum restrictions on the parameters of overloaded methods:

- It is not sufficient for two methods to differ only in their return type.
- It is not sufficient for two methods to differ only by virtue of a parameter having been declared as `ref` or `out`.

Properties

The idea of a property is that it is a method or pair of methods that is dressed to look like a field. A good example of this is the `Height` property of a Windows Form. Suppose that you have the following code:

```
// mainForm is of type System.Windows.Forms
mainForm.Height = 400;
```

On executing this code, the height of the window will be set to 400, and you will see the window resize on the screen. Syntactically, this code looks like you're setting a field, but in fact you are calling a property accessor that contains code to resize the form.

To define a property in C#, you use the following syntax:

```
public string SomeProperty
{
   get
   {
      return "This is the property value.";
   }
   set
```

```
      {
         // do whatever needs to be done to set the property.
      }
   }
```

The get accessor takes no parameters and must return the same type as the declared property. You should not specify any explicit parameters for the set accessor either, but the compiler assumes it takes one parameter, which is of the same type again, and which is referred to as value. As an example, the following code contains a property called Age, which sets a field called age. In this example, age is referred to as the backing variable for the property Age.

```
private int age;

public int Age
{
   get
   {
      return age;
   }
   set
   {
      age = value;
   }
}
```

Note the naming convention used here. You take advantage of C#'s case sensitivity by using the same name, Pascal-cased for the public property, and camel-cased for the equivalent private field if there is one. Some developers prefer to use field names that are prefixed by an underscore: _age; this provides an extremely convenient way of identifying fields.

Read-Only and Write-Only Properties

It is possible to create a read-only property by simply omitting the set accessor from the property definition. Thus, to make Name a read-only property, you would do the following:

```
private string name;

public string Name
{
   get
   {
      return Name;
   }
}
```

It is similarly possible to create a write-only property by omitting the get accessor. However, this is regarded as poor programming practice because it could be confusing to authors of client code. In general, it is recommended that if you are tempted to do this, you should use a method instead.

Access Modifiers for Properties

C# does allow the set and get accessors to have differing access modifiers. This would allow a property to have a public get and a private or protected set. This can help control how or when a property can be set. In the following code example, notice that the set has a private access modifier and the get does not have any. In this case, the get takes on the access level of the property. One of the accessors must follow the access level of the property. A compile error will be generated if the get accessor has the protected access level associated with it because that would make both accessors have a different access level from the property.

```
public string Name
{
  get
```

```
      {
        return _name;
      }
      private set
      {
        _name = value;
      }
    }
```

Auto-Implemented Properties

If there isn't going to be any logic in the properties `set` and `get`, then auto-implemented properties can be used. Auto-implemented properties implement the backing member variable automatically. The code for the earlier `Age` example would look like this:

```
public string Age {get; set;}
```

The declaration `private int age;` is not needed. The compiler will create this automatically.

By using auto-implemented properties, validation of the property cannot be done at the property set. So in the previous example we could not have checked to see if an invalid age is set. Also, both accessors must be present. So an attempt to make a property read-only would cause an error:

```
public string Age {get;}
```

However, the access level of each accessor can be different. So the following is acceptable:

```
public string Age {get; private set;}
```

A NOTE ABOUT INLINING

Some developers may worry that the previous sections have presented a number of situations in which standard C# coding practices have led to very small functions — for example, accessing a field via a property instead of directly. Is this going to hurt performance because of the overhead of the extra function call? The answer is that there is no need to worry about performance loss from these kinds of programming methodologies in C#. Recall that C# code is compiled to IL, then JIT compiled at runtime to native executable code. The JIT compiler is designed to generate highly optimized code and will ruthlessly inline code as appropriate (in other words, it replaces function calls with inline code). A method or property whose implementation simply calls another method or returns a field will almost certainly be inlined. Note, however, that the decision of where to inline is made entirely by the CLR. There is no way for you to control which methods are inlined by using, for example, some keyword similar to the inline keyword of C++.

Constructors

The syntax for declaring basic constructors is a method that has the same name as the containing class and that does not have any return type:

```
public class MyClass
{
   public MyClass()
   {
   }
   // rest of class definition
```

It's not necessary to provide a constructor for your class. We haven't supplied one for any of the examples so far in this book. In general, if you don't supply any constructor, the compiler will make up a default one for you behind the scenes. It will be a very basic constructor that just initializes all the member fields by zeroing them out (`null` reference for reference types, zero for numeric data types, and false for `bool`s). Often, that will be adequate; if not, you'll need to write your own constructor.

Constructors follow the same rules for overloading as other methods (that is, you can provide as many overloads to the constructor as you want, provided they are clearly different in signature):

```
   public MyClass()   // zeroparameter constructor
   {
      // construction code
   }
   public MyClass(int number)   // another overload
   {
      // construction code
   }
```

Note, however, that if you supply any constructors that take parameters, the compiler will not automatically supply a default one. This is done only if you have not defined any constructors at all. In the following example, because a one-parameter constructor is defined, the compiler assumes that this is the only constructor you want to be available, so it will not implicitly supply any others:

```
public class MyNumber
{
   private int number;
   public MyNumber(int number)
   {
      this.number = number;
   }
}
```

This code also illustrates typical use of the `this` keyword to distinguish member fields from parameters of the same name. If you now try instantiating a `MyNumber` object using a no-parameter constructor, you will get a compilation error:

```
MyNumber numb = new MyNumber();   // causes compilation error
```

We should mention that it is possible to define constructors as private or protected, so that they are invisible to code in unrelated classes too:

```
public class MyNumber
{
   private int number;
   private MyNumber(int number)   // another overload
   {
      this.number = number;
   }
}
```

This example hasn't actually defined any public or even any protected constructors for `MyNumber`. This would actually make it impossible for `MyNumber` to be instantiated by outside code using the `new` operator (though you might write a public static property or method in `MyNumber` that can instantiate the class). This is useful in two situations:

- If your class serves only as a container for some static members or properties and therefore should never be instantiated
- If you want the class to only ever be instantiated by calling some static member function (this is the so-called class factory approach to object instantiation)

Static Constructors

One novel feature of C# is that it is also possible to write a static no-parameter constructor for a class. Such a constructor will be executed only once, as opposed to the constructors written so far, which are instance constructors that are executed whenever an object of that class is created.

```
class MyClass
{
   static MyClass()
```

```
      {
         // initialization code
      }
      // rest of class definition
   }
```

One reason for writing a static constructor is if your class has some static fields or properties that need to be initialized from an external source before the class is first used.

The .NET runtime makes no guarantees about when a static constructor will be executed, so you should not place any code in it that relies on it being executed at a particular time (for example, when an assembly is loaded). Nor is it possible to predict in what order static constructors of different classes will execute. However, what is guaranteed is that the static constructor will run at most once, and that it will be invoked before your code makes any reference to the class. In C#, the static constructor is usually executed immediately before the first call to any member of the class.

Notice that the static constructor does not have any access modifiers. It's never called by any other C# code, but always by the .NET runtime when the class is loaded, so any access modifier such as `public` or `private` would be meaningless. For this same reason, the static constructor can never take any parameters, and there can be only one static constructor for a class. It should also be obvious that a static constructor can access only static members, not instance members, of the class.

Note that it is possible to have a static constructor and a zero-parameter instance constructor defined in the same class. Although the parameter lists are identical, there is no conflict. That's because the static constructor is executed when the class is loaded, but the instance constructor is executed whenever an instance is created — so there won't be any confusion about which constructor gets executed when.

Note that if you have more than one class that has a static constructor, the static constructor that will be executed first is undefined. This means that you should not put any code in a static constructor that depends on other static constructors having been or not having been executed. However, if any static fields have been given default values, these will be allocated before the static constructor is called.

The next example illustrates the use of a static constructor and is based on the idea of a program that has user preferences (which are presumably stored in some configuration file). To keep things simple, we'll assume just one user preference — a quantity called `BackColor`, which might represent the background color to be used in an application. And because we don't want to get into the details of writing code to read data from an external source here, we'll make the assumption that the preference is to have a background color of red on weekdays and green on weekends. All the program will do is display the preference in a console window — but this is enough to see a static constructor at work.

```
namespace Wrox.ProCSharp.StaticConstructorSample
{
   public class UserPreferences
   {
      public static readonly Color BackColor;

      static UserPreferences()
      {
         DateTime now = DateTime.Now;
         if (now.DayOfWeek == DayOfWeek.Saturday
            || now.DayOfWeek == DayOfWeek.Sunday)
            BackColor = Color.Green;
         else
            BackColor = Color.Red;
      }

      private UserPreferences()
      {
      }
   }
}
```

This code shows how the color preference is stored in a static variable, which is initialized in the static constructor. This field is declared as read-only, which means that its value can only be set in a constructor. You learn about read-only fields in more detail later in this chapter. The code uses a few helpful structs that Microsoft has supplied as part of the Framework class library: `System.DateTime` and `System.Drawing.Color`. `DateTime` implements a static property — `Now`, which returns the current time — and an instance property — `DayOfWeek`, which works out what day of the week a date-time represents. `Color` (which is discussed in the online Chapter 48, "Graphics with GDI+") is used to store colors. It implements various static properties, such as `Red` and `Green` as used in this example, which returns commonly used colors. To use `Color`, you need to reference the `System.Drawing.dll` assembly when compiling, and you must add a `using` statement for the `System.Drawing` namespace:

```
using System;
using System.Drawing;
```

You test the static constructor with this code:

```
    class MainEntryPoint
    {
       static void Main(string[] args)
       {
          Console.WriteLine("User-preferences: BackColor is: " +
                            UserPreferences.BackColor.ToString());
       }
    }
```

Compiling and running this code results in this output:

```
User-preferences: BackColor is: Color [Red]
```

Of course if the code is executed during the weekend, your color preference would be `Green`.

Calling Constructors from Other Constructors

You may sometimes find yourself in the situation where you have several constructors in a class, perhaps to accommodate some optional parameters for which the constructors have some code in common. For example, consider this:

```
class Car
{
   private string description;
   private uint nWheels;
   public Car(string description, uint nWheels)
   {
      this.description = description;
      this.nWheels = nWheels;
   }

   public Car(string description)
   {
      this.description = description;
      this.nWheels = 4;
   }
// etc.
```

Both constructors initialize the same fields. It would clearly be neater to place all the code in one place. C# has a special syntax known as a *constructor initializer* to allow this:

```
class Car
{
   private string description;
   private uint nWheels;

   public Car(string description, uint nWheels)
   {
      this.description = description;
      this.nWheels = nWheels;
   }

   public Car(string description): this(description, 4)
   {
   }
   // etc
```

In this context, the `this` keyword simply causes the constructor with the nearest matching parameters to be called. Note that any constructor initializer is executed before the body of the constructor. Say that the following code is run:

```
Car myCar = new Car("Proton Persona");
```

In this example, the two-parameter constructor executes before any code in the body of the one-parameter constructor (though in this particular case, because there is no code in the body of the one-parameter constructor, it makes no difference).

A C# constructor initializer may contain either one call to another constructor in the same class (using the syntax just presented) or one call to a constructor in the immediate base class (using the same syntax, but using the keyword `base` instead of `this`). It is not possible to put more than one call in the initializer.

readonly Fields

The concept of a constant as a variable that contains a value that cannot be changed is something that C# shares with most programming languages. However, constants don't necessarily meet all requirements. On occasion, you may have some variable whose value shouldn't be changed, but where the value is not known until runtime. C# provides another type of variable that is useful in this scenario: the `readonly` field.

The `readonly` keyword gives a bit more flexibility than `const`, allowing for situations in which you might want a field to be constant but also need to carry out some calculations to determine its initial value. The rule is that you can assign values to a `readonly` field inside a constructor, but not anywhere else. It's also possible for a `readonly` field to be an instance rather than a static field, having a different value for each instance of a class. This means that, unlike a `const` field, if you want a `readonly` field to be static, you have to declare it as such.

Suppose that you have an MDI program that edits documents, and, for licensing reasons, you want to restrict the number of documents that can be opened simultaneously. Now assume that you are selling different versions of the software, and it's possible that customers can upgrade their licenses to open more documents simultaneously. Clearly, this means you can't hard-code the maximum number in the source code. You'd probably need a field to represent this maximum number. This field will have to be read in — perhaps from a registry key or some other file storage — each time the program is launched. So your code might look something like this:

```
public class DocumentEditor
{
   public static readonly uint MaxDocuments;

   static DocumentEditor()
   {
      MaxDocuments = DoSomethingToFindOutMaxNumber();
   }
}
```

In this case, the field is static, because the maximum number of documents needs to be stored only once per running instance of the program. This is why it is initialized in the static constructor. If you had an instance `readonly` field, you would initialize it in the instance constructor(s). For example, presumably each document you edit has a creation date, which you wouldn't want to allow the user to change (because that would be rewriting the past!). Note that the field is also public — you don't normally need to make `readonly` fields private, because by definition they cannot be modified externally (the same principle also applies to constants).

As noted earlier, date is represented by the class `System.DateTime`. The following code uses a `System.DateTime` constructor that takes three parameters (the year, month, and day of the month — you can find details of this and other `DateTime` constructors in the MSDN documentation):

```
public class Document
{
   public readonly DateTime CreationDate;

   public Document()
   {
      // Read in creation date from file. Assume result is 1 Jan 2002
      // but in general this can be different for different instances
      // of the class
      CreationDate = new DateTime(2002, 1, 1);
      }
   }
```

`CreationDate` and `MaxDocuments` in the previous code snippet are treated like any other field, except that because they are read-only, they cannot be assigned outside the constructors:

```
void SomeMethod()
{
   MaxDocuments = 10;    // compilation error here. MaxDocuments is readonly
}
```

It's also worth noting that you don't have to assign a value to a `readonly` field in a constructor. If you don't do so, it will be left with the default value for its particular data type or whatever value you initialized it to at its declaration. That applies to both static and instance `readonly` fields.

ANONYMOUS TYPES

Chapter 2, "Core C#" discussed the `var` keyword in reference to implicitly typed variables. When used with the `new` keyword, anonymous types can be created. An anonymous type is simply a nameless class that inherits from `object`. The definition of the class is inferred from the initializer, just as with implicitly typed variables.

If you need an object that contains a person's first, middle, and last name, the declaration would look like this:

```
var captain = new {FirstName = "James", MiddleName = "T", LastName = "Kirk"};
```

This would produce an object with `FirstName`, `MiddleName`, and `LastName` properties. If you were to create another object that looked like this:

```
var doctor = new {FirstName = "Leonard", MiddleName = "", LastName = "McCoy"};
```

the types of `captain` and `doctor` are the same. You could set `captain = doctor`, for example.

If the values that are being set come from another object, then the initializer can be abbreviated. If you already have a class that contains the properties `FirstName`, `MiddleName`, and `LastName` and you have an instance of that class with the instance name `person`, then the `captain` object could be initialized like this:

```
var captain = new {person.FirstName, person.MiddleName, person.LastName};
```

The property names from the `person` object would be projected to the new object named `captain`. So the object named `captain` would have the `FirstName`, `MiddleName`, and `LastName` properties.

The actual type name of these new objects is unknown. The compiler "makes up" a name for the type, but only the compiler will ever be able to make use of it. So you can't and shouldn't plan on using any type reflection on the new objects because you will not get consistent results.

STRUCTS

So far, you have seen how classes offer a great way of encapsulating objects in your program. You have also seen how they are stored on the heap in a way that gives you much more flexibility in data lifetime, but with a slight cost in performance. This performance cost is small thanks to the optimizations of managed heaps. However, in some situations all you really need is a small data structure. In this case, a class provides more functionality than you need, and for performance reasons you will probably prefer to use a struct. Look at this example:

```
class Dimensions
{
   public double Length;
   public double Width;
}
```

This code defines a class called `Dimensions`, which simply stores the length and width of an item. Perhaps you're writing a furniture-arranging program to let people experiment with rearranging their furniture on the computer, and you want to store the dimensions of each item of furniture. It looks as though you're breaking the rules of good program design by making the fields public, but the point is that you don't really need all the facilities of a class for this. All you have is two numbers, which you'll find convenient to treat as a pair rather than individually. There is no need for a lot of methods, or for you to be able to inherit from the class, and you certainly don't want to have the .NET runtime go to the trouble of bringing in the heap with all the performance implications, just to store two `double`s.

As mentioned earlier in this chapter, the only thing you need to change in the code to define a type as a struct instead of a class is to replace the keyword `class` with `struct`:

```
struct Dimensions
{
   public double Length;
   public double Width;
}
```

Defining functions for structs is also exactly the same as defining them for classes. The following code demonstrates a constructor and a property for a struct:

```
struct Dimensions
{
   public double Length;
   public double Width;

   public Dimensions(double length, double width)
   {
      Length=length;
      Width=width;
   }

   public double Diagonal
   {
      get
      {
        return Math.Sqrt(Length*Length + Width*Width);
      }
   }
}
```

Structs are value types, not reference types. This means they are stored either in the stack or inline (if they are part of another object that is stored on the heap) and have the same lifetime restrictions as the simple data types.

- Structs do not support inheritance.
- There are some differences in the way constructors work for structs. In particular, the compiler always supplies a default no-parameter constructor, which you are not permitted to replace.
- With a struct, you can specify how the fields are to be laid out in memory (this is examined in Chapter 14, "Reflection," which covers attributes).

Because structs are really intended to group data items together, you'll sometimes find that most or all of their fields are declared as public. This is, strictly speaking, contrary to the guidelines for writing .NET code — according to Microsoft, fields (other than `const` fields) should always be private and wrapped by public properties. However, for simple structs, many developers would nevertheless consider public fields to be acceptable programming practice.

The following sections look at some of these differences between structs and classes in more detail.

Structs Are Value Types

Although structs are value types, you can often treat them syntactically in the same way as classes. For example, with the definition of the `Dimensions` class in the previous section, you could write:

```
Dimensions point = new Dimensions();
point.Length = 3;
point.Width = 6;
```

Note that because structs are value types, the `new` operator does not work in the same way as it does for classes and other reference types. Instead of allocating memory on the heap, the `new` operator simply calls the appropriate constructor, according to the parameters passed to it, initializing all fields. Indeed, for structs it is perfectly legal to write:

```
Dimensions point;
point.Length = 3;
point.Width = 6;
```

If `Dimensions` was a class, this would produce a compilation error, because `point` would contain an uninitialized reference — an address that points nowhere, so you could not start setting values to its fields. For a struct, however, the variable declaration actually allocates space on the stack for the entire struct, so it's ready to assign values to. Note, however, that the following code would cause a compilation error, with the compiler complaining that you are using an uninitialized variable:

```
Dimensions point;
Double D = point.Length;
```

Structs follow the same rules as any other data type — everything must be initialized before use. A struct is considered fully initialized either when the `new` operator has been called against it, or when values have been individually assigned to all its fields. And of course, a struct defined as a member field of a class is initialized by being zeroed-out automatically when the containing object is initialized.

The fact that structs are value types will affect performance, though depending on how you use your struct, this can be good or bad. On the positive side, allocating memory for structs is very fast because this takes place inline or on the stack. The same goes for removing structs when they go out of scope. On the negative side, whenever you pass a struct as a parameter or assign a struct to another struct (as in `A=B`, where `A` and `B` are structs), the full contents of the struct are copied, whereas for a class only the reference is copied. This will result in a performance loss that depends on the size of the struct, emphasizing the fact that structs are really intended for small data structures. Note, however, that when passing a struct as a parameter to a method, you can avoid this performance loss by passing it as a `ref` parameter — in this case, only the address in memory of the struct will be passed in, which is just as fast as passing in a class. If you do this, though, be aware that it means the called method can in principle change the value of the struct.

Structs and Inheritance

Structs are not designed for inheritance. This means that it is not possible to inherit from a struct. The only exception to this is that structs, in common with every other type in C#, derive ultimately from the class `System.Object`. Hence, structs also have access to the methods of `System.Object`, and it is even possible to override them in structs — an obvious example would be overriding the `ToString()` method. The actual inheritance chain for structs is that each struct derives from a class, `System.ValueType`, which in turn derives from `System.Object`. `ValueType` does not add any new members to `Object`, but provides implementations of some of them that are more suitable for structs. Note that you cannot supply a different base class for a struct: every struct is derived from `ValueType`.

Constructors for Structs

You can define constructors for structs in exactly the same way that you can for classes, except that you are not permitted to define a constructor that takes no parameters. This may seem nonsensical, and the reason is buried in the implementation of the .NET runtime. Some rare circumstances exist in which the .NET runtime would not be able to call a custom zero-parameter constructor that you have supplied. Microsoft has therefore taken the easy way out and banned zero-parameter constructors for structs in C#.

That said, the default constructor, which initializes all fields to zero values, is always present implicitly, even if you supply other constructors that take parameters. It's also impossible to circumvent the default constructor by supplying initial values for fields. The following code will cause a compile-time error:

```
struct Dimensions
{
   public double Length = 1;       // error. Initial values not allowed
   public double Width = 2;        // error. Initial values not allowed
}
```

Of course, if `Dimensions` had been declared as a class, this code would have compiled without any problems.

Incidentally, you can supply a `Close()` or `Dispose()` method for a struct in the same way you do for a class.

PARTIAL CLASSES

The `partial` keyword allows the class, struct, method or interface to span across multiple files. Typically, a class will reside entirely in a single file. However, in situations where multiple developers need access to the same class, or more likely in the situation where a code generator of some type is generating part of a class, then having the class in multiple files can be beneficial.

The way that the `partial` keyword is used is to simply place `partial` before `class`, `struct`, or `interface`. In the following example, the class `TheBigClass` resides in two separate source files, `BigClassPart1.cs` and `BigClassPart2.cs`:

```
//BigClassPart1.cs
partial class TheBigClass
{
  public void MethodOne()
  {
  }
}

//BigClassPart2.cs
partial class TheBigClass
```

```
{
  public void MethodTwo()
  {
  }
}
```

When the project that these two source files are part of is compiled, a single type called `TheBigClass` will be created with two methods, `MethodOne()` and `MethodTwo()`.

If any of the following keywords are used in describing the class, the same must apply to all partials of the same type:

- `public`
- `private`
- `protected`
- `internal`
- `abstract`
- `sealed`
- `new`
- generic constraints

Nested partials are allowed as long as the `partial` keyword precedes the `class` keyword in the nested type. Attributes, XML comments, interfaces, generic-type parameter attributes, and members will be combined when the partial types are compiled into the type. Given these two source files:

```
//BigClassPart1.cs
[CustomAttribute]
partial class TheBigClass: TheBigBaseClass, IBigClass
{
  public void MethodOne()
  {
  }
}

//BigClassPart2.cs
[AnotherAttribute]
partial class TheBigClass: IOtherBigClass
{
  public void MethodTwo()
  {
  }
}
```

after the compile, the equivalent source file would be:

```
[CustomAttribute]
[AnotherAttribute]
partial class TheBigClass: TheBigBaseClass, IBigClass, IOtherBigClass
{
  public void MethodOne()
  {
  }

  public void MethodTwo()
  {
  }
}
```

STATIC CLASSES

Earlier, this chapter discussed static constructors and how they allowed the initialization of static member variables. If a class contains nothing but static methods and properties, the class itself can become static. A static class is functionally the same as creating a class with a private static constructor. An instance of the class can never be created. By using the `static` keyword, the compiler can help by checking that instance members are never accidentally added to the class. If they are, a compile error happens. This can help guarantee that an instance is never created. The syntax for a static class looks like this:

```
static class StaticUtilities
{
  public static void HelperMethod()
  {
  }
}
```

An object of type `StaticUtilities` is not needed to call the `HelperMethod()`. The type name is used to make the call:

```
StaticUtilities.HelperMethod();
```

THE OBJECT CLASS

As indicated earlier, all .NET classes are ultimately derived from `System.Object`. In fact, if you don't specify a base class when you define a class, the compiler will automatically assume that it derives from `Object`. Because inheritance has not been used in this chapter, every class you have seen here is actually derived from `System.Object`. (As noted earlier, for structs this derivation is indirect — a struct is always derived from `System.ValueType`, which in turn derives from `System.Object`.)

The practical significance of this is that, besides the methods and properties and so on that you define, you also have access to a number of public and protected member methods that have been defined for the `Object` class. These methods are available in all other classes that you define.

System.Object Methods

For the time being, we simply summarize the purpose of each method in the following list, and then, in the next section, we provide more detail about the `ToString()` method in particular.

- `ToString()` — A fairly basic, quick-and-easy string representation, use it when you just want a quick idea of the contents of an object, perhaps for debugging purposes. It provides very little choice of how to format the data. For example, dates can, in principle, be expressed in a huge variety of different formats, but `DateTime.ToString()` does not offer you any choice in this regard. If you need a more sophisticated string representation that, for example, takes account of your formatting preferences or of the culture (the locale), then you should implement the `IFormattable` interface (see Chapter 9).
- `GetHashCode()` — If objects are placed in a data structure known as a map (also known as a hash table or dictionary), it is used by classes that manipulate these structures to determine where to place an object in the structure. If you intend your class to be used as a key for a dictionary, you will need to override `GetHashCode()`. Some fairly strict requirements exist for how you implement your overload, and you learn about those when you examine dictionaries in Chapter 10, "Collections."
- `Equals()` (both versions) and `ReferenceEquals()` — As you'll gather by the existence of three different methods aimed at comparing the equality of objects, the .NET Framework has quite a sophisticated scheme for measuring equality. Subtle differences exist between how these three methods, along with the comparison operator, ==, are intended to be used. Not only that, but restrictions also exist on how you should override the virtual, one-parameter version of `Equals()` if you choose to do

so, because certain base classes in the System.Collections namespace call the method and expect it to behave in certain ways. You explore the use of these methods in Chapter 7 when you examine operators.

- Finalize() — Covered in Chapter 13, this method is intended as the nearest that C# has to C++ style destructors and is called when a reference object is garbage collected to clean up resources. The Object implementation of Finalize() actually does nothing and is ignored by the garbage collector. You will normally override Finalize() if an object owns references to unmanaged resources that need to be removed when the object is deleted. The garbage collector cannot do this directly because it only knows about managed resources, so it relies on any finalizers that you supply.
- GetType() — Returns an instance of a class derived from System.Type so this object can provide an extensive range of information about the class of which your object is a member, including base type, methods, properties, and so on. System.Type also provides the entry point into .NET's reflection technology. Chapter 14 examines this topic.
- MemberwiseClone() — The only member of System.Object that isn't examined in detail anywhere in the book. There is no need to because it is fairly simple in concept. It simply makes a copy of the object and returns a reference (or in the case of a value type, a boxed reference) to the copy. Note that the copy made is a shallow copy — this means that it copies all the value types in the class. If the class contains any embedded references, then only the references will be copied, not the objects referred to. This method is protected and cannot be called to copy external objects. It is also not virtual, so you cannot override its implementation.

The ToString() Method

You've already encountered ToString() in Chapter 2. It provides the most convenient way to get a quick string representation of an object.

For example:

```
int i = 50;
string str = i.ToString();  // returns "-50"
```

Here's another example:

```
enum Colors {Red, Orange, Yellow};
// later on in code...
Colors favoriteColor = Colors.Orange;
string str = favoriteColor.ToString();     // returns "Orange"
```

Object.ToString() is actually declared as virtual, and all these examples are taking advantage of the fact that its implementation in the C# predefined data types has been overridden for us to return correct string representations of those types. You might not think that the Colors enum counts as a predefined data type. It actually gets implemented as a struct derived from System.Enum, and System.Enum has a rather clever override of ToString() that deals with all the enums you define.

If you don't override ToString() in classes that you define, your classes will simply inherit the System.Object implementation — which displays the name of the class. If you want ToString() to return a string that contains information about the value of objects of your class, you will need to override it. To illustrate this, the following example, Money, defines a very simple class, also called Money, which represents U.S. currency amounts. Money simply acts as a wrapper for the decimal class but supplies a ToString() method. Note that this method must be declared as override because it is replacing (overriding) the ToString() method supplied by Object. Chapter 4 discusses overriding in more detail. The complete code for this example is as follows (note that it also illustrates use of properties to wrap fields):

```
using System;

namespace Wrox
{
   class MainEntryPoint
```

```
      {
         static void Main(string[] args)
         {
            Money cash1 = new Money();
            cash1.Amount = 40M;
            Console.WriteLine("cash1.ToString() returns: " + cash1.ToString());
            Console.ReadLine();
         }
      }
      public class Money
      {
         private decimal amount;

         public decimal Amount
         {
            get
            {
               return amount;
            }
            set
            {
               amount = value;
            }
         }
         public override string ToString()
         {
            return "$" + Amount.ToString();
         }
      }

   }
```

This example is here just to illustrate syntactical features of C#. C# already has a predefined type to represent currency amounts, `decimal`, so in real life, you wouldn't write a class to duplicate this functionality unless you wanted to add various other methods to it. And in many cases, due to formatting requirements, you'd probably use the `String.Format()` method (which is covered in Chapter 8) rather than `ToString()` to display a currency string.

In the `Main()` method, you first instantiate a `Money` object. The `ToString()` method is then called, which actually executes the override version of the method. Running this code gives the following results:

```
cash1.ToString() returns: $40
```

EXTENSION METHODS

There are many ways to extend a class. If you have the source for the class, then inheritance, which is covered in Chapter 4, is a great way to add functionality to your objects. What if the source code isn't available? Extension methods can help by allowing you to change a class without requiring the source code for the class.

Extension methods are static methods that can appear to be part of a class without actually being in the source code for the class. Let's say that the `Money` class from the previous example needs to have a method `AddToAmount(decimal amountToAdd)`. However, for whatever reason the original source for the assembly cannot be changed directly. All that you have to do is create a static class and add the `AddToAmount` method as a static method. Here is what the code would look like:

```
namespace Wrox
{
  public static class MoneyExtension
  {
    public static void AddToAmount(this Money money, decimal amountToAdd)
```

```
        {
          money.Amount += amountToAdd;
        }
      }
    }
```

Notice the parameters for the `AddToAmount` method. For an extension method, the first parameter is the type that is being extended preceded by the `this` keyword. This is what tells the compiler that this method is part of the `Money` type. In this example, `Money` is the type that is being extended. In the extension method you have access to all the public methods and properties of the type being extended.

In the main program, the `AddToAmount` method appears just as another method. The first parameter doesn't appear, and you do not have to do anything with it. To use the new method, you make the call just like any other method:

```
cash1.AddToAmount(10M);
```

Even though the extension method is static, you use standard instance method syntax. Notice that we called `AddToAmount` using the `cash1` instance variable and not using the type name.

If the extension method has the same name as a method in the class, the extension method will never be called. Any instance methods already in the class take precedence.

SUMMARY

This chapter examined C# syntax for declaring and manipulating objects. You have seen how to declare static and instance fields, properties, methods, and constructors. You have also seen that C# adds some new features not present in the OOP model of some other languages — for example, static constructors provide a means of initializing static fields, whereas structs allow you to define types that do not require the use of the managed heap, which could lead to performance gains. You have also seen how all types in C# derive ultimately from the type `System.Object`, which means that all types start with a basic set of useful methods, including `ToString()`.

We mentioned inheritance a few times throughout this chapter. We examine implementation and interface inheritance in C# in Chapter 4.

4 Inheritance

WHAT'S IN THIS CHAPTER?

- ➤ Types of inheritance
- ➤ Implementing inheritance
- ➤ Access modifiers
- ➤ Interfaces

Chapter 3, "Objects and Types," examined how to use individual classes in C#. The focus in that chapter was how to define methods, properties, constructors, and other members of a single class (or a single struct). Although you learned that all classes are ultimately derived from the class `System.Object`, you did not learn how to create a hierarchy of inherited classes. Inheritance is the subject of this chapter. In this chapter, you see how C# and the .NET Framework handle inheritance.

TYPES OF INHERITANCE

Let's start by reviewing exactly what C# does and does not support as far as inheritance is concerned.

Implementation Versus Interface Inheritance

In object-oriented programming, there are two distinct types of inheritance — implementation inheritance and interface inheritance:

- ➤ **Implementation inheritance** means that a type derives from a base type, taking all the base type's member fields and functions. With implementation inheritance, a derived type adopts the base type's implementation of each function, unless it is indicated in the definition of the derived type that a function implementation is to be overridden. This type of inheritance is most useful when you need to add functionality to an existing type, or when a number of related types share a significant amount of common functionality.
- ➤ **Interface inheritance** means that a type inherits only the signatures of the functions and does not inherit any implementations. This type of inheritance is most useful when you want to specify that a type makes certain features available.

C# supports both implementation and interface inheritance. Both are baked into the framework and the language from the ground up, thereby allowing you to decide which to use based on the architecture of the application.

Multiple Inheritance

Some languages such as C++ support what is known as *multiple inheritance,* in which a class derives from more than one other class. The benefits of using multiple inheritance are debatable: On one hand, there is no doubt that it is possible to use multiple inheritance to write extremely sophisticated, yet compact, code, as demonstrated by the C++ ATL library. On the other hand, code that uses multiple implementation inheritance is often difficult to understand and debug (a point that is equally well-demonstrated by the C++ ATL library). As mentioned, making it easy to write robust code was one of the crucial design goals behind the development of C#. Accordingly, C# does not support multiple implementation inheritance. It does, however, allow types to be derived from multiple interfaces — multiple interface inheritance. This means that a C# class can be derived from one other class, and any number of interfaces. Indeed, we can be more precise: Thanks to the presence of `System.Object` as a common base type, every C# class (except for `Object`) has exactly one base class, and may additionally have any number of base interfaces.

Structs and Classes

Chapter 3 distinguishes between structs (value types) and classes (reference types). One restriction of using a struct is that structs do not support inheritance, beyond the fact that every struct is automatically derived from `System.ValueType`. In fact, we should be more careful. It's true that it is not possible to code a type hierarchy of structs; however, it is possible for structs to implement interfaces. In other words, structs don't really support implementation inheritance, but they do support interface inheritance. We can summarize the situation for any types that you define as follows:

- ➤ **Structs** are always derived from `System.ValueType`. They can also be derived from any number of interfaces.
- ➤ **Classes** are always derived from one other class of your choosing. They can also be derived from any number of interfaces.

IMPLEMENTATION INHERITANCE

If you want to declare that a class derives from another class, use the following syntax:

```
class MyDerivedClass: MyBaseClass
{
   // functions and data members here
}
```

If a class (or a struct) also derives from interfaces, the list of base class and interfaces is separated by commas:

```
public class MyDerivedClass: MyBaseClass, IInterface1, IInterface2
{
         // etc.
}
```

For a struct, the syntax is as follows:

```
public struct MyDerivedStruct: IInterface1, IInterface2
{
         // etc.
 }
```

If you do not specify a base class in a class definition, the C# compiler will assume that `System.Object` is the base class. Hence, the following two pieces of code yield the same result:

```
class MyClass: Object  // derives from System.Object
{
   // etc.
}
```

and

```
class MyClass   // derives from System.Object
{
   // etc.
}
```

For the sake of simplicity, the second form is more common.

Because C# supports the `object` keyword, which serves as a pseudonym for the `System.Object` class, you can also write:

```
class MyClass: object   // derives from System.Object
{
   // etc.
}
```

If you want to reference the `Object` class, use the `object` keyword, which is recognized by intelligent editors such as Visual Studio .NET and thus facilitates editing your code.

Virtual Methods

By declaring a base class function as `virtual`, you allow the function to be overridden in any derived classes:

```
class MyBaseClass
{
   public virtual string VirtualMethod()
   {
      return "This method is virtual and defined in MyBaseClass";
   }
}
```

It is also permitted to declare a property as `virtual`. For a virtual or overridden property, the syntax is the same as for a nonvirtual property, with the exception of the keyword `virtual`, which is added to the definition. The syntax looks like this:

```
public virtual string ForeName
{
   get { return foreName;}
   set { foreName = value;}
}
private string foreName;
```

For simplicity, the following discussion focuses mainly on methods, but it applies equally well to properties.

The concepts behind virtual functions in C# are identical to standard OOP concepts. You can override a virtual function in a derived class, and when the method is called, the appropriate method for the type of object is invoked. In C#, functions are not virtual by default but (aside from constructors) can be explicitly declared as `virtual`. This follows the C++ methodology: For performance reasons, functions are not virtual unless indicated. In Java, by contrast, all functions are virtual. C# does differ from C++ syntax, though, because it requires you to declare when a derived class's function overrides another function, using the `override` keyword:

```
class MyDerivedClass: MyBaseClass
{
   public override string VirtualMethod()
```

```
      {
         return "This method is an override defined in MyDerivedClass.";
      }
   }
```

This syntax for method overriding removes potential runtime bugs that can easily occur in C++, when a method signature in a derived class unintentionally differs slightly from the base version, resulting in the method failing to override the base version. In C#, this is picked up as a compile-time error because the compiler would see a function marked as `override` but no base method for it to override.

Neither member fields nor static functions can be declared as virtual. The concept simply wouldn't make sense for any class member other than an instance function member.

Hiding Methods

If a method with the same signature is declared in both base and derived classes, but the methods are not declared as `virtual` and `override`, respectively, then the derived class version is said to *hide* the base class version.

In most cases, you would want to override methods rather than hide them. By hiding them you risk calling the wrong method for a given class instance. However, as shown in the following example, C# syntax is designed to ensure that the developer is warned at compile time about this potential problem, thus making it safer to hide methods if that is your intention. This also has versioning benefits for developers of class libraries.

Suppose that you have a class called `HisBaseClass`:

```
class HisBaseClass
{
   // various members
}
```

At some point in the future, you write a derived class that adds some functionality to `HisBaseClass`. In particular, you add a method called `MyGroovyMethod()`, which is not present in the base class:

```
class MyDerivedClass: HisBaseClass
{
   public int MyGroovyMethod()
   {
      // some groovy implementation
      return 0;
   }
}
```

One year later, you decide to extend the functionality of the base class. By coincidence, you add a method that is also called `MyGroovyMethod()` and that has the same name and signature as yours, but probably doesn't do the same thing. When you compile your code using the new version of the base class, you have a potential clash because your program won't know which method to call. It's all perfectly legal in C#, but because your `MyGroovyMethod()` is not intended to be related in any way to the base class `MyGroovyMethod()`, the result is that running this code does not yield the result you want. Fortunately, C# has been designed to cope very well with these types of conflicts.

In these situations, C# generates a compilation warning that reminds you to use the `new` keyword to declare that you intend to hide a method, like this:

```
class MyDerivedClass: HisBaseClass
{
   public new int MyGroovyMethod()
   {
      // some groovy implementation
      return 0;
   }
}
```

However, because your version of `MyGroovyMethod()` is not declared as `new`, the compiler picks up on the fact that it's hiding a base class method without being instructed to do so and will generate a warning (this applies whether or not you declared `MyGroovyMethod()` as `virtual`). If you want, you can rename your version of the method. This is the recommended course of action because it eliminates future confusion. However, if you decide not to rename your method for whatever reason (for example, if you've published your software as a library for other companies, so you can't change the names of methods), all your existing client code will still run correctly, picking up your version of `MyGroovyMethod()`. This is because any existing code that accesses this method must be done through a reference to `MyDerivedClass` (or a further derived class).

Your existing code cannot access this method through a reference to `HisBaseClass`; it would generate a compilation error when compiled against the earlier version of `HisBaseClass`. The problem can only happen in client code you have yet to write. C# arranges things so that you get a warning that a potential problem might occur in future code — you will need to pay attention to this warning and take care not to attempt to call your version of `MyGroovyMethod()` through any reference to `HisBaseClass` in any future code you add. However, all your existing code will still work fine. It may be a subtle point, but it's quite an impressive example of how C# is able to cope with different versions of classes.

Calling Base Versions of Functions

C# has a special syntax for calling base versions of a method from a derived class: `base.<MethodName>()`. For example, if you want a method in a derived class to return 90 percent of the value returned by the base class method, you can use the following syntax:

```
class CustomerAccount
{
   public virtual decimal CalculatePrice()
   {
      // implementation
      return 0.0M;
   }
}
class GoldAccount: CustomerAccount
{
   public override decimal CalculatePrice()
   {
      return base.CalculatePrice() * 0.9M;
   }
}
```

Note that you can use the `base.<MethodName>()` syntax to call any method in the base class — you don't have to call it from inside an override of the same method.

Abstract Classes and Functions

C# allows both classes and functions to be declared as abstract. An abstract class cannot be instantiated, whereas an abstract function does not have an implementation, and must be overridden in any non-abstract derived class. Obviously, an abstract function is automatically virtual (although you don't need to supply the `virtual` keyword; doing so results in a syntax error). If any class contains any abstract functions, that class is also abstract and must be declared as such:

```
abstract class Building
{
   public abstract decimal CalculateHeatingCost();   // abstract method
}
```

Sealed Classes and Methods

C# allows classes and methods to be declared as `sealed`. In the case of a class, this means that you can't inherit from that class. In the case of a method, this means that you can't override that method.

```
sealed class FinalClass
{
   // etc
}
class DerivedClass: FinalClass       // wrong. Will give compilation error
{
   // etc
}
```

The most likely situation in which you'll mark a class or method as `sealed` is if the class or method is internal to the operation of the library, class, or other classes that you are writing, so that you ensure that any attempt to override some of its functionality will lead to instability in the code. You might also mark a class or method as `sealed` for commercial reasons, in order to prevent a third party from extending your classes in a manner that is contrary to the licensing agreements. In general, however, you should be careful about marking a class or member as `sealed` because by doing so you are severely restricting how it can be used. Even if you don't think it would be useful to inherit from a class or override a particular member of it, it's still possible that at some point in the future someone will encounter a situation you hadn't anticipated in which it is useful to do so. The .NET base class library frequently uses sealed classes to make these classes inaccessible to third-party developers who might want to derive their own classes from them. For example, `string` is a sealed class.

Declaring a method as `sealed` serves a similar purpose as for a class:

```
class MyClass: MyClassBase
{
   public sealed override void FinalMethod()
   {
      // etc.
   }
}
class DerivedClass: MyClass
{
   public override void FinalMethod()      // wrong. Will give compilation error
   {
   }
}
```

In order to use the `sealed` keyword on a method or property, it must have first been overridden from a base class. If you do not want a method or property in a base class overridden, then don't mark it as virtual.

Constructors of Derived Classes

Chapter 3 discusses how constructors can be applied to individual classes. An interesting question arises as to what happens when you start defining your own constructors for classes that are part of a hierarchy, inherited from other classes that may also have custom constructors.

Assume that you have not defined any explicit constructors for any of your classes. This means that the compiler supplies default zeroing-out constructors for all your classes. There is actually quite a lot going on under the hood when that happens, but the compiler is able to arrange it so that things work out nicely throughout the class hierarchy and every field in every class gets initialized to whatever its default value is. When you add a constructor of your own, however, you are effectively taking control of construction. This has implications right down through the hierarchy of derived classes, and you have to make sure that you don't inadvertently do anything to prevent construction through the hierarchy from taking place smoothly.

You might be wondering why there is any special problem with derived classes. The reason is that when you create an instance of a derived class, there is actually more than one constructor at work. The constructor of the class you instantiate isn't by itself sufficient to initialize the class — the constructors of the base classes must also be called. That's why we've been talking about construction through the hierarchy.

To see why base class constructors must be called, you're going to develop an example based on a cell phone company called MortimerPhones. The example contains an abstract base class, `GenericCustomer`, which represents any customer. There is also a (non-abstract) class, `Nevermore60Customer`, which represents any customer on a particular rate called the `Nevermore60` rate. All customers have a name, represented by a private field. Under the `Nevermore60` rate, the first few minutes of the customer's call time are charged at a higher rate, necessitating the need for the field `highCostMinutesUsed`, which details how many of these higher-cost minutes each customer has used up. The class definitions look like this:

```
abstract class GenericCustomer
{
   private string name;
   // lots of other methods etc.
}
class Nevermore60Customer: GenericCustomer
{
   private uint highCostMinutesUsed;
   // other methods etc.
}
```

code snippet MortimerPhones.cs

We won't worry about what other methods might be implemented in these classes, because we are concentrating solely on the construction process here. And if you download the sample code for this chapter, you'll find that the class definitions include only the constructors.

Take a look at what happens when you use the `new` operator to instantiate a `Nevermore60Customer`:

```
   GenericCustomer customer = new Nevermore60Customer();
```

Clearly, both of the member fields `name` and `highCostMinutesUsed` must be initialized when `customer` is instantiated. If you don't supply constructors of your own, but rely simply on the default constructors, then you'd expect `name` to be initialized to the `null` reference, and `highCostMinutesUsed` initialized to zero. Let's look in a bit more detail at how this actually happens.

The `highCostMinutesUsed` field presents no problem: the default `Nevermore60Customer` constructor supplied by the compiler will initialize this field to zero.

What about `name`? Looking at the class definitions, it's clear that the `Nevermore60Customer` constructor can't initialize this value. This field is declared as private, which means that derived classes don't have access to it. So, the default `Nevermore60Customer` constructor simply won't know that this field exists. The only code items that have that knowledge are other members of `GenericCustomer`. This means that if `name` is going to be initialized, that'll have to be done by some constructor in `GenericCustomer`. No matter how big your class hierarchy is, this same reasoning applies right down to the ultimate base class, `System.Object`.

Now that you have an understanding of the issues involved, you can look at what actually happens whenever a derived class is instantiated. Assuming that default constructors are used throughout, the compiler first grabs the constructor of the class it is trying to instantiate, in this case `Nevermore60Customer`. The first thing that the default `Nevermore60Customer` constructor does is attempt to run the default constructor for the immediate base class, `GenericCustomer`. The `GenericCustomer` constructor attempts to run the constructor for its immediate base class, `System.Object`. `System.Object` doesn't have any base classes, so its constructor just executes and returns control to the `GenericCustomer` constructor. That constructor now executes, initializing `name` to `null`, before returning control to the `Nevermore60Customer` constructor. That constructor in turn executes, initializing `highCostMinutesUsed` to zero, and exits. At this point, the `Nevermore60Customer` instance has been successfully constructed and initialized.

The net result of all this is that the constructors are called in order of `System.Object` first, and then progress down the hierarchy until the compiler reaches the class being instantiated. Notice also that in this process, each constructor handles initialization of the fields in its own class. That's how it should normally work, and when you start adding your own constructors you should try to stick to that principle.

Notice the order in which this happens. It's always the base class constructors that get called first. This means that there are no problems with a constructor for a derived class invoking any base class methods, properties, and any other members that it has access to, because it can be confident that the base class has already been constructed and its fields initialized. It also means that if the derived class doesn't like the way that the base class has been initialized, it can change the initial values of the data, provided that it has access to do so. However, good programming practice almost invariably means you'll try to prevent that situation from occurring if you can, and you will trust the base class constructor to deal with its own fields.

Now that you know how the process of construction works, you can start fiddling with it by adding your own constructors.

Adding a Constructor in a Hierarchy

We'll take the easiest case first and see what happens if you simply replace the default constructor somewhere in the hierarchy with another constructor that takes no parameters. Suppose that you decide that you want everyone's name to be initially set to the string `"<no name>"` instead of to the `null` reference. You'd modify the code in `GenericCustomer` like this:

```
public abstract class GenericCustomer
{
   private string name;
   public GenericCustomer()
    : base()  // We could omit this line without affecting the compiled code.
   {
      name = "<no name>";
   }
```

Adding this code will work fine. `Nevermore60Customer` still has its default constructor, so the sequence of events described earlier will proceed as before, except that the compiler will use the custom `GenericCustomer` constructor instead of generating a default one, so the `name` field will always be initialized to `"<no name>"` as required.

Notice that in your constructor you've added a call to the base class constructor before the `GenericCustomer` constructor is executed, using a syntax similar to that used earlier when we discussed how to get different overloads of constructors to call each other. The only difference is that this time you use the `base` keyword instead of `this` to indicate that it's a constructor to the `base` class rather than a constructor to the current class you want to call. There are no parameters in the brackets after the `base` keyword — that's important because it means you are not passing any parameters to the base constructor, so the compiler will have to look for a parameterless constructor to call. The result of all this is that the compiler will inject code to call the `System.Object` constructor, just as would happen by default anyway.

In fact, you can omit that line of code and write the following (as was done for most of the constructors so far in this chapter):

```
public GenericCustomer()
{
   name = "<no name>";
}
```

If the compiler doesn't see any reference to another constructor before the opening curly brace, it assumes that you intended to call the base class constructor; this fits in with the way that default constructors work.

The `base` and `this` keywords are the only keywords allowed in the line that calls another constructor. Anything else causes a compilation error. Also note that only one other constructor can be specified.

So far, this code works fine. One way to mess up the progression through the hierarchy of constructors, however, is to declare a constructor as `private`:

```
private GenericCustomer()
{
   name = "<no name>";
}
```

If you try this, you'll find you get an interesting compilation error, which could really throw you if you don't understand how construction down a hierarchy works:

```
'Wrox.ProCSharp.GenericCustomer.GenericCustomer()' is inaccessible due to its protection level
```

The interesting thing is that the error occurs not in the `GenericCustomer` class, but in the derived class, `Nevermore60Customer`. What's happened is that the compiler has tried to generate a default constructor for `Nevermore60Customer` but has not been able to because the default constructor is supposed to invoke the no-parameter `GenericCustomer` constructor. By declaring that constructor as `private`, you've made it inaccessible to the derived class. A similar error occurs if you supply a constructor to `GenericCustomer`, which takes parameters, but at the same time you fail to supply a no-parameter constructor. In this case, the compiler will not generate a default constructor for `GenericCustomer`, so when it tries to generate the default constructors for any derived class, it will again find that it can't because a no-parameter base class constructor is not available. A workaround would be to add your own constructors to the derived classes — even if you don't actually need to do anything in these constructors — so that the compiler doesn't try to generate any default constructors for them.

Now that you have all the theoretical background you need, you're ready to move on to an example of how you can neatly add constructors to a hierarchy of classes. In the next section, you start adding constructors that take parameters to the MortimerPhones example.

Adding Constructors with Parameters to a Hierarchy

You're going to start with a one-parameter constructor for `GenericCustomer`, which specifies that customers can be instantiated only when they supply their names:

```
abstract class GenericCustomer
{
   private string name;
   public GenericCustomer(string name)
   {
      this.name = name;
   }
```

So far, so good. However, as mentioned previously, this will cause a compilation error when the compiler tries to create a default constructor for any derived classes because the default compiler-generated constructors for `Nevermore60Customer` will try to call a no-parameter `GenericCustomer` constructor, and `GenericCustomer` does not possess such a constructor. Therefore, you'll need to supply your own constructors to the derived classes to avoid a compilation error:

```
class Nevermore60Customer: GenericCustomer
{
   private uint highCostMinutesUsed;
   public Nevermore60Customer(string name)
    :   base(name)
   {
   }
```

Now instantiation of `Nevermore60Customer` objects can occur only when a string containing the customer's name is supplied, which is what you want anyway. The interesting thing is what the `Nevermore60Customer` constructor does with this string. Remember that it can't initialize the `name` field itself because it has no access to private fields in its base class. Instead, it passes the name through to the base class for the `GenericCustomer` constructor to handle. It does this by specifying that the base class constructor to be executed first is the one that takes the name as a parameter. Other than that, it doesn't take any action of its own.

Next, you investigate what happens if you have different overloads of the constructor as well as a class hierarchy to deal with. To this end, assume that Nevermore60 customers may have been referred to MortimerPhones by a friend as part of one of those sign-up-a-friend-and-get-a-discount offers. This means that when you construct a `Nevermore60Customer`, you may need to pass in the referrer's name as well. In real life, the constructor would have to do something complicated with the name, such as process the discount, but here you'll just store the referrer's name in another field.

The `Nevermore60Customer` definition will now look like this:

```
class Nevermore60Customer: GenericCustomer
{
   public Nevermore60Customer(string name, string referrerName)
    : base(name)
   {
      this.referrerName = referrerName;
   }

   private string referrerName;
   private uint highCostMinutesUsed;
```

The constructor takes the name and passes it to the `GenericCustomer` constructor for processing. `referrerName` is the variable that is your responsibility here, so the constructor deals with that parameter in its main body.

However, not all `Nevermore60Customers` will have a referrer, so you still need a constructor that doesn't require this parameter (or a constructor that gives you a default value for it). In fact, you will specify that if there is no referrer, then the `referrerName` field should be set to `"<None>"`, using the following one-parameter constructor:

```
public Nevermore60Customer(string name)
 : this(name, "<None>")
{
}
```

You now have all your constructors set up correctly. It's instructive to examine the chain of events that now occurs when you execute a line like this:

```
GenericCustomer customer=new Nevermore60Customer("Arabel Jones");
```

The compiler sees that it needs a one-parameter constructor that takes one string, so the constructor it will identify is the last one that you've defined:

```
public Nevermore60Customer(string Name)
 : this(Name, "<None>")
```

When you instantiate `customer`, this constructor will be called. It immediately transfers control to the corresponding `Nevermore60Customer` two-parameter constructor, passing it the values `"ArabelJones"`, and `"<None>"`. Looking at the code for this constructor, you see that it in turn immediately passes control to the one-parameter `GenericCustomer` constructor, giving it the string `"ArabelJones"`, and in turn that constructor passes control to the `System.Object` default constructor. Only now do the constructors execute. First, the `System.Object` constructor executes. Next comes the `GenericCustomer` constructor, which initializes the `name` field. Then the `Nevermore60Customer` two-parameter constructor gets control back and sorts out initializing the `referrerName` to `"<None>"`. Finally, the `Nevermore60Customer` one-parameter constructor gets to execute; this constructor doesn't do anything else.

As you can see, this is a very neat and well-designed process. Each constructor handles initialization of the variables that are obviously its responsibility, and, in the process, your class is correctly instantiated and prepared for use. If you follow the same principles when you write your own constructors for your classes, you should find that even the most complex classes get initialized smoothly and without any problems.

MODIFIERS

You have already encountered quite a number of so-called modifiers — keywords that can be applied to a type or to a member. Modifiers can indicate the visibility of a method, such as `public` or `private`, or the nature of an item, such as whether a method is `virtual` or `abstract`. C# has a number of modifiers, and at this point it's worth taking a minute to provide the complete list.

Visibility Modifiers

Visibility modifiers indicate which other code items can view an item.

MODIFIER	APPLIES TO	DESCRIPTION
`public`	Any types or members	The item is visible to any other code.
`protected`	Any member of a type, also any nested type	The item is visible only to any derived type.
`internal`	Any member of a type, also any nested type	The item is visible only within its containing assembly.
`private`	Any types or members	The item is visible only inside the type to which it belongs.
`protected internal`	Any member of a type, also any nested type	The item is visible to any code within its containing assembly and also to any code inside a derived type.

Note that type definitions can be internal or public, depending on whether you want the type to be visible outside its containing assembly.

```
public class MyClass
{
  // etc.
```

You cannot define types as protected, private, or protected internal because these visibility levels would be meaningless for a type contained in a namespace. Hence, these visibilities can be applied only to members. However, you can define nested types (that is, types contained within other types) with these visibilities because in this case the type also has the status of a member. Hence, the following code is correct:

```
public class OuterClass
{
  protected class InnerClass
  {
         // etc.
  }
  // etc.
}
```

If you have a nested type, the inner type is always able to see all members of the outer type. Therefore, with the preceding code, any code inside `InnerClass` always has access to all members of `OuterClass`, even where those members are private.

Other Modifiers

The modifiers in the following table can be applied to members of types and have various uses. A few of these modifiers also make sense when applied to types.

MODIFIER	APPLIES TO	DESCRIPTION
`new`	Function members	The member hides an inherited member with the same signature.
`static`	All members	The member does not operate on a specific instance of the class.
`virtual`	Function members only	The member can be overridden by a derived class.
`abstract`	Function members only	A virtual member that defines the signature of the member, but doesn't provide an implementation.
`override`	Function members only	The member overrides an inherited virtual or abstract member.
`sealed`	Classes, methods, and properties	For classes, the class cannot be inherited from. For properties and methods, the member overrides an inherited virtual member, but cannot be overridden by any members in any derived classes. Must be used in conjunction with `override`.
`extern`	Static [`DllImport`] methods only	The member is implemented externally, in a different language.

INTERFACES

As mentioned earlier, by deriving from an interface, a class is declaring that it implements certain functions. Because not all object-oriented languages support interfaces, this section examines C#'s implementation of interfaces in detail.

This section illustrates interfaces by presenting the complete definition of one of the interfaces that has been predefined by Microsoft — `System.IDisposable`. `IDisposable` contains one method, `Dispose()`, which is intended to be implemented by classes to clean up code:

```
public interface IDisposable
{
   void Dispose();
}
```

This code shows that declaring an interface works syntactically in pretty much the same way as declaring an abstract class. You should be aware, however, that it is not permitted to supply implementations of any of the members of an interface. In general, an interface can only contain declarations of methods, properties, indexers, and events.

You can never instantiate an interface; it contains only the signatures of its members. An interface has neither constructors (how can you construct something that you can't instantiate?) nor fields (because that would imply some internal implementation). An interface definition is also not allowed to contain operator overloads, although that's not because there is any problem with declaring them — there isn't; it is because interfaces are usually intended to be public contracts, and having operator overloads would cause some incompatibility problems with other .NET languages, such as Visual Basic .NET, which do not support operator overloading.

It is also not permitted to declare modifiers on the members in an interface definition. Interface members are always implicitly `public`, and cannot be declared as `virtual` or `static`. That's up to implementing classes to decide. Therefore, it is fine for implementing classes to declare access modifiers, as is done in the example in this section.

For example, take IDisposable. If a class wants to declare publicly that it implements the Dispose() method, it must implement IDisposable — which in C# terms means that the class derives from IDisposable.

```
class SomeClass: IDisposable
{
   // This class MUST contain an implementation of the
   // IDisposable.Dispose() method, otherwise
   // you get a compilation error.
   public void Dispose()
   {
      // implementation of Dispose() method
   }
   // rest of class
}
```

In this example, if SomeClass derives from IDisposable but doesn't contain a Dispose() implementation with the exact same signature as defined in IDisposable, you get a compilation error because the class would be breaking its agreed-on contract to implement IDisposable. Of course, there's no problem for the compiler about a class having a Dispose() method but not deriving from IDisposable. The problem, then, would be that other code would have no way of recognizing that SomeClass has agreed to support the IDisposable features.

Defining and Implementing Interfaces

This section illustrates how to define and use interfaces through developing a short program that follows the interface inheritance paradigm. The example is based on bank accounts. Assume that you are writing code that will ultimately allow computerized transfers between bank accounts. And assume for this example that there are many companies that may implement bank accounts, but they have all mutually agreed that any classes that represent bank accounts will implement an interface, IBankAccount, which exposes methods to deposit or withdraw money, and a property to return the balance. It is this interface that will allow outside code to recognize the various bank account classes implemented by different bank accounts. Although the aim is to allow the bank accounts to talk to each other to allow transfers of funds between accounts, we won't introduce that feature just yet.

To keep things simple, you will keep all the code for the example in the same source file. Of course, if something like the example were used in real life, you could surmise that the different bank account classes would not only be compiled to different assemblies, but would also be hosted on different machines owned by the different banks. That's all much too complicated for our purposes here. However, to maintain some attempt at realism, you will define different namespaces for the different companies.

To begin, you need to define the IBankAccount interface:

```
namespace Wrox.ProCSharp
{
   public interface IBankAccount
   {
      void PayIn(decimal amount);
      bool Withdraw(decimal amount);
      decimal Balance
      {
         get;
      }
   }
}
```

Notice the name of the interface, `IBankAccount`. It's a convention that an interface name traditionally starts with the letter I, so that you know it's an interface.

The idea is that you can now write classes that represent bank accounts. These classes don't have to be related to each other in any way; they can be completely different classes. They will, however, all declare that they represent bank accounts by the mere fact that they implement the `IBankAccount` interface.

Let's start off with the first class, a saver account run by the Royal Bank of Venus:

```
namespace Wrox.ProCSharp.VenusBank
{
   public class SaverAccount: IBankAccount
   {
      private decimal balance;
      public void PayIn(decimal amount)
      {
         balance += amount;
      }
      public bool Withdraw(decimal amount)
      {
         if (balance >= amount)
         {
            balance -= amount;
            return true;
         }
         Console.WriteLine("Withdrawal attempt failed.");
         return false;
      }
      public decimal Balance
      {
         get
         {
            return balance;
         }
      }
      public override string ToString()
      {
         return String.Format("Venus Bank Saver: Balance = {0,6:C}", balance);
      }
   }
}
```

code snippet BankAccounts.cs

It should be pretty obvious what the implementation of this class does. You maintain a private field, `balance`, and adjust this amount when money is deposited or withdrawn. You display an error message if an attempt to withdraw money fails because there is insufficient money in the account. Notice also that, because you want to keep the code as simple as possible, you are not implementing extra properties, such as the account holder's name! In real life that would be pretty essential information, but for this example it's unnecessarily complicated.

The only really interesting line in this code is the class declaration:

```
public class SaverAccount: IBankAccount
```

You've declared that SaverAccount is derived from one interface, IBankAccount, and you have not explicitly indicated any other base classes (which of course means that SaverAccount is derived directly from System.Object). By the way, derivation from interfaces acts completely independently from derivation from classes.

Being derived from IBankAccount means that SaverAccount gets all the members of IBankAccount. But because an interface doesn't actually implement any of its methods, SaverAccount must provide its own implementations of all of them. If any implementations are missing, you can rest assured that the compiler will complain. Recall also that the interface just indicates the presence of its members. It's up to the class to decide if it wants any of them to be virtual or abstract (though abstract functions are of course only allowed if the class itself is abstract). For this particular example, you don't have any reason to make any of the interface functions virtual.

To illustrate how different classes can implement the same interface, assume that the Planetary Bank of Jupiter also implements a class to represent one of its bank accounts — a Gold Account:

```
namespace Wrox.ProCSharp.JupiterBank
{
   public class GoldAccount: IBankAccount
   {
      // etc
   }
}
```

We won't present details of the GoldAccount class here; in the sample code, it's basically identical to the implementation of SaverAccount. We stress that GoldAccount has no connection with SaverAccount, other than they both happen to implement the same interface.

Now that you have your classes, you can test them out. You first need a couple of using statements:

```
using System;
using Wrox.ProCSharp;
using Wrox.ProCSharp.VenusBank;
using Wrox.ProCSharp.JupiterBank;
```

Now you need a Main() method:

```
namespace Wrox.ProCSharp
{
   class MainEntryPoint
   {
      static void Main()
      {
         IBankAccount venusAccount = new SaverAccount();
         IBankAccount jupiterAccount = new GoldAccount();
         venusAccount.PayIn(200);
         venusAccount.Withdraw(100);
         Console.WriteLine(venusAccount.ToString());
         jupiterAccount.PayIn(500);
         jupiterAccount.Withdraw(600);
         jupiterAccount.Withdraw(100);
         Console.WriteLine(jupiterAccount.ToString());
      }
   }
}
```

This code (which if you download the sample, you can find in the file BankAccounts.cs) produces this output:

```
C:> BankAccounts
Venus Bank Saver: Balance = £100.00
Withdrawal attempt failed.
Jupiter Bank Saver: Balance = £400.00
```

The main point to notice about this code is the way that you have declared both your reference variables as `IBankAccount` references. This means that they can point to any instance of any class that implements this interface. However, it also means that you can call only methods that are part of this interface through these references — if you want to call any methods implemented by a class that are not part of the interface, you need to cast the reference to the appropriate type. In the example code, you were able to call `ToString()` (not implemented by `IBankAccount`) without any explicit cast, purely because `ToString()` is a `System.Object` method, so the C# compiler knows that it will be supported by any class (put differently, the cast from any interface to `System.Object` is implicit). Chapter 7, “Operators and Casts,” covers the syntax for how to perform casts.

Interface references can in all respects be treated as class references — but the power of an interface reference is that it can refer to any class that implements that interface. For example, this allows you to form arrays of interfaces, where each element of the array is a different class:

```
IBankAccount[] accounts = new IBankAccount[2];
accounts[0] = new SaverAccount();
accounts[1] = new GoldAccount();
```

Note, however, that we’d get a compiler error if we tried something like this:

```
accounts[1] = new SomeOtherClass();    // SomeOtherClass does NOT implement
                                                // IBankAccount: WRONG!!
```

This causes a compilation error similar to this:

```
Cannot implicitly convert type 'Wrox.ProCSharp. SomeOtherClass' to
 'Wrox.ProCSharp.IBankAccount'
```

Derived Interfaces

It’s possible for interfaces to inherit from each other in the same way that classes do. This concept is illustrated by defining a new interface, `ITransferBankAccount`, which has the same features as `IBankAccount` but also defines a method to transfer money directly to a different account:

```
namespace Wrox.ProCSharp
{
   public interface ITransferBankAccount: IBankAccount
   {
      bool TransferTo(IBankAccount destination, decimal amount);
   }
}
```

Because `ITransferBankAccount` is derived from `IBankAccount`, it gets all the members of `IBankAccount` as well as its own. That means that any class that implements (derives from) `ITransferBankAccount` must implement all the methods of `IBankAccount`, as well as the new `TransferTo()` method defined in `ITransferBankAccount`. Failure to implement all these methods will result in a compilation error.

Note that the `TransferTo()` method uses an `IBankAccount` interface reference for the destination account. This illustrates the usefulness of interfaces: When implementing and then invoking this method, you don’t need to know anything about what type of object you are transferring money to — all you need to know is that this object implements `IBankAccount`.

To illustrate `ITransferBankAccount`, assume that the Planetary Bank of Jupiter also offers a current account. Most of the implementation of the `CurrentAccount` class is identical to the implementations of `SaverAccount` and `GoldAccount` (again, this is just to keep this example simple — that won’t normally be the case), so in the following code just the differences are highlighted:

```
public class CurrentAccount: ITransferBankAccount
{
   private decimal balance;
   public void PayIn(decimal amount)
   {
      balance += amount;
   }
   public bool Withdraw(decimal amount)
   {
      if (balance >= amount)
      {
         balance -= amount;
         return true;
      }
      Console.WriteLine("Withdrawal attempt failed.");
      return false;
   }
   public decimal Balance
   {
      get
      {
         return balance;
      }
   }
   public bool TransferTo(IBankAccount destination, decimal amount)
   {
      bool result;
      result = Withdraw(amount);
      if (result)
      {
         destination.PayIn(amount);
      }
      return result;
   }
   public override string ToString()
   {
       return String.Format("Jupiter Bank Current Account: Balance = {0,6:C}",balance);
   }
}
```

The class can be demonstrated with this code:

```
static void Main()
{
   IBankAccount venusAccount = new SaverAccount();
   ITransferBankAccount jupiterAccount = new CurrentAccount();
   venusAccount.PayIn(200);
   jupiterAccount.PayIn(500);
   jupiterAccount.TransferTo(venusAccount, 100);
   Console.WriteLine(venusAccount.ToString());
   Console.WriteLine(jupiterAccount.ToString());
}
```

code snippet CurrentAccounts.cs

This code (`CurrentAccounts.cs`) produces the following output, which, as you can verify, shows that the correct amounts have been transferred:

```
C:> CurrentAccount
Venus Bank Saver: Balance = £300.00
Jupiter Bank Current Account: Balance = £400.00
```

SUMMARY

This chapter examined how to code inheritance in C#. You have seen that C# offers rich support for both multiple interface and single implementation inheritance. You have also learned that C# provides a number of useful syntactical constructs designed to assist in making code more robust. These include the `override` keyword, which indicates when a function should override a base function; the `new` keyword, which indicates when a function hides a base function; and rigid rules for constructor initializers that are designed to ensure that constructors are designed to interoperate in a robust manner.

5

Generics

WHAT'S IN THIS CHAPTER?

- ➤ An overview of generics
- ➤ Creating generic classes
- ➤ Features of generic classes
- ➤ Generic interfaces
- ➤ Generic structs
- ➤ Generic methods

Since the release of .NET 2.0, .NET has supported generics. Generics are not just a part of the C# programming language, but are also deeply integrated with the IL (Intermediate Language) code in the assemblies. With generics, you can create classes and methods that are independent of contained types. Instead of writing a number of methods or classes with the same functionality for different types, you can create just one method or class.

Another option to reduce the code is using the `Object` class. However, the `Object` class is not type-safe. Generic classes make use of generic types that are replaced with specific types as needed. This allows for type safety: the compiler complains if a specific type is not supported with the generic class.

Generics are not limited to classes; in this chapter, you also see generics with interfaces and methods. Generics with delegates can be found in Chapter 8, "Delegates, Lambdas, and Events."

GENERICS OVERVIEW

Generics are not a completely new construct; similar concepts exist with other languages. For example, C++ templates have some similarity to generics. However, there's a big difference between C++ templates and .NET generics. With C++ templates, the source code of the template is required when a template is instantiated with a specific type. Unlike C++ templates, generics are not only a construct of the C# language, but are defined with the CLR. This makes it possible to instantiate generics with a specific type in Visual Basic even though the generic class was defined with C#.

The following sections explore the advantages and disadvantages of generics, particularly in regard to:

- Performance
- Type safety
- Binary code reuse
- Code bloat
- Naming guidelines

Performance

One of the big advantages of generics is performance. In Chapter 10, "Collections," you will see non-generic and generic collection classes from the namespaces `System.Collections` and `System.Collections.Generic`. Using value types with non-generic collection classes results in boxing and unboxing when the value type is converted to a reference type and vice versa.

Boxing and unboxing is discussed in Chapter 7, "Operators and Casts." Here is just a short refresher about these terms.

Value types are stored on the stack. Reference types are stored on the heap. C# classes are reference types; structs are value types. .NET makes it easy to convert value types to reference types, so you can use a value type everywhere an object (which is a reference type) is needed. For example, an `int` can be assigned to an object. The conversion from a value type to a reference type is known as *boxing*. Boxing happens automatically if a method requires an object as a parameter, and a value type is passed. On the other side, a boxed value type can be converted to a value type by using unboxing. With unboxing, the cast operator is required.

The following example shows the `ArrayList` class from the namespace `System.Collections`. `ArrayList` stores objects; the `Add()` method is defined to require an object as a parameter, and so an integer type is boxed. When the values from an `ArrayList` are read, unboxing occurs when the object is converted to an integer type. This may be obvious with the cast operator that is used to assign the first element of the `ArrayList` collection to the variable `i1`, but also happens inside the `foreach` statement where the variable `i2` of type `int` is accessed:

```
var list = new ArrayList();
list.Add(44);   // boxing — convert a value type to a reference type

int i1 = (int)list[0];   // unboxing — convert a reference type to
                         // a value type

foreach (int i2 in list)
{
   Console.WriteLine(i2);   // unboxing
}
```

Boxing and unboxing are easy to use but have a big performance impact, especially when iterating through many items.

Instead of using objects, the `List<T>` class from the namespace `System.Collections.Generic` allows you to define the type when it is used. In the example here, the generic type of the `List<T>` class is defined as `int`, so the `int` type is used inside the class that is generated dynamically from the JIT compiler. Boxing and unboxing no longer happens:

```
var list = new List<int>();
list.Add(44);   // no boxing — value types are stored in the List<int>

int i1 = list[0];   // no unboxing, no cast needed
```

```
foreach (int i2 in list)
{
   Console.WriteLine(i2);
}
```

Type Safety

Another feature of generics is type safety. As with the `ArrayList` class, if objects are used, any type can be added to this collection. This example shows adding an integer, a string, and an object of type `MyClass` to the collection of type `ArrayList`:

```
var list = new ArrayList();
list.Add(44);
list.Add("mystring");
list.Add(new MyClass());
```

Now if this collection is iterated using the following `foreach` statement, which iterates using integer elements, the compiler accepts this code. However, because not all elements in the collection can be cast to an `int`, a runtime exception will occur:

```
foreach (int i in list)
{
   Console.WriteLine(i);
}
```

Errors should be detected as early as possible. With the generic class `List<T>`, the generic type `T` defines what types are allowed. With a definition of `List<int>`, only integer types can be added to the collection. The compiler doesn't compile this code because the `Add()` method has invalid arguments:

```
var list = new List<int>();
list.Add(44);
list.Add("mystring");   // compile time error
list.Add(new MyClass());   // compile time error
```

Binary Code Reuse

Generics allow better binary code reuse. A generic class can be defined once and can be instantiated with many different types. Unlike C++ templates, it is not necessary to access the source code.

As an example, here the `List<T>` class from the namespace `System.Collections.Generic` is instantiated with an `int`, a `string`, and a `MyClass` type:

```
var list = new List<int>();
list.Add(44);

var stringList = new List<string>();
stringList.Add("mystring");

var myClassList = new List<MyClass>();
myClassList.Add(new MyClass());
```

Generic types can be defined in one language and used from any other .NET language.

Code Bloat

How much code is created with generics when instantiating them with different specific types?

Because a generic class definition goes into the assembly, instantiating generic classes with specific types doesn't duplicate these classes in the IL code. However, when the generic classes are compiled by the JIT compiler to native code, a new class for every specific value type is created. Reference types share all the same implementation of the same native class. This is because with reference types, only a 4-byte memory address (with 32-bit systems) is needed within the generic instantiated class to reference a reference type.

Value types are contained within the memory of the generic instantiated class, and because every value type can have different memory requirements, a new class for every value type is instantiated.

Naming Guidelines

If generics are used in the program, it helps when generic types can be distinguished from non-generic types. Here are naming guidelines for generic types:

- Generic type names should be prefixed with the letter `T`.
- If the generic type can be replaced by any class because there's no special requirement, and only one generic type is used, the character `T` is good as a generic type name:

```
public class List<T> { }

public class LinkedList<T> { }
```

- If there's a special requirement for a generic type (for example, it must implement an interface or derive from a base class), or if two or more generic types are used, descriptive names should be used for the type names:

```
public delegate void EventHandler<TEventArgs>(object sender, TEventArgs e);

public delegate TOutput Converter<TInput, TOutput>(TInput from);

public class SortedList<TKey, TValue> { }
```

CREATING GENERIC CLASSES

First start with a normal, non-generic simplified linked list class that can contain objects of any kind, and later convert this class to a generic class.

With a linked list, one element references the next one. So, you must create a class that wraps the object inside the linked list and references the next object. The class `LinkedListNode` contains a property named `Value` that is initialized with the constructor. In addition to that, the `LinkedListNode` class contains references to the next and previous elements in the list that can be accessed from properties.

```
public class LinkedListNode
{
   public LinkedListNode(object value)
   {
      this.Value = value;
   }

   public object Value { get; private set; }

   public LinkedListNode Next { get; internal set; }
   public LinkedListNode Prev { get; internal set; }
}
```

code snippet LinkedListObjects/LinkedListNode.cs

The `LinkedList` class includes `First` and `Last` properties of type `LinkedListNode` that mark the beginning and end of the list. The method `AddLast()` adds a new element to the end of the list. First, an object of type `LinkedListNode` is created. If the list is empty, the `First` and `Last` properties are set to the new element; otherwise, the new element is added as the last element to the list. By implementing the `GetEnumerator()` method, it is possible to iterate through the list with the `foreach` statement. The `GetEnumerator()` method makes use of the `yield` statement for creating an enumerator type.

```
<public class LinkedList: IEnumerable
{
   public LinkedListNode First { get; private set; }
   public LinkedListNode Last { get; private set; }

   public LinkedListNode AddLast(object node)
   {
      var newNode = new LinkedListNode(node);
      if (First == null)
      {
         First = newNode;
         Last = First;
      }
      else
      {
         Last.Next = newNode;
         Last = newNode;
      }
      return newNode;
   }

   public IEnumerator GetEnumerator()
   {
      LinkedListNode current = First;
      while (current != null)
      {
         yield return current.Value;
         current = current.Next;
      }
   }
}
```

code snippet LinkedListObjects/LinkedListNode.cs

Now you can use the `LinkedList` class with any type. The following code segment instantiates a new `LinkedList` object and adds two integer types and one string type. As the integer types are converted to an object, boxing occurs as explained earlier. With the `foreach` statement, unboxing happens. In the `foreach` statement the elements from the list are cast to an integer, so with the third element in the list a runtime exception occurs as casting to an `int` fails.

```
var list1 = new LinkedList();
list1.AddLast(2);
list1.AddLast(4);
list1.AddLast("6");

foreach (int i in list1)
{
   Console.WriteLine(i);
}
```

code snippet LinkedListObjects/Program.cs

Now let's make a generic version of the linked list. A generic class is defined similarly to a normal class with the generic type declaration. The generic type can then be used within the class as a field member, or with parameter types of methods. The class `LinkedListNode` is declared with a generic type `T`. The property `Value` is now type `T` instead of `object`; the constructor is changed as well to accept an object of type `T`. A generic type can also be returned and set, so the properties `Next` and `Prev` are now of type `LinkedListNode<T>`:

```
public class LinkedListNode<T>
{
   public LinkedListNode(T value)
   {
      this.Value = value;
   }

   public T Value { get; private set; }
   public LinkedListNode<T> Next { get; internal set; }
   public LinkedListNode<T> Prev { get; internal set; }
}
```

code snippet LinkedListSample/LinkedListNode.cs

In the following code the class `LinkedList` is changed to a generic class as well. `LinkedList<T>` contains `LinkedListNode<T>` elements. The type `T` from the `LinkedList` defines the type `T` of the properties `First` and `Last`. The method `AddLast()` now accepts a parameter of type `T` and instantiates an object of `LinkedListNode<T>`.

Besides the interface `IEnumerable`, a generic version is also available: `IEnumerable<T>`. `IEnumerable<T>` derives from `IEnumerable` and adds the `GetEnumerator()` method that returns `IEnumerator<T>`. `LinkedList<T>` implements the generic interface `IEnumerable<T>`.

```
public class LinkedList<T>: IEnumerable<T>
{
   public LinkedListNode<T> First { get; private set; }
   public LinkedListNode<T> Last { get; private set; }

   public LinkedListNode<T> AddLast(T node)
   {
      var newNode = new LinkedListNode<T>(node);
      if (First == null)
      {
         First = newNode;
         Last = First;
      }
      else
      {
         Last.Next = newNode;
         Last = newNode;
      }
      return newNode;
   }

   public IEnumerator<T> GetEnumerator()
   {
      LinkedListNode<T> current = First;

      while (current != null)
      {
         yield return current.Value;
         current = current.Next;
```

```
            }
         }

         IEnumerator IEnumerable.GetEnumerator()
         {
            return GetEnumerator();
         }
      }
```

code snippet LinkedListSample/LinkedList.cs

Using the generic `LinkedList<T>`, you can instantiate it with an `int` type, and there's no boxing. Also, you get a compiler error if you don't pass an `int` with the method `AddLast()`. Using the generic `IEnumerable<T>`, the `foreach` statement is also type-safe, and you get a compiler error if that variable in the `foreach` statement is not an `int`:

```
var list2 = new LinkedList<int>();
list2.AddLast(1);
list2.AddLast(3);
list2.AddLast(5);

foreach (int i in list2)
{
   Console.WriteLine(i);
}
```

code snippet LinkedListSample/Program.cs

Similarly, you can use the generic `LinkedList<T>` with a `string` type and pass strings to the `AddLast()` method:

```
var list3 = new LinkedList<string>();
list3.AddLast("2");
list3.AddLast("four");
list3.AddLast("foo");

foreach (string s in list3)
{
   Console.WriteLine(s);
}
```

Every class that deals with the object type is a possible candidate for a generic implementation. Also, if classes make use of hierarchies, generics can be very helpful in making casting unnecessary.

GENERICS FEATURES

When creating generic classes, you might need some more C# keywords. For example, it is not possible to assign `null` to a generic type. In this case, the keyword `default` can be used, as demonstrated in the next section. If the generic type does not require the features of the `Object` class, but you need to invoke some specific methods in the generic class, you can define constraints.

This section discusses the following topics:

- Default values
- Constraints
- Inheritance
- Static members

Let's start this example with a generic document manager. The document manager is used to read and write documents from a queue. Start by creating a new Console project named `DocumentManager` and add the class `DocumentManager<T>`. The method `AddDocument()` adds a document to the queue. The read-only property `IsDocumentAvailable` returns true if the queue is not empty:

```
using System;
using System.Collections.Generic;

namespace Wrox.ProCSharp.Generics
{
   public class DocumentManager<T>
   {
      private readonly Queue<T> documentQueue = new Queue<T>();

      public void AddDocument(T doc)
      {
         lock (this)
         {
            documentQueue.Enqueue(doc);
         }
      }

      public bool IsDocumentAvailable
      {
         get { return documentQueue.Count > 0; }
      }
   }
}
```

code snippet DocumentManager/DocumentManager.cs

Default Values

Now you add a `GetDocument()` method to the `DocumentManager<T>` class. Inside this method the type `T` should be assigned to `null`. However, it is not possible to assign `null` to generic types. The reason is that a generic type can also be instantiated as a value type, and `null` is allowed only with reference types. To circumvent this problem, you can use the `default` keyword. With the `default` keyword, `null` is assigned to reference types and `0` is assigned to value types:

```
      public T GetDocument()
      {
         T doc = default(T);
         lock (this)
         {
            doc = documentQueue.Dequeue();
         }
         return doc;
     }
```

The `default` keyword has multiple meanings depending on the context where it is used. The `switch` statement uses a `default` for defining the default case, and with generics `default` is used to initialize generic types either to `null` or `0` depending on if it is a reference or value type.

Constraints

If the generic class needs to invoke some methods from the generic type, you have to add constraints.

With `DocumentManager<T>`, all the titles of the documents should be displayed in the `DisplayAllDocuments()` method. The `Document` class implements the interface `IDocument` with the properties `Title` and `Content`:

```
public interface IDocument
{
   string Title { get; set; }
   string Content { get; set; }
}

public class Document: IDocument
{
   public Document()
   {
   }

   public Document(string title, string content)
   {
      this.Title = title;
      this.Content = content;
   }

   public string Title { get; set; }
   public string Content { get; set; }
}
```

code snippet DocumentManager/Document.cs

For displaying the documents with the `DocumentManager<T>` class, you can cast the type `T` to the interface `IDocument` to display the title:

```
public void DisplayAllDocuments()
{
   foreach (T doc in documentQueue)
   {
      Console.WriteLine(((IDocument)doc).Title);
   }
}
```

code snippet DocumentManager/DocumentManager.cs

The problem is that doing a cast results in a runtime exception if type `T` does not implement the interface `IDocument`. Instead, it would be better to define a constraint with the `DocumentManager<TDocument>` class that the type `TDocument` must implement the interface `IDocument`. To clarify the requirement in the name of the generic type, `T` is changed to `TDocument`. The `where` clause defines the requirement to implement the interface `IDocument`:

```
public class DocumentManager<TDocument>
    where TDocument: IDocument
{
```

This way you can write the `foreach` statement in such a way that the type `TDocument` contains the property `Title`. You get support from Visual Studio IntelliSense and from the compiler:

```
public void DisplayAllDocuments()
{
    foreach (TDocument doc in documentQueue)
    {
        Console.WriteLine(doc.Title);
    }
}
```

In the `Main()` method the `DocumentManager<T>` class is instantiated with the type `Document` that implements the required interface `IDocument`. Then new documents are added and displayed, and one of the documents is retrieved:

```
<static void Main()
{
   var dm = new DocumentManager<Document>();
   dm.AddDocument(new Document("Title A", "Sample A"));
   dm.AddDocument(new Document("Title B", "Sample B"));

   dm.DisplayAllDocuments();

   if (dm.IsDocumentAvailable)
   {
      Document d = dm.GetDocument();
      Console.WriteLine(d.Content);
   }
}
```

code snippet DocumentManager/Program.cs

The `DocumentManager` now works with any class that implements the interface `IDocument`.

In the sample application, you've seen an interface constraint. Generics support several constraint types, indicated in the following table.

CONSTRAINT	DESCRIPTION
`where T: struct`	With a struct constraint, type `T` must be a value type.
`where T: class`	The class constraint indicates that type `T` must be a reference type.
`where T: IFoo`	`where T: IFoo` specifies that type `T` is required to implement interface `IFoo`.
`where T: Foo`	`where T: Foo` specifies that type `T` is required to derive from base class `Foo`.
`where T: new()`	`where T: new()` is a constructor constraint and specifies that type `T` must have a default constructor.
`where T1: T2`	With constraints it is also possible to specify that type `T1` derives from a generic type `T2`. This constraint is known as *naked type constraint.*

Constructor constraints can only be defined for the default constructor. It is not possible to define a constructor constraint for other constructors.

With a generic type, you can also combine multiple constraints. The constraint `where T: IFoo, new()` with the `MyClass<T>` declaration specifies that type `T` implements the interface `IFoo` and has a default constructor:

```
public class MyClass<T>
   where T: IFoo, new()
{
   //...
```

Inheritance

The `LinkedList<T>` class created earlier implements the interface `IEnumerable<out T>`:

```
public class LinkedList<T>: IEnumerable<T>
{
   //...
```

A generic type can implement a generic interface. The same is possible by deriving from a class. A generic class can be derived from a generic base class:

```
public class Base<T>
{
}

public class Derived<T>: Base<T>
{
}
```

The requirement is that the generic types of the interface must be repeated, or the type of the base class must be specified, as in this case:

```
public class Base<T>
{
}

public class Derived<T>: Base<string>
{
}
```

This way, the derived class can be a generic or non-generic class. For example, you can define an abstract generic base class that is implemented with a concrete type in the derived class. This allows you to do specialization for specific types:

```
public abstract class Calc<T>
{
   public abstract T Add(T x, T y);
   public abstract T Sub(T x, T y);
}

public class IntCalc: Calc<int>
{
   public override int Add(int x, int y)
   {
      return x + y;
   }

   public override int Sub(int x, int y)
   {
      return x — y;
   }
}
```

Static Members

Static members of generic classes require special attention. Static members of a generic class are only shared with one instantiation of the class. Let's have a look at one example, where the class `StaticDemo<T>` contains the static field `x`:

```
public class StaticDemo<T>
{
   public static int x;
}
```

Because the class StaticDemo<T> is used with both a string type and an int type, two sets of static fields exist:

```
StaticDemo<string>.x = 4;
StaticDemo<int>.x = 5;
Console.WriteLine(StaticDemo<string>.x);    // writes 4
```

GENERIC INTERFACES

Using generics, you can define interfaces that define methods with generic parameters. In the linked list sample, you've already implemented the interface IEnumerable<out T>, which defines a GetEnumerator() method to return IEnumerator<out T>. .NET offers a lot of generic interfaces for different scenarios; examples include IComparable<T>, ICollection<T>, and IExtensibleObject<T>. Often older, non-generic versions of the same interface exist; for example .NET 1.0 had an IComparable interface which was based on objects. IComparable<in T> is based on a generic type:

```
public interface IComparable<in T>
{
   int CompareTo(T other);
}
```

The older, non-generic IComparable interface requires an object with the CompareTo() method. This requires a cast to specific types, such as to the Person class for using the LastName property:

```
   public class Person: IComparable
   {
      public int CompareTo(object obj)
      {
         Person other = obj as Person;
         return this.lastname.CompareTo(other.LastName);
      }
//
```

When implementing the generic version, it is no longer necessary to cast the object to a Person:

```
   public class Person: IComparable<Person>
   {
      public int CompareTo(Person other)
      {
         return this.LastName.CompareTo(other.LastName);
      }
      //...
```

Covariance and Contra-variance

Previous to .NET 4, generic interfaces were invariant. .NET 4 adds an important extension for generic interfaces and generic delegates with covariance and contra-variance. Covariance and contra-variance are about the conversion of types with argument and return types. For example, can you pass a Rectangle to a method that requests a Shape? Let's get into examples to see the advantages of these extensions.

With .NET, parameter types are covariant. Assume you have the classes Shape and Rectangle, and Rectangle derives from the Shape base class. The Display() method is declared to accept an object of the Shape type as its parameter:

```
public void Display(Shape o) { }
```

Now you can pass any object that derives from the Shape base class. Because Rectangle derives from Shape, a Rectangle fulfills all the requirements of a Shape and the compiler accepts this method call:

```
Rectangle r = new Rectangle { Width= 5, Height=2.5};
Display(r);
```

Return types of methods are contra-variant. When a method returns a `Shape` it is not possible to assign it to a `Rectangle` because a `Shape` is not necessarily always a `Rectangle`. The opposite is possible. If a method returns a `Rectangle` as the `GetRectangle()` method,

```
public Rectangle GetRectangle();
```

the result can be assigned to a `Shape`.

```
Shape s = GetRectangle();
```

Before version 4 of the .NET Framework, this behavior was not possible with generics. With C# 4, the language is extended to support covariance and contra-variance with generic interfaces and generic delegates. Let's start by defining a `Shape` base class and a `Rectangle` class:

```
public class Shape
{
    public double Width { get; set; }
    public double Height { get; set; }

    public override string ToString()
    {
        return String.Format("Width: {0}, Height: {1}", Width, Height);
    }
}
```

code snippet Variance/Shape.cs

```
public class Rectangle: Shape
{
}
```

code snippet Variance/Rectangle.cs

Covariance with Generic Interfaces

A generic interface is covariant if the generic type is annotated with the `out` keyword. This also means that type `T` is allowed only with return types. The interface `IIndex` is covariant with type `T` and returns this type from a read-only indexer:

```
public interface IIndex<out T>
{
    T this[int index] { get; }
    int Count { get; }
}
```

code snippet Variance/IIndex.cs

If a read-write indexer is used with the IIndex interface, the generic type T is passed to the method and also retrieved from the method. This is not possible with covariance — the generic type must be defined as invariant. Defining the type as invariant is done without `out` *and* `in` *annotations.*

The `IIndex<T>` interface is implemented with the `RectangleCollection` class. `RectangleCollection` defines `Rectangle` for generic type `T`:

```
public class RectangleCollection: IIndex<Rectangle>
{
    private Rectangle[] data = new Rectangle[3]
    {
        new Rectangle { Height=2, Width=5},
        new Rectangle { Height=3, Width=7},
        new Rectangle { Height=4.5, Width=2.9}
    };

    public static RectangleCollection GetRectangles()
    {
        return new RectangleCollection();
    }

    public Rectangle this[int index]
    {
        get
        {
            if (index < 0 || index > data.Length)
                throw new ArgumentOutOfRangeException("index");
            return data[index];
        }
    }
    public int Count
    {
        get
        {
            return data.Length;
        }
    }
}
```

code snippet Variance/RectangleCollection.cs

The `RectangleCollection.GetRectangles()` method returns a `RectangleCollection` that implements the `IIndex<Rectangle>` interface, so you can assign the return value to a variable *rectangle* of the `IIndex<Rectangle>` type. Because the interface is covariant, it is also possible to assign the returned value to a variable of `IIndex<Shape>`. `Shape` does not need anything more than a `Rectangle` has to offer. Using the `shapes` variable, the indexer from the interface and the `Count` property are used within the `for` loop:

```
static void Main()
{
    IIndex<Rectangle> rectangles = RectangleCollection.GetRectangles();
    IIndex<Shape> shapes = rectangles;

    for (int i = 0; i < shapes.Count; i++)
    {
        Console.WriteLine(shapes[i]);
    }
}
```

code snippet Variance/Program.cs

Contra-Variance with Generic Interfaces

A generic interface is contra-variant if the generic type is annotated with the `in` keyword. This way the interface is only allowed to use generic type `T` as input to its methods:

```
public interface IDisplay<in T>
{
    void Show(T item);
}
```

code snippet Variance/IDisplay.cs

The ShapeDisplay class implements IDisplay<Shape> and uses a Shape object as an input parameter:

```
public class ShapeDisplay: IDisplay<Shape>
{
    public void Show(Shape s)
    {
        Console.WriteLine("{0} Width: {1}, Height: {2}", s.GetType().Name,
                          s.Width, s.Height);
    }
}
```

code snippet Variance/ShapeDisplay.cs

Creating a new instance of ShapeDisplay returns IDisplay<Shape>, which is assigned to the shapeDisplay variable. Because IDisplay<T> is contra-variant, it is possible to assign the result to IDisplay<Rectangle> where Rectangle derives from Shape. This time the methods of the interface only define the generic type as input, and Rectangle fulfills all the requirements of a Shape:

```
static void Main()
{
    //...

    IDisplay<Shape> shapeDisplay = new ShapeDisplay();
    IDisplay<Rectangle> rectangleDisplay = shapeDisplay;
    rectangleDisplay.Show(rectangles[0]);

}
```

code snippet Variance/Program.cs

GENERIC STRUCTS

Similar to classes, structs can be generic as well. They are very similar to generic classes with the exception of inheritance features. In this section you look at the generic struct Nullable<T>, which is defined by the .NET Framework.

An example of a generic struct in the .NET Framework is Nullable<T>. A number in a database and a number in a programming language have an important difference in their characteristics, as a number in the database can be null. A number in C# cannot be null. Int32 is a struct, and because structs are implemented as value types, they cannot be null. The problem exists not only with databases but also with mapping XML data to .NET types.

This difference often causes headaches and a lot of additional work to map the data. One solution is to map numbers from databases and XML files to reference types, because reference types can have a null value. However, this also means additional overhead during runtime.

With the structure Nullable<T>, this can be easily resolved. The following code segment shows a simplified version of how Nullable<T> is defined.

The structure Nullable<T> defines a constraint that the generic type T needs to be a struct. With classes as generic types, the advantage of low overhead would be gone, and because objects of classes can be null anyway, there's no point in using a class with the Nullable<T> type. The only overhead in addition to the T type defined by Nullable<T> is the hasValue Boolean field that defines whether the value is set or null. Other than that, the generic struct defines the read-only properties HasValue and Value and some operator overloads. The operator overload to cast the Nullable<T> type to T is defined as explicit because it can throw an exception in case `hasValue` is `false`. The operator overload to cast to `Nullable<T>` is defined as implicit because it always succeeds:

```
public struct Nullable<T>
    where T: struct
 {
     public Nullable(T value)
     {
         this.hasValue = true;
         this.value = value;
     }
     private bool hasValue;
     public bool HasValue
     {
         get
         {
             return hasValue;
         }
     }

     private T value;
     public T Value
     {
         get
         {
             if (!hasValue)
             {
                 throw new InvalidOperationException("no value");
             }
             return value;
         }
     }

     public static explicit operator T(Nullable<T> value)
     {
         return value.Value;
     }
     public static implicit operator Nullable<T>(T value)
     {
         return new Nullable<T>(value);
     }

     public override string ToString()
     {
         if (!HasValue)
             return String.Empty;
         return this.value.ToString();
     }

 }
```

In this example, `Nullable<T>` is instantiated with `Nullable<int>`. The variable `x` can now be used as an `int`, assigning values and using operators to do some calculation. This behavior is made possible by casting operators of the `Nullable<T>` type. However, `x` can also be `null`. The `Nullable<T>` properties `HasValue` and `Value` can check whether there is a value, and the value can be accessed:

```
Nullable<int> x;
x = 4;
x += 3;
if (x.HasValue)
{
   int y = x.Value;
}
x = null;
```

Because nullable types are used often, C# has a special syntax for defining variables of this type. Instead of using syntax with the generic structure, the `?` operator can be used. In the following example, the variables `x1` and `x2` are both instances of a nullable `int` type:

```
Nullable<int> x1;
int? x2;
```

A nullable type can be compared with `null` and also numbers, as shown. Here, the value of `x` is compared with `null`, and if it is not `null`, it is compared with a value less than `0`:

```
int? x = GetNullableType();
if (x == null)
{
   Console.WriteLine("x is null");
}
else if (x < 0)
{
   Console.WriteLine("x is smaller than 0");
}
```

Now that you know how `Nullable<T>` is defined, let's get into using nullable types. Nullable types can also be used with arithmetic operators. The variable `x3` is the sum of the variables `x1` and `x2`. If any of the nullable types have a `null` value, the result is `null`:

```
int? x1 = GetNullableType();
int? x2 = GetNullableType();
int? x3 = x1 + x2;
```

The `GetNullableType()` *method, which is called here, is just a placeholder for any method that returns a nullable* `int`*. For testing you can implement it as simply to return* `null` *or to return any integer value.*

Non-nullable types can be converted to nullable types. With the conversion from a non-nullable type to a nullable type, an implicit conversion is possible where casting is not required. This conversion always succeeds:

```
int y1 = 4;
int? x1 = y1;
```

In the reverse situation, a conversion from a nullable type to a non-nullable type can fail. If the nullable type has a `null` value and the `null` value is assigned to a non-nullable type, an exception of type `InvalidOperationException` is thrown. That's the reason the cast operator is required to do an explicit conversion:

```
int? x1 = GetNullableType();
int y1 = (int)x1;
```

Instead of doing an explicit cast, it is also possible to convert a nullable type to a non-nullable type with the coalescing operator. The coalescing operator uses the syntax `??` to define a default value for the conversion in case the nullable type has a value of `null`. Here, `y1` gets a `0` value if `x1` is `null`:

```
int? x1 = GetNullableType();
int y1 = x1 ?? 0;
```

GENERIC METHODS

In addition to defining generic classes, it is also possible to define generic methods. With a generic method, the generic type is defined with the method declaration. Generic methods can be defined within non-generic classes.

The method `Swap<T>()` defines `T` as a generic type that is used for two arguments and a variable `temp`:

```
void Swap<T>(ref T x, ref T y)
{
   T temp;
   temp = x;
   x = y;
   y = temp;
}
```

A generic method can be invoked by assigning the generic type with the method call:

```
int i = 4;
int j = 5;
Swap<int>(ref i, ref j);
```

However, because the C# compiler can get the type of the parameters by calling the `Swap()` method, it is not required to assign the generic type with the method call. The generic method can be invoked as simply as non-generic methods:

```
int i = 4;
int j = 5;
Swap(ref i, ref j);
```

Generic Methods Example

Here's an example where a generic method is used to accumulate all elements of a collection. To show the features of generic methods, the following `Account` class that contains `Name` and `Balance` properties is used:

```
public class Account
{
   public string Name { get; private set; }
   public decimal Balance { get; private set; }

   public Account(string name, Decimal balance)
   {
      this.Name = name;
      this.Balance = balance;
   }
}
```

code snippet GenericMethods/Account.cs

All the accounts where the balance should be accumulated are added to an accounts list of type `List<Account>`:

```
var accounts = new List<Account>()
{
    new Account("Christian", 1500),
    new Account("Stephanie", 2200),
    new Account("Angela", 1800)
};
```

code snippet GenericMethods/Program.cs

A traditional way to accumulate all `Account` objects is by looping through all `Account` objects with a `foreach` statement, as shown here. Because the `foreach` statement uses the `IEnumerable` interface to iterate the elements of a collection, the argument of the `AccumulateSimple()` method is of type `IEnumerable`. The `foreach` statement works with every object implementing `IEnumerable`. This way, the `AccumulateSimple()` method can be used with all collection classes that implement the interface

IEnumerable<Account>. In the implementation of this method, the property Balance of the Account object is directly accessed:

```
public static class Algorithm
{
   public static decimal AccumulateSimple(IEnumerable<Account> source)
   {
      decimal sum = 0;
      foreach (Account a in source)
      {
         sum += a.Balance;
      }
      return sum;
   }
}
```

code snippet GenericMethods/Algorithm.cs

The AccumulateSimple() method is invoked this way:

```
decimal amount = Algorithm.AccumulateSimple(accounts);
```

Generic Methods with Constraints

The problem with the first implementation is that it works only with Account objects. This can be avoided by using a generic method.

The second version of the Accumulate() method accepts any type that implements the interface IAccount. As you've seen earlier with generic classes, generic types can be restricted with the where clause. The same clause that is used with generic classes can be used with generic methods. The parameter of the Accumulate() method is changed to IEnumerable<T>. IEnumerable<T> is a generic interface that is implemented by generic collection classes:

```
public static decimal Accumulate<TAccount>(IEnumerable<TAccount> source)
     where TAccount: IAccount
{
   decimal sum = 0;

   foreach (TAccount a in source)
   {
      sum += a.Balance;
   }
   return sum;
}
```

code snippet GenericMethods/Algorithm.cs

The Account class is now re-factored to implement the interface IAccount:

```
public class Account: IAccount
{
   //...
```

code snippet GenericMethods/Account.cs

The IAccount interface defines the read-only properties Balance and Name:

```
public interface IAccount
{
   decimal Balance { get; }
   string Name { get; }
}
```

code snippet GenericMethods/IAccount.cs

The new `Accumulate()` method can be invoked by defining the `Account` type as generic type parameter:

```
decimal amount = Algorithm.Accumulate<Account>(accounts);
```

code snippet GenericMethods/Program.cs

Because the generic type parameter can be automatically inferred by the compiler from the parameter type of the method, it is valid to invoke the `Accumulate()` method this way:

```
decimal amount = Algorithm.Accumulate(accounts);
```

Generic Methods with Delegates

The requirement for the generic types to implement the interface `IAccount` may be too restrictive. The following example hints at how the `Accumulate()` method can be changed by passing a generic delegate. Chapter 8 gives you all the details about how to work with generic delegates, and how to use Lambda expressions.

This `Accumulate()` method uses two generic parameters, `T1` and `T2`. `T1` is used for the collection-implementing `IEnumerable<T1>` parameter, which is the first one of the method. The second parameter uses the generic delegate `Func<T1, T2, TResult>`. Here, the second and third generic parameters are of the same `T2` type. A method needs to be passed that has two input parameters (`T1` and `T2`) and a return type of `T2`:

```
public static T2 Accumulate<T1, T2>(IEnumerable<T1> source,
                                    Func<T1, T2, T2> action)
{
    T2 sum = default(T2);
    foreach (T1 item in source)
    {
        sum = action(item, sum);
    }
    return sum;
}
```

code snippet GenericMethods/Algorithm.cs

In calling this method, it is necessary to specify the generic parameter types because the compiler cannot infer it automatically. With the first parameter of the method, the `accounts` collection that is assigned is of type `IEnumerable<Account>`. With the second parameter, a Lambda expression is used that defines two parameters of type `Account` and `decimal`, and returns a decimal. This Lambda expression gets invoked for every item by the `Accumulate()` method:

```
decimal amount = Algorithm.Accumulate<Account, decimal>(
                     accounts, (item, sum) => sum += item.Balance);
```

code snippet GenericMethods/Program.cs

Don't scratch your head with this syntax yet. The sample should give you a glimpse about the possible ways to extend the `Accumulate()` method. Chapter 8 gives you all the details about Lambda expressions.

Generic Methods Specialization

Generic methods can be overloaded to define specializations for specific types. This is true for methods with generic parameters as well. The `Foo()` method is defined in two versions. The first accepts a generic parameter; the second one is a specialized version for the `int` parameter. During compile time, the best match is taken. If an `int` is passed, then the method with the `int` parameter is selected. With any other parameter type, the compiler chooses the generic version of the method:

```
public class MethodOverloads
{
    public void Foo<T>(T obj)
    {
        Console.WriteLine("Foo<T>(T obj), obj type: {0}", obj.GetType().Name);
    }

    public void Foo(int x)
    {
        Console.WriteLine("Foo(int x)");
    }

    public void Bar<T>(T obj)
    {
        Foo(obj);
    }
}
```

code snippet Specialization/Program.cs

The `Foo()` method can now be invoked with any parameter type. The sample code passes an `int` and a `string` to the method:

```
    static void Main()
    {
        var test = new MethodOverloads();
        test.Foo(33);
        test.Foo("abc");
    }
```

code snippet GenericMethods/Program.cs

Running the program, you can see by the output that the method with the best match is taken:

```
Foo(int x)
Foo<T>(T obj), obj type: String
```

You need to be aware that the method invoked is defined during compile time and not runtime. This can be easily demonstrated by adding a generic `Bar()` method that invokes the `Foo()` method, passing the generic parameter value along:

```
public class MethodOverloads
{
    // ...

    public void Bar<T>(T obj)
    {
        Foo(obj);
    }
```

The `Main()` method is now changed to invoke the `Bar()` method passing an `int` value:

```
    static void Main()
    {
        var test = new MethodOverloads();
        test.Bar(44);
```

From the output on the console you can see that the generic `Foo()` method was selected by the `Bar()` method and not the overload with the `int` parameter. The reason is that the compiler selects the method that is invoked by the `Bar()` method during compile time. Because the `Bar()` method defines a generic parameter, and because there's a `Foo()` method that matches this type, the generic `Foo()` method is called. This is not changed during runtime when an `int` value is passed to the `Bar()` method:

```
    Foo<T>(T obj), obj type: Int32
```

SUMMARY

This chapter introduced a very important feature of the CLR: generics. With generic classes you can create type-independent classes, and generic methods allow type-independent methods. Interfaces, structs, and delegates can be created in a generic way as well. Generics make new programming styles possible. You've seen how algorithms, particularly actions and predicates, can be implemented to be used with different classes — and all type-safe. Generic delegates make it possible to decouple algorithms from collections.

You will see more features and uses of generics throughout this book. Chapter 8 introduces delegates that are often implemented as generics; Chapter 10 gives information about generic collection classes; and Chapter 11 ("Language Integrated Query") discusses generic extension methods.

The next chapter demonstrates the use of generic methods with arrays.

6
Arrays and Tuples

WHAT'S IN THIS CHAPTER?

- Simple arrays
- Multidimensional arrays
- Jagged arrays
- The `Array` class
- Arrays as parameters
- Enumerations
- Tuples
- Structural comparison

If you need to work with multiple objects of the same type, you can use collections (see Chapter 10) and arrays. C# has a special notation to declare, initialize, and use arrays. Behind the scenes, the `Array` class comes into play, which offers several methods to sort and filter the elements inside the array. Using an enumerator, you can iterate through all the elements of the array.

Also, .NET 4 introduces a new type `Tuple` that can be used to combine multiple objects of different types. See the "Tuples" section later in this chapter.

SIMPLE ARRAYS

If you need to use multiple objects of the same type, you can use an array. An *array* is a data structure that contains a number of elements of the same type.

Array Declaration

An array is declared by defining the type of elements inside the array followed by empty brackets and a variable name. For example, an array containing integer elements is declared as this:

```
int[] myArray;
```

Array Initialization

After declaring an array, memory must be allocated to hold all the elements of the array. An array is a reference type, so memory on the heap must be allocated. You do this by initializing the variable of the array using the `new` operator with the type and the number of elements inside the array. Here you specify the size of the array:

```
myArray = new int[4];
```

Value and reference types are covered in Chapter 3, "Objects and Types."

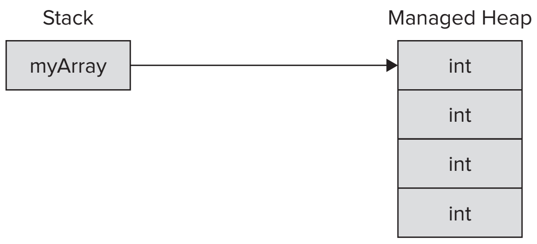

FIGURE 6-1

The array cannot be resized after the size was specified without copying all elements. If you don't know the number of elements that should be in the array in advance, you can use a collection (see Chapter 10).

Instead of using a separate line to declare and initialize an array, you can use a single line:

```
int[] myArray = new int[4];
```

You can also assign values to every array element using an array initializer. Array initializers can be used only while declaring an array variable, not after the array is declared:

```
int[] myArray = new int[] {4, 7, 11, 2};
```

If you initialize the array using curly brackets, the size of the array can also be left out, because the compiler can count the number of elements itself:

```
int[] myArray = new int[] {4, 7, 11, 2};
```

There's even a shorter form using the C# compiler. Using curly brackets you can write the array declaration and initialization. The code generated from the compiler is the same as in the previous example:

```
int[] myArray = {4, 7, 11, 2};
```

Accessing Array Elements

After an array is declared and initialized, you can access the array elements using an indexer. Arrays only support indexers that have integer parameters.

With the indexer, you pass the element number to access the array. The indexer always starts with a value of 0 for the first element. The highest number you can pass to the indexer is the number of elements minus one, because the index starts at zero. In the following example, the array *myArray* is declared and initialized with four integer values. The elements can be accessed with indexer values 0, 1, 2, and 3.

```
int[] myArray = new int[] {4, 7, 11, 2};
int v1 = myArray[0];  // read first element
int v2 = myArray[1];  // read second element
myArray[3] = 44;      // change fourth element
```

If you use a wrong indexer value where no element exists, an exception of type `IndexOutOfRangeException` *is thrown.*

If you don't know the number of elements in the array, you can use the `Length` property that is used in this `for` statement:

```
    for (int i = 0; i < myArray.Length; i++)
    {
        Console.WriteLine(myArray[i]);
    }
```

Instead of using a `for` statement to iterate through all elements of the array, you can also use the `foreach` statement:

```
    foreach (var val in myArray)
    {
        Console.WriteLine(val);
    }
```

Using Reference Types

In addition to being able to declare arrays of predefined types, you can also declare arrays of custom types. Let's start with this `Person` class, the properties `FirstName` and `LastName` using auto-implemented properties, and an override of the `ToString()` method from the `Object` class:

```
public class Person
{
    public string FirstName { get; set; }
    public string LastName { get; set; }

    public override string ToString()
    {
        return String.Format("{0} {1}", FirstName, LastName);
    }
}
```

code snippet Sample1/Person.cs

Declaring an array of two `Person` elements is similar to declaring an array of `int`:

```
Person[] myPersons = new Person[2];
```

However, you must be aware that if the elements in the array are reference types, memory must be allocated for every array element. In case you use an item in the array where no memory was allocated, a `NullReferenceException` is thrown.

For information about errors and exceptions, see Chapter 15.

You can allocate every element of the array by using an indexer starting from 0:

```
myPersons[0] = new Person { FirstName="Ayrton", LastName="Senna" };
myPersons[1] = new Person { FirstName="Michael", LastName="Schumacher" };
```

Figure 6-2 shows the objects in the managed heap with the `Person` array. `myPersons` is a variable that is stored on the stack. This variable references an array of `Person` elements that is stored on the managed heap. This array has enough space for two references. Every item in the array references a `Person` object that is also stored in the managed heap.

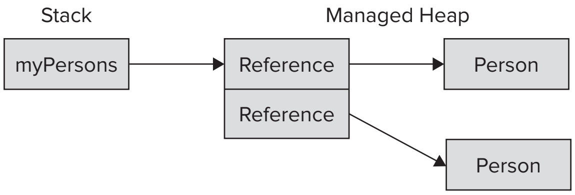

FIGURE 6-2

Similar to the `int` type, you can also use an array initializer with custom types:

```
Person[] myPersons2 =
{
    new Person { FirstName="Ayrton", LastName="Senna"},
    new Person { FirstName="Michael", LastName="Schumacher"}
};
```

MULTIDIMENSIONAL ARRAYS

Ordinary arrays (also known as one-dimensional arrays) are indexed by a single integer. A multidimensional array is indexed by two or more integers.

Figure 6-3 shows the mathematical notation for a two-dimensional array that has three rows and three columns. The first row has the values 1, 2, and 3, and the third row has the values 7, 8, and 9.

$$a = \begin{bmatrix} 1, & 2, & 3 \\ 4, & 5, & 6 \\ 7, & 8, & 9 \end{bmatrix}$$

FIGURE 6-3

Declaring this two-dimensional array with C# is done by putting a comma inside the brackets. The array is initialized by specifying the size of every dimension (also known as rank). Then the array elements can be accessed by using two integers with the indexer:

```
<nt[,] twodim = new int[3, 3];
twodim[0, 0] = 1;
twodim[0, 1] = 2;
twodim[0, 2] = 3;
twodim[1, 0] = 4;
twodim[1, 1] = 5;
twodim[1, 2] = 6;
twodim[2, 0] = 7;
twodim[2, 1] = 8;
twodim[2, 2] = 9;
```

code snippet Sample1/Program.cs

You cannot change the rank after declaring an array.

You can also initialize the two-dimensional array by using an array indexer if you know the value for the elements in advance. For the initialization of the array, one outer curly bracket is used, and every row is initialized by using curly brackets inside the outer curly brackets.

```
int[,] twodim = {
                 {1, 2, 3},
                 {4, 5, 6},
                 {7, 8, 9}
                };
```

When using an array initializer, you must initialize every element of the array. It is not possible to leave the initialization of some values for later.

By using two commas inside the brackets, you can declare a three-dimensional array:

```
int[,,] threedim = {
        { { 1, 2 }, { 3, 4 } },
        { { 5, 6 }, { 7, 8 } },
        { { 9, 10 }, { 11, 12 } }
       };

Console.WriteLine(threedim[0, 1, 1]);
```

JAGGED ARRAYS

A two-dimensional array has a rectangular size (for example, 3 × 3 elements). A jagged array is more flexible in sizing the array. With a jagged array every row can have a different size.

Figure 6-4 contrasts a two-dimensional array that has 3 × 3 elements with a jagged array. The jagged array shown contains three rows where the first row has two elements, the second row has six elements, and the third row has three elements.

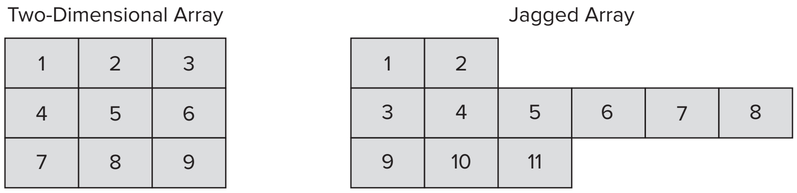

FIGURE 6-4

A jagged array is declared by placing one pair of opening and closing brackets after another. With the initialization of the jagged array, only the size that defines the number of rows in the first pair of brackets is set. The second brackets that define the number of elements inside the row are kept empty because every row has a different number of elements. Next, the element number of the rows can be set for every row:

```
int[][] jagged = new int[3][];
jagged[0] = new int[2] { 1, 2 };
jagged[1] = new int[6] { 3, 4, 5, 6, 7, 8 };
jagged[2] = new int[3] { 9, 10, 11 };
```

code snippet Sample1/Program.cs

Iterating through all elements of a jagged array can be done with nested `for` loops. In the outer `for` loop every row is iterated, and the inner `for` loop iterates through every element inside a row.

```
            for (int row = 0; row < jagged.Length; row++)
            {
                for (int element = 0; element < jagged[row].Length; element++)
                {
                    Console.WriteLine("row: {0}, element: {1}, value: {2}",
                        row, element, jagged[row][element]);
                }
            }
```

The outcome of the iteration displays the rows and every element within the rows:

```
row: 0, element: 0, value: 1
row: 0, element: 1, value: 2
row: 1, element: 0, value: 3
row: 1, element: 1, value: 4
row: 1, element: 2, value: 5
row: 1, element: 3, value: 6
row: 1, element: 4, value: 7
row: 1, element: 5, value: 8
row: 2, element: 1, value: 9
row: 2, element: 2, value: 10
row: 2, element: 3, value: 11
```

ARRAY CLASS

Declaring an array with brackets is a C# notation using the `Array` class. Using the C# syntax behind the scenes creates a new class that derives from the abstract base class `Array`. This makes it possible to use methods and properties that are defined with the `Array` class with every C# array. For example, you've already used the `Length` property or iterated through the array by using the `foreach` statement. By doing this, you are using the `GetEnumerator()` method of the `Array` class.

Other properties that are implemented by the `Array` class are `LongLength` for arrays where the number of items doesn't fit within an integer, and `Rank` to get the number of dimensions.

Let's have a look at other members of the `Array` class by getting into various features.

Creating Arrays

The `Array` class is abstract, so you cannot create an array by using a constructor. However, instead of using the C# syntax to create array instances, it is also possible to create arrays by using the static `CreateInstance()` method. This is extremely useful if you don't know the type of elements in advance, because the type can be passed to the `CreateInstance()` method as a `Type` object.

The following example shows how to create an array of type `int` with a size of 5. The first argument of the `CreateInstance()` method requires the type of the elements, and the second argument defines the size. You can set values with the `SetValue()` method and read values with the `GetValue()` method.

```
Array intArray1 = Array.CreateInstance(typeof(int), 5);
for (int i = 0; i < 5; i++)
{
    intArray1.SetValue(33, i);
}

for (int i = 0; i < 5; i++)
{
    Console.WriteLine(intArray1.GetValue(i));
}
```

code snippet Sample1/Program.cs

You can also cast the created array to an array declared as `int[]`:

```
int[] intArray2 = (int[])intArray1;
```

The `CreateInstance()` method has many overloads to create multidimensional arrays and also to create arrays that are not 0-based. The following example creates a two-dimensional array with 2 × 3 elements. The first dimension is 1-based; the second dimension is 10-based.

```
int[] lengths = { 2, 3 };
int[] lowerBounds = { 1, 10 };
Array racers = Array.CreateInstance(typeof(Person), lengths, lowerBounds);
```

Setting the elements of the array, the `SetValue()` method accepts indices for every dimension:

```
racers.SetValue(new Person
{
    FirstName = "Alain",
    LastName = "Prost"
}, 1, 10);
racers.SetValue(new Person
{
    FirstName = "Emerson",
    LastName = "Fittipaldi"
}, 1, 11);
racers.SetValue(new Person
{
    FirstName = "Ayrton",
    LastName = "Senna"
}, 1, 12);
racers.SetValue(new Person
{
    FirstName = "Ralf",
    LastName = "Schumacher"
}, 2, 10);
racers.SetValue(new Person
{
    FirstName = "Fernando",
    LastName = "Alonso"
}, 2, 11);
racers.SetValue(new Person
{
    FirstName = "Jenson",
    LastName = "Button"
}, 2, 12);
```

code snippet Sample1/Program.cs

Although the array is not 0-based, you can assign it to a variable with the normal C# notation. You just have to pay attention not to cross the boundaries.

```
Person[,] racers2 = (Person[,])racers;
Person first = racers2[1, 10];
Person last = racers2[2, 12];
```

Copying Arrays

Because arrays are reference types, assigning an array variable to another one just gives you two variables referencing the same array. For copying arrays, the array implements the interface `ICloneable`. The `Clone()` method that is defined with this interface creates a shallow copy of the array.

If the elements of the array are value types, as in the following code segment, all values are copied, as you can see in Figure 6-5.

```
int[] intArray1 = {1, 2};
int[] intArray2 = (int[])intArray1.Clone();
```

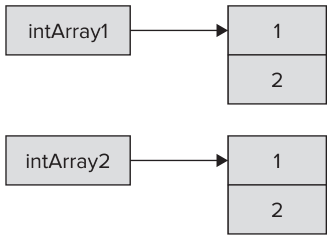

FIGURE 6-5

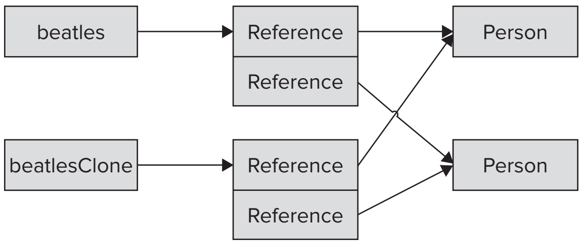

FIGURE 6-6

Instead of using the `Clone()` method, you can use the `Array.Copy()` method, which creates a shallow copy as well. But there's one important difference with `Clone()` and `Copy()`: `Clone()` creates a new array; with `Copy()` you have to pass an existing array with the same rank and enough elements.

If you need a deep copy of an array containing reference types, you have to iterate the array and create new objects.

Sorting

The `Array` class uses the QuickSort algorithm for sorting the elements in the array. The `Sort()` method requires the interface `IComparable` to be implemented by the elements in the array. Simple types such as `System.String` and `System.Int32` implement `IComparable`, so you can sort elements containing these types.

With the sample program, the array name contains elements of type string, and this array can be sorted:

```
string[] names = {
       "Christina Aguilera",
       "Shakira",
       "Beyonce",
       "Gwen Stefani"
    };

Array.Sort(names);

foreach (var name in names)
{
   Console.WriteLine(name);
}
```

code snippet SortingSample/Program.cs

The output of the application shows the sorted result of the array:

```
Beyonce
Christina Aguilera
Gwen Stefani
Shakira
```

If you are using custom classes with the array, you must implement the interface `IComparable`. This interface defines just one method, `CompareTo()`, that must return 0 if the objects to compare are equal, a value smaller than 0 if the instance should go before the object from the parameter, and a value larger than 0 if the instance should go after the object from the parameter.

Change the `Person` class to implement the interface `IComparable<Person>`. The comparison is done on the value of the `LastName`. Because the `LastName` is of type `string`, and the `String` class already implements the `IComparable` interface, with the implementation you can rely on the `CompareTo()` method of the `String` class. If the `LastName` has the same value, the `FirstName` is compared:

```
public class Person: IComparable<Person>
{
   public int CompareTo(Person other)
   {
      if (other == null) throw new ArgumentNullException("other");

      int result = this.LastName.CompareTo(
                other.LastName);
      if (result == 0)
      {
         result = this.FirstName.CompareTo(
               other.FirstName);
      }
      return result;
   }
   //...
```

code snippet SortingSample/Person.cs

Now it is possible to sort an array of `Person` objects by the last name:

```
Person[] persons = {
   new Person { FirstName="Damon", LastName="Hill" },
   new Person { FirstName="Niki", LastName="Lauda" },
   new Person { FirstName="Ayrton", LastName="Senna" },
   new Person { FirstName="Graham", LastName="Hill" }
};

Array.Sort(persons);
foreach (var p in persons)
{
   Console.WriteLine(p);
}
```

code snippet SortingSample/Program.cs

Using the sort of the `Person` class, the output returns the names sorted by the last name:

```
Damon Hill
Graham Hill
Niki Lauda
Ayrton Senna
```

If the `Person` object should be sorted differently, or if you don't have the option to change the class that is used as an element in the array, you can implement the interface `IComparer` or `IComparer<T>`. These interfaces define the method `Compare()`. One of these interfaces must be implemented by the class that should be compared. The IComparer interface is independent of the class to compare. That's why the Compare() method defines two arguments that should be compared. The return value is similar to the CompareTo() method of the IComparable interface.

The class PersonComparer implements the IComparer<Person> interface to sort Person objects either by firstName or by lastName The enumeration PersonCompareType defines the different sorting options that are available with the PersonComparer: FirstName and LastName. How the compare should happen is defined with the constructor of the class PersonComparer where a PersonCompareType value is set. The Compare() method is implemented with a switch statement to compare either by LastName or by FirstName.

```
public enum PersonCompareType
{
   FirstName,
   LastName
}

public class PersonComparer: IComparer<Person>
{
   private PersonCompareType compareType;

   public PersonComparer(PersonCompareType compareType)
   {
      this.compareType = compareType;
   }

   public int Compare(Person x, Person y)
   {
      if (x == null) throw new ArgumentNullException("x");
      if (y == null) throw new ArgumentNullException("y");

      switch (compareType)
      {
         case PersonCompareType.FirstName:
            return x.FirstName.CompareTo(y.FirstName);
         case PersonCompareType.LastName:
            return x.LastName.CompareTo(y.LastName);
         default:
            throw new ArgumentException(
                  "unexpected compare type");
      }
   }
}
```

code snippet SortingSample/PersonComparer.cs

Now you can pass a PersonComparer object to the second argument of the Array.Sort() method. Here the persons are sorted by first name:

```
Array.Sort(persons,
   new PersonComparer(PersonCompareType.FirstName));
foreach (var p in persons)
{
   Console.WriteLine(p);
}
```

code snippet SortingSample/Program.cs

The `persons` array is now sorted by the first name:

```
Ayrton Senna
Damon Hill
Graham Hill
Niki Lauda
```

ARRAYS AS PARAMETERS

Arrays can be passed as parameters to methods, and returned from methods. Returning an array, you just have to declare the array as the return type, as shown with the following method `GetPersons()`:

```
        static Person[] GetPersons()
        {
            return new Person[] {
                new Person { FirstName="Damon", LastName="Hill" },
                new Person { FirstName="Niki", LastName="Lauda" },
                new Person { FirstName="Ayrton", LastName="Senna" },
                new Person { FirstName="Graham", LastName="Hill" }
            };
        }
```

code snippet SortingSample/Program.cs

Passing arrays to a method, the array is declared with the parameter, as shown with the method `DisplayPersons()`:

```
        static void DisplayPersons(Person[] persons)
        {
            //...
```

Array Covariance

With arrays, covariance is supported. This means that an array can be declared as a base type and elements of derived types can be assigned to the elements.

For example, you can declare a parameter of type `object[]` as shown and pass a `Person[]` to it:

```
static void DisplayArray(object[] data)
{
    //...
}
```

Array covariance is only possible with reference types, not with value types.

Array covariance has an issue that can only resolved with runtime exceptions. If you assign a `Person` *array to an object array, the object array can then be used with anything that derives from the object. The compiler accepts, for example, passing a string to array elements. However, because really a* `Person` *array is referenced by the object array, a runtime exception occurs.*

ArraySegment<T>

The struct `ArraySegment<T>` represents a segment of an array. If parts of an array should be returned from or passed to a method, a segment can be used. Instead of passing the array, offset, and count with separate parameters to a method, you can pass a single parameter with `ArraySegment<T>`. With this structure the information about the segment (the offset and count) is contained within the members of the structure.

The method `SumOfSegments` takes an array of `ArraySegment<int>` elements to calculate the sum of all the integers that are defined with the segments and returns the sum:

```
static int SumOfSegments(ArraySegment<int>[] segments)
{
    int sum = 0;
    foreach (var segment in segments)
    {
        for (int i = segment.Offset; i < segment.Offset +
            segment.Count; i++)
        {
            sum += segment.Array[i];
        }
    }
    return sum;
}
```

code snippet ArraySegmentSample/Program.cs

This method is used by passing an array of segments. The first array element references three elements of `ar1` starting with the first element; the second array element references three elements of `ar2` starting with the fourth element:

```
int[] ar1 = { 1, 4, 5, 11, 13, 18 };
int[] ar2 = { 3, 4, 5, 18, 21, 27, 33 };

var segments = new ArraySegment<int>[2]
{
    new ArraySegment<int>(ar1, 0, 3),
    new ArraySegment<int>(ar2, 3, 3)
};
var sum = SumOfSegments(segments);
```

It's important to note that array segments don't copy the elements of the originating array. Instead, the originating array can be accessed through `ArraySegment<T>`. If elements of the array segment are changed, the changes can be seen in the original array.

ENUMERATIONS

By using the `foreach` statement you can iterate elements of a collection (see Chapter 10) without the need to know the number of elements inside the collection. The `foreach` statement uses an enumerator. Figure 6-7 shows the relationship between the client invoking the `foreach` method and the collection. The array or collection implements the `IEnumerable` interface with the `GetEnumerator()` method. The `GetEnumerator()` method returns an enumerator implementing the `IEnumerator` interface. The interface `IEnumerator` then is used by the `foreach` statement to iterate through the collection.

> *The `GetEnumerator()` method is defined with the interface `IEnumerable`. The foreach statement doesn't really need this interface implemented in the collection class. It's enough to have a method with the name `GetEnumerator()` that returns an object implementing the `IEnumerator` interface.*

IEnumerator Interface

The `foreach` statement uses the methods and properties of the `IEnumerator` interface to iterate all elements in a collection. For this, `IEnumerator` defines the property `Current` to return the element where the cursor is positioned, and the method `MoveNext()` to move to the next element of the collection. `MoveNext()` returns `true` if there's an element, and `false` if no more elements are available.

The generic version of this interface `IEnumerator<T>` derives from the interface `IDisposable` and thus defines a `Dispose()` method to clean up resources allocated by the enumerator.

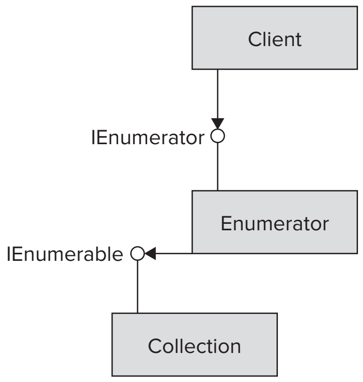

FIGURE 6-7

> *The `IEnumerator` interface also defines the `Reset()` method for COM interoperability. Many .NET enumerators implement this by throwing an exception of type `NotSupportedException`.*

foreach Statement

The C# `foreach` statement is not resolved to a `foreach` statement in the IL code. Instead, the C# compiler converts the `foreach` statement to methods and properties of the `IEnumerator` interface. Here's a simple `foreach` statement to iterate all elements in the `persons` array and to display them person by person:

```
foreach (var p in persons)
{
   Console.WriteLine(p);
}
```

The `foreach` statement is resolved to the following code segment. First, the `GetEnumerator()` method is invoked to get an enumerator for the array. Inside a `while` loop — as long as `MoveNext()` returns `true` — the elements of the array are accessed using the `Current` property:

```
IEnumerator<Person> enumerator = persons.GetEnumerator();
while (enumerator.MoveNext())
{
   Person p = enumerator.Current;
   Console.WriteLine(p);
}
```

yield Statement

Since the first release of C#, it has been easy to iterate through collections by using the `foreach` statement. With C# 1.0, it was still a lot of work to create an enumerator. C# 2.0 added the `yield` statement for creating enumerators easily. The `yield return` statement returns one element of a collection and moves the position to the next element, and `yield break` stops the iteration.

The next example shows the implementation of a simple collection using the `yield return` statement. The class `HelloCollection` contains the method `GetEnumerator()`. The implementation of the `GetEnumerator()` method contains two `yield return` statements where the strings `Hello` and `World` are returned:

```
using System;
using System.Collections;

namespace Wrox.ProCSharp.Arrays
{
   public class HelloCollection
   {
      public IEnumerator<string> GetEnumerator()
      {
         yield return "Hello";
         yield return "World";
      }
   }
```

code snippet YieldDemo/Program.cs

A method or property that contains yield statements is also known as an iterator block. An iterator block must be declared to return an `IEnumerator` *or* `IEnumerable` *interface, or the generic versions of these interfaces. This block may contain multiple* `yield return` *or* `yield break` *statements; a* `return` *statement is not allowed.*

Now it is possible to iterate through the collection using a `foreach` statement:

```
   public void HelloWorld()
   {
      var helloCollection = new HelloCollection();
      foreach (var s in helloCollection)
      {
         Console.WriteLine(s);
      }
   }
}
```

With an iterator block the compiler generates a yield type, including a state machine, as shown with the following code segment. The yield type implements the properties and methods of the interfaces `IEnumerator` and `IDisposable`. In the sample, you can see the yield type as the inner class `Enumerator`. The `GetEnumerator()` method of the outer class instantiates and returns a new yield type. Within the yield type, the variable `state` defines the current position of the iteration and is changed every time the method `MoveNext()` is invoked. `MoveNext()` encapsulates the code of the iterator block and sets the value of the `current` variable so that the `Current` property returns an object depending on the position.

```
public class HelloCollection
{
   public IEnumerator GetEnumerator()
   {
      return new Enumerator(0);
   }

   public class Enumerator: IEnumerator<string>, IEnumerator, IDisposable
   {
      private int state;
      private string current;

      public Enumerator(int state)
      {
         this.state = state;
      }
      bool System.Collections.IEnumerator.MoveNext()
      {
         switch (state)
         {
            case 0:
               current = "Hello";
               state = 1;
               return true;
            case 1:
               current = "World";
               state = 2;
               return true;
            case 2:
               break;
         }

         return false;
      }

      void System.Collections.IEnumerator.Reset()
      {
         throw new NotSupportedException();
      }

      string System.Collections.Generic.IEnumerator<string>.Current
      {
         get
         {
            return current;
         }
      }
      object System.Collections.IEnumerator.Current
      {
         get
         {
            return current;
         }
      }

      void IDisposable.Dispose()
      {
      }
   }
}
```

Different Ways to Iterate Through Collections

In a slightly larger and more realistic way than the Hello World example, you can use the `yield return` statement to iterate through a collection in different ways. The class `MusicTitles` allows iterating the titles in a default way with the `GetEnumerator()` method, in reverse order with the `Reverse()` method, and to iterate through a subset with the `Subset()` method:

```
public class MusicTitles
{
    string[] names = { "Tubular Bells", "Hergest Ridge", "Ommadawn",
                       "Platinum" };

    public IEnumerator<string> GetEnumerator()
    {
        for (int i = 0; i < 4; i++)
        {
            yield return names[i];
        }
    }

    public IEnumerable<string> Reverse()
    {
        for (int i = 3; i >= 0; i--)
        {
            yield return names[i];
        }
    }

    public IEnumerable<string> Subset(int index, int length)
    {
        for (int i = index; i < index + length; i++)
        {
            yield return names[i];
        }
    }
}
```

code snippet YieldDemo/Program.cs

The default iteration that's supported by a class is the `GetEnumerator()` *method that is defined to return* `IEnumerator`. *Named iterations return* `IEnumerable`.

The client code to iterate through the string array first uses the `GetEnumerator()` method, which you don't have to write in your code because this one is used by default. Then the titles are iterated in reverse, and finally a subset is iterated by passing the index and number of items to iterate to the `Subset()` method:

```
var titles = new MusicTitles();
foreach (var title in titles)
{
    Console.WriteLine(title);
```

```
        }
        Console.WriteLine();

        Console.WriteLine("reverse");
        foreach (var title in titles.Reverse())
        {
            Console.WriteLine(title);
        }
        Console.WriteLine();

        Console.WriteLine("subset");
        foreach (var title in titles.Subset(2, 2))
        {
            Console.WriteLine(title);
        }
```

Returning Enumerators with Yield Return

With the yield statement you can also do more complex things, for example, returning an enumerator from `yield return`.

With the TicTacToe game, players alternate putting a cross or a circle in one of nine fields. These moves are simulated by the `GameMoves` class. The methods `Cross()` and `Circle()` are the iterator blocks for creating iterator types. The variables `cross` and `circle` are set to `Cross()` and `Circle()` inside the constructor of the `GameMoves` class. By setting these fields the methods are not invoked, but they are set to the iterator types that are defined with the iterator blocks. Within the `Cross()` iterator block, information about the move is written to the console and the move number is incremented. If the move number is higher than 8, the iteration ends with `yield break`; otherwise, the enumerator object of the circle yield type is returned with each iteration. The `Circle()` iterator block is very similar to the `Cross()` iterator block; it just returns the cross iterator type with each iteration.

```
public class GameMoves
{
    private IEnumerator cross;
    private IEnumerator circle;

    public GameMoves()
    {
        cross = Cross();
        circle = Circle();
    }

    private int move = 0;
    const int MaxMoves = 9;

    public IEnumerator Cross()
    {
        while (true)
        {
            Console.WriteLine("Cross, move {0}", move);
            if (++move >= MaxMoves)
                yield break;
            yield return circle;
        }
    }

    public IEnumerator Circle()
    {
        while (true)
        {
            Console.WriteLine("Circle, move {0}", move);
            if (++move >= MaxMoves)
```

```
                    yield break;
                yield return cross;
            }
        }
    }
```

code snippet YieldDemo/GameMoves.cs

From the client program, you can use the class `GameMoves` as follows. The first move is set by setting enumerator to the enumerator type returned by `game.Cross()`. In a `while` loop, `enumerator.MoveNext()` is called. The first time this is invoked, the `Cross()` method is called, which returns the other enumerator with a `yield` statement. The returned value can be accessed with the `Current` property and is set to the `enumerator` variable for the next loop:

```
            var game = new GameMoves();
            IEnumerator enumerator = game.Cross();
            while (enumerator.MoveNext())
            {
                enumerator = enumerator.Current as IEnumerator;
            }
```

code snippet YieldDemo/Program.cs

The outcome of this program shows alternating moves until the last move:

```
Cross, move 0
Circle, move 1
Cross, move 2
Circle, move 3
Cross, move 4
Circle, move 5
Cross, move 6
Circle, move 7
Cross, move 8
```

TUPLES

Arrays combine objects of the same type; tuples can combine objects of different types. Tuples have the origin in functional programming languages such as F# where they are used often. With .NET 4, tuples are available with the .NET Framework for all .NET languages.

.NET 4 defines eight generic `Tuple` classes and one static `Tuple` class that act as a factory of tuples. The different generic `Tuple` classes are here for supporting a different number of elements; e.g., `Tuple<T1>` contains one element, `Tuple<T1, T2>` contains two elements, and so on.

The method `Divide()` demonstrates returning a tuple with two members — `Tuple<int, int>`. The parameters of the generic class define the types of the members, which are both integers. The tuple is created with the static `Create()` method of the static `Tuple` class. Again, the generic parameters of the `Create()` method define the type of tuple that is instantiated. The newly created tuple is initialized with the `result` and `reminder` variables to return the result of the division:

```
        public static Tuple<int, int> Divide(int dividend, int divisor)
        {
            int result = dividend / divisor;
            int reminder = dividend % divisor;

            return Tuple.Create<int, int>(result, reminder);
        }
```

code snippet TuplesSample/Program.cs

The following code shows invoking the `Divide()` method. The items of the tuple can be accessed with the properties `Item1` and `Item2`:

```
            var result = Divide(5, 2);
            Console.WriteLine("result of division: {0}, reminder: {1}",
                result.Item1, result.Item2);
```

In case you have more than eight items that should be included in a tuple, you can use the `Tuple` class definition with eight parameters. The last template parameter is named `TRest` to indicate that you must pass a tuple itself. That way you can create tuples with any number of parameters.

To demonstrate this functionality:

```
    public class Tuple<T1, T2, T3, T4, T5, T6, T7, TRest>
```

Here, the last template parameter is a tuple type itself, so you can create a tuple with any number of items:

```
            var tuple = Tuple.Create<string, string, string, int, int, int, double,
                Tuple<int, int>>(
                    "Stephanie", "Alina", "Nagel", 2009, 6, 2, 1.37,
                    Tuple.Create<int, int>(52, 3490));
```

STRUCTURAL COMPARISON

Both arrays and tuples implement the interfaces `IStructuralEquatable` and `IStructuralComparable`. These interfaces are new with .NET 4 and not only compare references but the content as well. This interface is implemented explicitly, so it is necessary to cast the arrays and tuples to this interface on use. `IStructuralEquatable` is used to compare whether two tuples or arrays have the same content; `IStructuralComparable` is used to sort tuples or arrays.

With the sample demonstrating `IStructuralEquatable`, the `Person` class implementing the interface `IEquatable` is used. `IEquatable` defines a strongly typed `Equals()` method where the values of the `FirstName` and `LastName` properties are compared:

```
        public class Person: IEquatable<Person>
        {
            public int Id { get; private set; }
            public string FirstName { get; set; }
            public string LastName { get; set; }

            public override string ToString()
            {
                return String.Format("{0}, {1} {2}", Id, FirstName, LastName);
            }

            public override bool Equals(object obj)
            {
                if (obj == null) throw new ArgumentNullException("obj");
                return Equals(obj as Person);
            }

            public override int GetHashCode()
            {
                return Id.GetHashCode();
            }

            public bool Equals(Person other)
            {
                if (other == null) throw new ArgumentNullException("other");

                return this.Id == other.Id && this.FirstName == other.FirstName &&
                    this.LastName == other.LastName;
            }
        }
```

code snippet StructuralComparison/Person.cs

Now two arrays containing `Person` items are created. Both arrays contain the same `Person` object with the variable name `janet`, and two different `Person` objects that have the same content. The comparison operator `!=` returns `true` because there are indeed two different arrays referenced from two variable names `persons1` and `persons2`. Because the `Equals()` method with one parameter is not overridden by the `Array` class, the same happens as with the `==` operator to compare the references, and they are not the same:

```
            var janet = new Person { FirstName = "Janet", LastName = "Jackson" };
            Person[] persons1 = {
                                    new Person
                                    {
                                        FirstName = "Michael",
                                        LastName = "Jackson"
                                    },
                                    janet
                                };
            Person[] persons2 = {
                                    new Person
                                    {
                                        FirstName = "Michael",
                                        LastName = "Jackson"
                                    },
                                    janet
                                };
            if (persons1 != persons2)
                Console.WriteLine("not the same reference");
```

code snippet StructuralComparison/Program.cs

Invoking the `Equals()` method defined by the `IStructuralEquatable` that is the method with the first parameter of type `object` and the second parameter of type `IEqualityComparer`, you can define how the comparison should be done by passing an object that implements `IEqualityComparer<T>`. A default implementation of the `IEqualityComparer` is done by the `EqualityComparer<T>` class. This implementation checks if the type implements the interface `IEquatable`, and invokes the `IEquatable.Equals()` method. If the type does not implement `IEquatable`, the `Equals()` method from the base class `Object` is invoked to do the comparison.

`Person` implements `IEquatable<Person>`, where the content of the objects is compared and the arrays indeed contain the same content:

```
            if ((persons1 as IStructuralEquatable).Equals(persons2,
                EqualityComparer<Person>.Default))
            {
                Console.WriteLine("the same content");
            }
```

You'll see next how the same thing can be done with tuples. Here, two tuple instances are created that have the same content. Of course, because the references `t1` and `t2` reference two different objects, the comparison operator `!=` returns true:

```
            var t1 = Tuple.Create<int, string>(1, "Stephanie");
            var t2 = Tuple.Create<int, string>(1, "Stephanie");
            if (t1 != t2)
                Console.WriteLine("not the same reference to the tuple");
```

The `Tuple<>` class offers two `Equals()` methods: one that is overridden from the `Object` base class with an `object` as parameter, and the second that is defined by the `IStructuralEqualityComparer` interface with `object` and `IEqualityComparer` as parameters. Another tuple can be passed to the first method as shown. This method uses `EqualityComparer<object>.Default` to get an `ObjectEqualityComparer<object>` for the comparison. This way every item of the tuple is compared by invoking the `Object.Equals()` method. If every item returns `true`, the final result of the `Equals()` method is `true`, which is the case here with the same int and string values:

```
            if (t1.Equals(t2))
                Console.WriteLine("the same content");
```

You can also create a custom `IEqualityComparer`, as shown with the class `TupleComparer`. This class implements the two methods `Equals()` and `GetHashCode()` of the `IEqualityComparer` interface:

```
    class TupleComparer: IEqualityComparer
    {
        public new bool Equals(object x, object y)
        {
            return x.Equals(y);
        }

        public int GetHashCode(object obj)
        {
            return obj.GetHashCode();
        }
    }
```

code snippet StructuralComparison/Program.cs

The implementation of the `Equals()` method of the `IEqualityComparer` interface requires the new modifier or an implicit interface implementation because the base class `Object` defines a static `Equals()` method with two parameters as well.

The `TupleComparer` is used, passing a new instance to the `Equals()` method of the `Tuple<T1, T2>` class. The `Equals()` method of the `Tuple` class invokes the `Equals()` method of the `TupleComparer` for every item to be compared. So with the `Tuple<T1, T2>` class, the `TupleComparer` is invoked two times to check whether all items are equal:

```
            if (t1.Equals(t2, new TupleComparer()))
                Console.WriteLine("equals using TupleComparer");
```

SUMMARY

In this chapter, you've seen the C# notation to create and use simple, multidimensional, and jagged arrays. The `Array` class is used behind the scenes of C# arrays, and this way you can invoke properties and methods of this class with array variables.

You've seen how to sort elements in the array by using the `IComparable` and `IComparer` interfaces. You've learned using and creating enumerators, the interfaces `IEnumerable` and `IEnumerator`, and the `yield` statement. You've seen tuples, a new feature of .NET 4.

Moving on, the next chapter focuses on operators and casts.

7 Operators and Casts

WHAT'S IN THIS CHAPTER?

- Operators in C#
- The idea of equality when dealing with reference and value types
- Data conversion between primitive data types
- Converting value types to reference types using boxing
- Converting between reference types by casting
- Overloading the standard operators for custom types
- Adding cast operators to custom types

The preceding chapters have covered most of what you need to start writing useful programs using C#. This chapter completes the discussion of the essential language elements and illustrates some powerful aspects of C# that allow you to extend the capabilities of the C# language.

OPERATORS

Although most of C#'s operators should be familiar to C and C++ developers, this section discusses the most important operators for the benefit of new programmers and Visual Basic converts, and sheds light on some of the changes introduced with C#.

C# supports the operators listed in the following table:

CATEGORY	OPERATOR
Arithmetic	`+ – * / %`
Logical	`& | ^ ~ && || !`
String concatenation	`+`
Increment and decrement	`++ ––`
Bit shifting	`<< >>`
Comparison	`== != < > <= >=`

continues

(continued)

CATEGORY	OPERATOR
Assignment	`= += -= *= /= %= &= |= ^= <<= >>=`
Member access (for objects and structs)	`.`
Indexing (for arrays and indexers)	`[]`
Cast	`()`
Conditional (the ternary operator)	`?:`
Delegate concatenation and removal (discussed in Chapter 8, "Delegates, Lambdas, and Events")	`+ -`
Object creation	`new`
Type information	`sizeof is typeof as`
Overflow exception control	`checked unchecked`
Indirection and address	`[]`
Namespace alias qualifier (discussed in Chapter 2, "Core C#")	`::`
Null coalescing operator	`??`

Note that four specific operators (`sizeof`, `*`, `->`, and `&`, listed in the following table), however, are available only in unsafe code (code that bypasses C#'s type-safety checking), which is discussed in Chapter 13, "Memory Management and Pointers." It is also important to note that the `sizeof` operator keywords, when used with the very early versions of the .NET Framework 1.0 and 1.1, required the unsafe mode. This is not a requirement since the .NET Framework 2.0 version.

CATEGORY	OPERATOR
Operator keywords	`sizeof` (for .NET Framework versions 1.0 and 1.1 only)
Operators	`* -> &`

One of the biggest pitfalls to watch out for when using C# operators is that, as with other C-style languages, C# uses different operators for assignment (`=`) and comparison (`==`). For instance, the following statement means *let x equal three*:

```
x = 3;
```

If you now want to compare `x` to a value, you need to use the double equals sign `==`:

```
if (x == 3)
{

}
```

Fortunately, C#'s strict type-safety rules prevent the very common C error where assignment is performed instead of comparison in logical statements. This means that in C# the following statement will generate a compiler error:

```
if (x = 3)
{

}
```

Visual Basic programmers who are accustomed to using the ampersand (`&`) character to concatenate strings will have to make an adjustment. In C#, the plus sign (`+`) is used instead for concatenation, whereas the `&` symbol denotes a bitwise `AND` between two different integer values. The symbol `|` allows you to perform a bitwise `OR` between two integers. Visual Basic programmers also might not recognize the modulus (`%`)

arithmetic operator. This returns the remainder after division, so, for example, `x % 5` returns `2` if `x` is equal to `7`.

You will use few pointers in C#, and, therefore, few indirection operators. More specifically, the only place you will use them is within blocks of unsafe code, because that is the only place in C# where pointers are allowed. Pointers and unsafe code are discussed in Chapter 13.

Operator Shortcuts

The following table shows the full list of shortcut assignment operators available in C#.

SHORTCUT OPERATOR	EQUIVALENT TO
`x++, ++x`	`x = x + 1`
`x--, --x`	`x = x - 1`
`x += y`	`x = x + y`
`x -= y`	`x = x - y`
`x *= y`	`x = x * y`
`x /= y`	`x = x / y`
`x %= y`	`x = x % y`
`x >>= y`	`x = x >> y`
`x <<= y`	`x = x << y`
`x &= y`	`x = x & y`
`x |= y`	`x = x | y`

You may be wondering why there are two examples each for the `++` increment and the `--` decrement operators. Placing the operator *before* the expression is known as a *prefix*, placing the operator *after* the expression is known as a *postfix*, and it is important to note that there is a difference in the way they behave.

The increment and decrement operators can act both as whole expressions and within expressions. When used by themselves, the effect of both the prefix and postfix versions is identical and corresponds to the statement `x = x + 1`. When used within larger expressions, the prefix operator will increment the value of `x` *before* the expression is evaluated; in other words, `x` is incremented and the new value is used in the expression. In contrast, the postfix operator increments the value of `x` *after* the expression is evaluated — the expression is evaluated using the original value of `x`. The following example uses the increment operator (`++`) as an example to demonstrate the difference between the prefix and postfix behavior:

```
int x = 5;

if (++x == 6)  // true – x is incremented to 6 before the evaluation
{
   Console.WriteLine("This will execute");
}

if (x++ == 7) // false – x is incremented to 7 after the evaluation
{
   Console.WriteLine("This won't");
}
```

The first `if` condition evaluates to `true`, because `x` is incremented from `5` to `6` *before* the expression is evaluated. The condition in the second `if` statement is `false`, however, because `x` is incremented to `7` only after the entire expression has been evaluated (while `x == 6`).

The prefix and postfix operators `--x` and `x--` behave in the same way, but decrement rather than increment the operand.

The other shortcut operators, such as `+=` and `-=`, require two operands, and are used to modify the value of the first operand by performing an arithmetic, logical, or bitwise operation on it. For example, the next two lines are equivalent:

```
x += 5;
x = x + 5;
```

The following sections look at some of the primary and cast operators that you will frequently use within your C# code.

The Conditional Operator

The conditional operator (`?:`), also known as the ternary operator, is a shorthand form of the `if...else` construction. It gets its name from the fact that it involves three operands. It allows you to evaluate a condition, returning one value if that condition is true, or another value if it is false. The syntax is

```
condition ? true_value: false_value
```

Here, *condition* is the Boolean expression to be evaluated, *true_value* is the value that will be returned if *condition* is true, and *false_value* is the value that will be returned otherwise.

When used sparingly, the conditional operator can add a dash of terseness to your programs. It is especially handy for providing one of a couple of arguments to a function that is being invoked. You can use it to quickly convert a Boolean value to a string value of `true` or `false`. It is also handy for displaying the correct singular or plural form of a word, for example:

```
int x = 1;
string s = x + " ";
s += (x == 1 ? "man": "men");
Console.WriteLine(s);
```

This code displays `1 man` if `x` is equal to one but will display the correct plural form for any other number. Note, however, that if your output needs to be localized to different languages, you will have to write more sophisticated routines to take into account the different grammatical rules of different languages.

The checked and unchecked Operators

Consider the following code:

```
byte b = 255;
b++;
Console.WriteLine(b.ToString());
```

The `byte` data type can hold values only in the range 0 to 255, so incrementing the value of `b` causes an overflow. How the CLR handles this depends on a number of issues, including compiler options, so whenever there's a risk of an unintentional overflow, you need some way of making sure that you get the result you want.

To do this, C# provides the `checked` and `unchecked` operators. If you mark a block of code as `checked`, the CLR will enforce overflow checking, and throw an `OverflowException` if an overflow occurs. Let's change the code to include the `checked` operator:

```
byte b = 255;
checked
{
   b++;
}
Console.WriteLine(b.ToString());
```

When you try to run this code, you will get an error message like this:

```
Unhandled Exception: System.OverflowException: Arithmetic operation resulted in an
   overflow at Wrox.ProCSharp.Basics.OverflowTest.Main(String[] args)
```

You can enforce overflow checking for all unmarked code in your program by specifying the `/checked` *compiler option.*

If you want to suppress overflow checking, you can mark the code as `unchecked`:

```
byte b = 255;
unchecked
{
   b++;
}
Console.WriteLine(b.ToString());
```

In this case, no exception will be raised, but you will lose data — because the `byte` type cannot hold a value of 256, the overflowing bits will be discarded, and your `b` variable will hold a value of zero (0).

Note that `unchecked` is the default behavior. The only time you are likely to need to explicitly use the `unchecked` keyword is if you need a few unchecked lines of code inside a larger block that you have explicitly marked as `checked`.

The is Operator

The `is` operator allows you to check whether an object is compatible with a specific type. The phrase "is compatible" means that an object either is of that type or is derived from that type. For example, to check whether a variable is compatible with the `object` type, you could use the following bit of code:

```
int i = 10;
if (i is object)
{
   Console.WriteLine("i is an object");
}
```

`int`, like all C# data types, inherits from `object`; therefore, the expression `i is object` will evaluate to `true` in this case, and the appropriate message will be displayed.

The as Operator

The `as` operator is used to perform explicit type conversions of reference types. If the type being converted is compatible with the specified type, conversion is performed successfully. However, if the types are incompatible, the `as` operator returns the value `null`. As shown in the following code, attempting to convert an `object` reference to a `string` will return `null` if the `object` reference does not actually refer to a `string` instance:

```
object o1 = "Some String";
object o2 = 5;

string s1 = o1 as string;   // s1 = "Some String"
string s2 = o2 as string;   // s2 = null
```

The `as` operator allows you to perform a safe type conversion in a single step without the need to first test the type using the `is` operator and then perform the conversion.

The sizeof Operator

You can determine the size (in bytes) required on the stack by a value type using the `sizeof` operator:

```
Console.WriteLine(sizeof(int));
```

This will display the number `4`, because an `int` is 4 bytes long.

If you are using the `sizeof` operator with complex types (and not primitive types), you will need to block the code within an `unsafe` block as illustrated here:

```
unsafe
{
   Console.WriteLine(sizeof(Customer));
}
```

Chapter 13 looks at unsafe code in more detail.

The typeof Operator

The `typeof` operator returns a `System.Type` object representing a specified type. For example, `typeof(string)` will return a `Type` object representing the `System.String` type. This is useful when you want to use reflection to find information about an object dynamically. Chapter 14, "Reflection," looks at reflection.

Nullable Types and Operators

Looking at the Boolean type, you have a true or false value that you can assign to this type. However, what if you wanted to define the value of the type as undefined? This is where using nullable types can have a distinct value to your applications. If you use nullable types in your programs, you must always consider the effect a `null` value can have when used in conjunction with the various operators. Usually, when using a unary or binary operator with nullable types, the result will be `null` if one or both of the operands is `null`. For example:

```
int? a = null;

int? b = a + 4;      // b = null
int? c = a * 5;      // c = null
```

However, when comparing nullable types, if only one of the operands is `null`, the comparison will always equate to `false`. This means that you cannot assume a condition is `true` just because its opposite is `false`, as often happens in programs using non-nullable types. For example:

```
int? a = null;
int? b = -5;

if (a > = b)
   Console.WriteLine("a > = b");
else
   Console.WriteLine("a < b");
```

The possibility of a `null` value means that you cannot freely combine nullable and non-nullable types in an expression. This is discussed in the "Type Conversions" section later in this chapter.

The Null Coalescing Operator

The null coalescing operator (`??`) provides a shorthand mechanism to cater to the possibility of `null` values when working with nullable and reference types. The operator is placed between two operands — the first operand must be a nullable type or reference type, and the second operand must be of the same type as the first or of a type that is implicitly convertible to the type of the first operand. The null coalescing operator evaluates as follows:

- ➤ If the first operand is not `null`, then the overall expression has the value of the first operand.
- ➤ If the first operand is `null`, then the overall expression has the value of the second operand.

For example:

```
int? a = null;
int b;

b = a ?? 10;     // b has the value 10
a = 3;
b = a ?? 10;     // b has the value 3
```

If the second operand cannot be implicitly converted to the type of the first operand, a compile-time error is generated.

Operator Precedence

The following table shows the order of precedence of the C# operators. The operators at the top of the table are those with the highest precedence (that is, the ones evaluated first in an expression containing multiple operators).

GROUP	OPERATORS
Primary	`() . [] x++ x-- new typeof sizeof checked unchecked`
Unary	`+ — ! ~ ++x --x and casts`
Multiplication/division	`* / %`
Addition/subtraction	`+ -`
Bitwise shift operators	`<< >>`
Relational	`< ><= >= is as`
Comparison	`== !=`
Bitwise AND	`&`
Bitwise XOR	`^`
Bitwise OR	`|`
Boolean AND	`&&`
Boolean OR	`||`
Conditional operator	`?:`
Assignment	`= += -= *= /= %= &= |= ^= <<= >>= >>>=`

In complex expressions, you should avoid relying on operator precedence to produce the correct result. Using parentheses to specify the order in which you want operators applied clarifies your code and prevents potential confusion.

TYPE SAFETY

Chapter 1, ".NET Architecture," noted that the Intermediate Language (IL) enforces strong type safety upon its code. Strong typing enables many of the services provided by .NET, including security and language interoperability. As you would expect from a language compiled into IL, C# is also strongly typed. Among other things, this means that data types are not always seamlessly interchangeable. This section looks at conversions between primitive types.

Type Conversions

Often, you need to convert data from one type to another. Consider the following code:

```
byte value1 = 10;
byte value2 = 23;
byte total;
total = value1 + value2;
Console.WriteLine(total);
```

When you attempt to compile these lines, you get the following error message:

```
Cannot implicitly convert type 'int' to 'byte'
```

The problem here is that when you add 2 bytes together, the result will be returned as an `int`, not as another `byte`. This is because a `byte` can contain only 8 bits of data, so adding 2 bytes together could very easily result in a value that cannot be stored in a single `byte`. If you do want to store this result in a `byte` variable, you are going to have to convert it back to a `byte`. The following sections discuss two conversion mechanisms supported by C# — *implicit* and *explicit*.

Implicit Conversions

Conversion between types can normally be achieved automatically (implicitly) only if you can guarantee that the value is not changed in any way. This is why the previous code failed; by attempting a conversion from an `int` to a `byte`, you were potentially losing 3 bytes of data. The compiler is not going to let you do that unless you explicitly tell it that that's what you want to do. If you store the result in a `long` instead of a `byte`, however, you will have no problems:

```
byte value1 = 10;
byte value2 = 23;
long total;               // this will compile fine
total = value1 + value2;
Console.WriteLine(total);
```

Your program has compiled with no errors at this point because a `long` holds more bytes of data than a `byte`, so there is no risk of data being lost. In these circumstances, the compiler is happy to make the conversion for you, without your needing to ask for it explicitly.

The following table shows the implicit type conversions supported in C#:

FROM	TO
sbyte	short, int, long, float, double, decimal, BigInteger
byte	short, ushort, int, uint long, ulong, float, double, decimal, BigInteger
short	int, long, float, double, decimal, BigInteger
ushort	int, uint, long, ulong, float, double, decimal, BigInteger
int	long, float double, decimal, BigInteger
uint	long, ulong, float, double, decimal, BigInteger

FROM	TO
`long, ulong`	`float, double, decimal, BigInteger`
`float`	`double, BigInteger`
`char`	`ushort, int, uint, long, ulong, float, double, decimal, BigInteger`

As you would expect, you can perform implicit conversions only from a smaller integer type to a larger one, not from larger to smaller. You can also convert between integers and floating-point values; however, the rules are slightly different here. Though you can convert between types of the same size, such as `int`/`uint` to `float` and `long`/`ulong` to `double`, you can also convert from `long`/`ulong` back to `float`. You might lose 4 bytes of data doing this, but this only means that the value of the `float` you receive will be less precise than if you had used a `double`; this is regarded by the compiler as an acceptable possible error because the magnitude of the value is not affected. You can also assign an unsigned variable to a signed variable as long as the limits of value of the unsigned type fit between the limits of the signed variable.

Nullable types introduce additional considerations when implicitly converting value types:

- Nullable types implicitly convert to other nullable types following the conversion rules described for non-nullable types in the previous table; that is, `int?` implicitly converts to `long?`, `float?`, `double?`, and `decimal?`.
- Non-nullable types implicitly convert to nullable types according to the conversion rules described in the preceding table; that is, `int` implicitly converts to `long?`, `float?`, `double?`, and `decimal?`.
- Nullable types *do not* implicitly convert to non-nullable types; you must perform an explicit conversion as described in the next section. This is because there is the chance a nullable type will have the value `null`, which cannot be represented by a non-nullable type.

Explicit Conversions

Many conversions cannot be implicitly made between types, and the compiler will give you an error if any are attempted. These are some of the conversions that cannot be made implicitly:

- `int` to `short` — Data loss is possible.
- `int` to `uint` — Data loss is possible.
- `uint` to `int` — Data loss is possible.
- `float` to `int` — You will lose everything after the decimal point.
- Any numeric type to `char` — Data loss is possible.
- `decimal` to any numeric type — The decimal type is internally structured differently from both integers and floating-point numbers.
- `int?` to `int` — The nullable type may have the value `null`.

However, you can explicitly carry out such conversions using *casts*. When you cast one type to another, you deliberately force the compiler to make the conversion. A cast looks like this:

```
long val = 30000;
int i = (int)val;   // A valid cast. The maximum int is 2147483647
```

You indicate the type to which you are casting by placing its name in parentheses before the value to be converted. If you are familiar with C, this is the typical syntax for casts. If you are familiar with the C++ special cast keywords such as `static_cast`, note that these do not exist in C# and that you have to use the older C-type syntax.

Casting can be a dangerous operation to undertake. Even a simple cast from a `long` to an `int` can cause problems if the value of the original `long` is greater than the maximum value of an `int`:

```
long val = 3000000000;
int i = (int)val;         // An invalid cast. The maximum int is 2147483647
```

In this case, you will not get an error, but you also will not get the result you expect. If you run this code and output the value stored in `i`, this is what you get:

```
-1294967296
```

It is good practice to assume that an explicit cast will not give the results you expect. As you saw earlier, C# provides a `checked` operator that you can use to test whether an operation causes an arithmetic overflow. You can use the `checked` operator to check that a cast is safe and to force the runtime to throw an overflow exception if it is not:

```
long val = 3000000000;
int i = checked((int)val);
```

Bearing in mind that all explicit casts are potentially unsafe, you should take care to include code in your application to deal with possible failures of the casts. Chapter 15, "Errors and Exceptions," introduces structured exception handling using the `try` and `catch` statements.

Using casts, you can convert most primitive data types from one type to another; for example, in this code, the value 0.5 is added to `price`, and the total is cast to an `int`:

```
double price = 25.30;
int approximatePrice = (int)(price + 0.5);
```

This gives the price rounded to the nearest dollar. However, in this conversion, data is lost — namely, everything after the decimal point. Therefore, such a conversion should never be used if you want to go on to do more calculations using this modified price value. However, it is useful if you want to output the approximate value of a completed or partially completed calculation — if you do not want to bother the user with lots of figures after the decimal point.

This example shows what happens if you convert an unsigned integer into a `char`:

```
ushort c = 43;
char symbol = (char)c;
Console.WriteLine(symbol);
```

The output is the character that has an ASCII number of 43, the + sign. You can try any kind of conversion you want between the numeric types (including `char`), and it will work, such as converting a `decimal` into a `char`, or vice versa.

Converting between value types is not restricted to isolated variables, as you have seen. You can convert an array element of type `double` to a struct member variable of type `int`:

```
struct ItemDetails
{
   public string Description;
   public int ApproxPrice;
}

//..

double[] Prices = { 25.30, 26.20, 27.40, 30.00 };

ItemDetails id;
id.Description = "Hello there.";
id.ApproxPrice = (int)(Prices[0] + 0.5);
```

To convert a nullable type to a non-nullable type or another nullable type where data loss may occur, you must use an explicit cast. This is true even when converting between elements with the same basic underlying type, for example, `int?` to `int` or `float?` to `float`. This is because the nullable type may have the value `null`, which cannot be represented by the non-nullable type. As long as an explicit cast between two equivalent non-nullable types is possible, so is the explicit cast between nullable types. However, when casting from a nullable to non-nullable type and the variable has the value `null`, an `InvalidOperationException` is thrown. For example:

```
int? a = null;
int  b = (int)a;     // Will throw exception
```

Using explicit casts and a bit of care and attention, you can convert any instance of a simple value type to almost any other. However, there are limitations on what you can do with explicit type conversions — as far as value types are concerned, you can only convert to and from the numeric and `char` types and `enum` types. You cannot directly cast Booleans to any other type or vice versa.

If you need to convert between numeric and string, you can use methods provided in the .NET class library. The `Object` class implements a `ToString()` method, which has been overridden in all the .NET predefined types and which returns a string representation of the object:

```
int i = 10;
string s = i.ToString();
```

Similarly, if you need to parse a string to retrieve a numeric or Boolean value, you can use the `Parse()` method supported by all the predefined value types:

```
string s = "100";
int i = int.Parse(s);
Console.WriteLine(i + 50);   // Add 50 to prove it is really an int
```

Note that `Parse()` will register an error by throwing an exception if it is unable to convert the string (for example, if you try to convert the string `Hello` to an integer). Again, exceptions are covered in Chapter 15.

Boxing and Unboxing

In Chapter 2, "Core C#," you learned that all types, both the simple predefined types such as `int` and `char`, and the complex types such as classes and structs, derive from the `object` type. This means that you can treat even literal values as though they are objects:

```
string s = 10.ToString();
```

However, you also saw that C# data types are divided into value types, which are allocated on the stack, and reference types, which are allocated on the heap. How does this square with the ability to call methods on an `int`, if the `int` is nothing more than a 4-byte value on the stack?

The way C# achieves this is through a bit of magic called *boxing*. Boxing and its counterpart, *unboxing,* allow you to convert value types to reference types and then back to value types. We include this in the section on casting because this is essentially what you are doing — you are casting your value to the `object` type. Boxing is the term used to describe the transformation of a value type to a reference type. Basically, the runtime creates a temporary reference-type box for the object on the heap.

This conversion can occur implicitly, as in the preceding example, but you can also perform it explicitly:

```
int myIntNumber = 20;
object myObject = myIntNumber;
```

Unboxing is the term used to describe the reverse process, where the value of a previously boxed value type is cast back to a value type. We use the term *cast* here, because this has to be done explicitly. The syntax is similar to explicit type conversions already described:

```
int myIntNumber = 20;
object myObject = myIntNumber;        // Box the int
int mySecondNumber = (int)myObject;   // Unbox it back into an int
```

You can only unbox a variable that has previously been boxed. If you execute the last line when `myObject` is not a boxed `int`, you will get an exception thrown at runtime.

One word of warning: when unboxing, you have to be careful that the receiving value variable has enough room to store all the bytes in the value being unboxed. C#'s `int`s, for example, are only 32 bits long, so unboxing a `long` value (64 bits) into an `int` as shown here will result in an `InvalidCastException`:

```
long myLongNumber = 333333423;
object myObject = (object)myLongNumber;
int myIntNumber = (int)myObject;
```

COMPARING OBJECTS FOR EQUALITY

After discussing operators and briefly touching on the equality operator, it is worth considering for a moment what equality means when dealing with instances of classes and structs. Understanding the mechanics of object equality is essential for programming logical expressions and is important when implementing operator overloads and casts, which is the topic of the rest of this chapter.

The mechanisms of object equality are different depending on whether you are comparing reference types (instances of classes) or value types (the primitive data types, instances of structs or enums). The following sections present the equality of reference and value types independently.

Comparing Reference Types for Equality

You might be surprised to learn that `System.Object` defines three different methods for comparing objects for equality: `ReferenceEquals()` and two versions of `Equals()`. Add to this the comparison operator (==), and you actually have four ways of comparing for equality. Some subtle differences exist between the different methods, which are examined next.

The ReferenceEquals() Method

`ReferenceEquals()` is a `static` method that tests whether two references refer to the same instance of a class, specifically whether the two references contain the same address in memory. As a `static` method, it is not possible to override, so the `System.Object` implementation is what you always have. `ReferenceEquals()` will always return `true` if supplied with two references that refer to the same object instance, and `false` otherwise. It does, however, consider `null` to be equal to `null`:

```
SomeClass x, y;
x = new SomeClass();
y = new SomeClass();
bool B1 = ReferenceEquals(null, null);     // returns true
bool B2 = ReferenceEquals(null,x);         // returns false
bool B3 = ReferenceEquals(x, y);           // returns false because x and y
                                           // point to different objects
```

The virtual Equals() Method

The `System.Object` implementation of the virtual version of `Equals()` also works by comparing references. However, because this method is virtual, you can override it in your own classes to compare objects by value. In particular, if you intend instances of your class to be used as keys in a dictionary, you will need to override this method to compare values. Otherwise, depending on how you override `Object.GetHashCode()`, the dictionary class that contains your objects will either not work at all or will work very inefficiently. One point you should note when overriding `Equals()` is that your override should never throw exceptions. Once again, this is because doing so could cause problems for dictionary classes and possibly certain other .NET base classes that internally call this method.

The static Equals() Method

The static version of `Equals()` actually does the same thing as the virtual instance version. The difference is that the static version takes two parameters and compares them for equality. This method is able to cope when either of the objects is `null`, and, therefore, provides an extra safeguard against throwing exceptions if there is a risk that an object might be `null`. The static overload first checks whether the references it has been passed are `null`. If they are both `null`, it returns `true` (because `null` is considered to be equal to `null`). If just one of them is `null`, it returns `false`. If both references actually refer to something, it calls the virtual instance version of `Equals()`. This means that when you override the instance version of `Equals()`, the effect is as if you were overriding the static version as well.

Comparison Operator (==)

It is best to think of the comparison operator as an intermediate option between strict value comparison and strict reference comparison. In most cases, writing the following means that you are comparing references:

```
bool b = (x == y);   // x, y object references
```

However, it is accepted that there are some classes whose meanings are more intuitive if they are treated as values. In those cases, it is better to override the comparison operator to perform a value comparison. Overriding operators is discussed next, but the obvious example of this is the `System.String` class for which Microsoft has overridden this operator to compare the contents of the strings rather than their references.

Comparing Value Types for Equality

When comparing value types for equality, the same principles hold as for reference types: `ReferenceEquals()` is used to compare references, `Equals()` is intended for value comparisons, and the comparison operator is viewed as an intermediate case. However, the big difference is that value types need to be boxed to be converted to references so that methods can be executed on them. In addition, Microsoft has already overloaded the instance `Equals()` method in the `System.ValueType` class to test equality appropriate to value types. If you call `sA.Equals(sB)` where `sA` and `sB` are instances of some struct, the return value will be `true` or `false`, according to whether `sA` and `sB` contain the same values in all their fields. On the other hand, no overload of == is available by default for your own structs. Writing `(sA == sB)` in any expression will result in a compilation error unless you have provided an overload of == in your code for the struct in question.

Another point is that `ReferenceEquals()` always returns `false` when applied to value types because, to call this method, the value types need to be boxed into objects. Even if you write the following, you will still get the answer of `false`:

```
bool b = ReferenceEquals(v,v);   // v is a variable of some value type
```

The reason for this is that `v` will be boxed separately when converting each parameter, which means you get different references. Because of this, there really is no reason to call `ReferenceEquals()` to compare value types because it doesn't make much sense.

Although the default override of `Equals()` supplied by `System.ValueType` will almost certainly be adequate for the vast majority of structs that you define, you might want to override it again for your own structs to improve performance. Also, if a value type contains reference types as fields, you might want to override `Equals()` to provide appropriate semantics for these fields because the default override of `Equals()` will simply compare their addresses.

OPERATOR OVERLOADING

This section looks at another type of member that you can define for a class or a struct: the *operator overload*.

Operator overloading is something that will be familiar to C++ developers. However, because the concept will be new to both Java and Visual Basic developers, we explain it here. C++ developers will probably prefer to skip ahead to the main operator overloading example.

The point of operator overloading is that you do not always just want to call methods or properties on objects. Often, you need to do things like adding quantities together, multiplying them, or performing logical operations such as comparing objects. Suppose that you had defined a class that represents a mathematical matrix. Now in the world of math, matrices can be added together and multiplied, just like numbers. Therefore, it is quite plausible that you would want to write code like this:

```
Matrix a, b, c;
// assume a, b and c have been initialized
Matrix d = c * (a + b);
```

By overloading the operators, you can tell the compiler what + and * do when used in conjunction with a `Matrix` object, allowing you to write code like the preceding. If you were coding in a language that did not support operator overloading, you would have to define methods to perform those operations. The result would certainly be less intuitive and would probably look something like this:

```
Matrix d = c.Multiply(a.Add(b));
```

With what you have learned so far, operators like + and * have been strictly for use with the predefined data types, and for good reason: the compiler knows what all the common operators mean for those data types. For example, it knows how to add two `long`s or how to divide one `double` by another `double`, and it can generate the appropriate intermediate language code. When you define your own classes or structs, however, you have to tell the compiler everything: what methods are available to call, what fields to store with each instance, and so on. Similarly, if you want to use operators with your own types, you will have to tell the compiler what the relevant operators mean in the context of that class. The way you do that is by defining overloads for the operators.

The other thing we should stress is that overloading is not concerned just with arithmetic operators. You also need to consider the comparison operators, ==, <, >, !=, >=, and <=. Take the statement `if (a==b)`. For classes, this statement will, by default, compare the references `a` and `b`. It tests to see if the references point to the same location in memory, rather than checking to see if the instances actually contain the same data. For the `string` class, this behavior is overridden so that comparing strings really does compare the contents of each string. You might want to do the same for your own classes. For structs, the == operator does not do anything at all by default. Trying to compare two structs to see if they are equal produces a compilation error unless you explicitly overload == to tell the compiler how to perform the comparison.

A large number of situations exist in which being able to overload operators allows you to generate more readable and intuitive code, including:

- Almost any mathematical object such as coordinates, vectors, matrices, tensors, functions, and so on. If you are writing a program that does some mathematical or physical modeling, you will almost certainly use classes representing these objects.
- Graphics programs that use mathematical or coordinate-related objects when calculating positions on-screen.
- A class that represents an amount of money (for example, in a financial program).
- A word processing or text analysis program that uses classes representing sentences, clauses, and so on; you might want to use operators to combine sentences (a more sophisticated version of concatenation for strings).

However, there are also many types for which operator overloading would not be relevant. Using operator overloading inappropriately will make code that uses your types far more difficult to understand. For example, multiplying two `DateTime` objects just does not make any sense conceptually.

How Operators Work

To understand how to overload operators, it's quite useful to think about what happens when the compiler encounters an operator. Using the addition operator (+) as an example, suppose that the compiler processes the following lines of code:

```
int myInteger = 3;
uint myUnsignedInt = 2;
double myDouble = 4.0;
long myLong = myInteger + myUnsignedInt;
double myOtherDouble = myDouble + myInteger;
```

What happens when the compiler encounters the following line?

```
long myLong = myInteger + myUnsignedInt;
```

The compiler identifies that it needs to add two integers and assign the result to a `long`. However, the expression `myInteger + myUnsignedInt` is really just an intuitive and convenient syntax for calling a method that adds two numbers together. The method takes two parameters, `myInteger` and `myUnsignedInt`, and returns their sum. Therefore, the compiler does the same thing as it does for any method call — it looks for the best matching overload of the addition operator based on the parameter types — in this case, one that takes two integers. As with normal overloaded methods, the desired return type does not influence the compiler's choice as to which version of a method it calls. As it happens, the overload called in the example takes two `int` parameters and returns an `int`; this return value is subsequently converted to a `long`.

The next line causes the compiler to use a different overload of the addition operator:

```
double myOtherDouble = myDouble + myInteger;
```

In this instance, the parameters are a `double` and an `int`, but there is not an overload of the addition operator that takes this combination of parameters. Instead, the compiler identifies the best matching overload of the addition operator as being the version that takes two `double`s as its parameters, and it implicitly casts the `int` to a `double`. Adding two `double`s requires a different process from adding two integers. Floating-point numbers are stored as a mantissa and an exponent. Adding them involves bit-shifting the mantissa of one of the `double`s so that the two exponents have the same value, adding the mantissas, then shifting the mantissa of the result and adjusting its exponent to maintain the highest possible accuracy in the answer.

Now, you are in a position to see what happens if the compiler finds something like this:

```
Vector vect1, vect2, vect3;
// initialize vect1 and vect2
vect3 = vect1 + vect2;
vect1 = vect1*2;
```

Here, `Vector` is the struct, which is defined in the following section. The compiler will see that it needs to add two `Vector` instances, `vect1` and `vect2`, together. It will look for an overload of the addition operator, which takes two `Vector` instances as its parameters.

If the compiler finds an appropriate overload, it will call up the implementation of that operator. If it cannot find one, it will look to see if there is any other overload for + that it can use as a best match — perhaps something that has two parameters of other data types that can be implicitly converted to `Vector` instances. If the compiler cannot find a suitable overload, it will raise a compilation error, just as it would if it could not find an appropriate overload for any other method call.

Operator Overloading Example: The Vector Struct

This section demonstrates operator overloading through developing a struct named `Vector` that represents a three-dimensional mathematical vector. Do not worry if mathematics is not your strong point — we will keep the vector example very simple. As far as you are concerned, a 3D-vector is just a set of three numbers (`double`s) that tell you how far something is moving. The variables representing the numbers are called `x`, `y`, and `z`: `x` tells you how far something moves east, `y` tells you how far it moves north, and `z` tells you how far it moves upward (in height). Combine the three numbers and you get the total movement. For example, if `x=3.0`, `y=3.0`, and `z=1.0` (which you would normally write as `(3.0, 3.0, 1.0)`, you're moving 3 units east, 3 units north, and rising upward by 1 unit.

You can add or multiply vectors by other vectors or by numbers. Incidentally, in this context, we use the term *scalar,* which is math-speak for a simple number — in C# terms that is just a `double`. The significance of addition should be clear. If you move first by the vector `(3.0, 3.0, 1.0)` then you move by the vector `(2.0, -4.0, -4.0)`, the total amount you have moved can be worked out by adding the two vectors. Adding vectors means adding each component individually, so you get `(5.0, -1.0, -3.0)`. In this context, mathematicians write `c=a+b`, where `a` and `b` are the vectors and `c` is the resulting vector. You want to be able to use the `Vector` struct the same way.

The following is the definition for `Vector` — containing the member fields, constructors, a `ToString()` override so you can easily view the contents of a `Vector`, and, finally, that operator overload:

```
namespace Wrox.ProCSharp.OOCSharp
{
   struct Vector
   {
      public double x, y, z;

      public Vector(double x, double y, double z)
      {
         this.x = x;
         this.y = y;
         this.z = z;
      }

      public Vector(Vector rhs)
      {
         x = rhs.x;
         y = rhs.y;
         z = rhs.z;
      }

      public override string ToString()
      {
         return "( " + x + ", " + y + ", " + z + " )";
      }
```

code download VectorStruct solution

This example has two constructors that require the initial value of the vector to be specified, either by passing in the values of each component or by supplying another `Vector` whose value can be copied. Constructors like the second one that takes a single `Vector` argument are often termed *copy constructors* because they effectively allow you to initialize a class or struct instance by copying another instance. Note that to keep things simple, the fields are left as `public`. We could have made them `private` and written corresponding properties to access them, but it would not have made any difference to the example, other than to make the code longer.

Here is the interesting part of the `Vector` struct — the operator overload that provides support for the addition operator:

```
      public static Vector operator + (Vector lhs, Vector rhs)
      {
         Vector result = new Vector(lhs);
         result.x += rhs.x;
         result.y += rhs.y;
         result.z += rhs.z;

         return result;
      }
   }
}
```

The operator overload is declared in much the same way as a method, except that the `operator` keyword tells the compiler it is actually an operator overload you are defining. The `operator` keyword is followed by the actual symbol for the relevant operator, in this case the addition operator (+). The return type is whatever type you get when you use this operator. Adding two vectors results in a vector, therefore, the return type is also a `Vector`. For this particular override of the addition operator, the return type is the same as the containing class, but that is not necessarily the case, as you will see later in this example. The two parameters are the things you are operating on. For binary operators (those that take two parameters), such as the addition and subtraction operators, the first parameter is the value on the left of the operator, and the second parameter is the value on the right.

Note that it is convention to name your left-hand parameters `lhs` *(for left-hand side) and your right-hand parameters* `rhs` *(for right-hand side).*

C# requires that all operator overloads be declared as `public` and `static`, which means that they are associated with their class or struct, not with a particular instance. Because of this, the body of the operator overload has no access to non-static class members and has no access to the `this` identifier. This is fine because the parameters provide all the input data the operator needs to know to perform its task.

Now that you understand the syntax for the addition operator declaration, you can look at what happens inside the operator:

```
{
   Vector result = new Vector(lhs);
   result.x += rhs.x;
   result.y += rhs.y;
   result.z += rhs.z;

   return result;
}
```

This part of the code is exactly the same as if you were declaring a method, and you should easily be able to convince yourself that this really will return a vector containing the sum of `lhs` and `rhs` as defined. You simply add the members `x`, `y`, and `z` together individually.

Now all you need to do is write some simple code to test the `Vector` struct. Here it is:

```
static void Main()
{
   Vector vect1, vect2, vect3;

   vect1 = new Vector(3.0, 3.0, 1.0);
   vect2 = new Vector(2.0, -4.0, -4.0);
   vect3 = vect1 + vect2;

   Console.WriteLine("vect1 = " + vect1.ToString());
   Console.WriteLine("vect2 = " + vect2.ToString());
   Console.WriteLine("vect3 = " + vect3.ToString());
}
```

Saving this code as `Vectors.cs` and compiling and running it returns this result:

```
vect1 = ( 3, 3, 1 )
vect2 = ( 2, -4, -4 )
vect3 = ( 5, -1, -3 )
```

Adding More Overloads

In addition to adding vectors, you can multiply and subtract them and compare their values. In this section, you develop the `Vector` example further by adding a few more operator overloads. You will not develop the complete set that you'd probably need for a fully functional `Vector` type, but just enough to demonstrate some other aspects of operator overloading. First, you'll overload the multiplication operator to support multiplying vectors by a scalar and multiplying vectors by another vector.

Multiplying a vector by a scalar simply means multiplying each component individually by the scalar: for example, `2 * (1.0, 2.5, 2.0)` returns `(2.0, 5.0, 4.0)`. The relevant operator overload looks similar to this:

```
public static Vector operator * (double lhs, Vector rhs)
{
   return new Vector(lhs * rhs.x, lhs * rhs.y, lhs * rhs.z);
}
```

code download VectorStructMoreOverloads.sln

This by itself, however, is not sufficient. If `a` and `b` are declared as type `Vector`, it allows you to write code like this:

```
b = 2 * a;
```

The compiler will implicitly convert the integer `2` to a `double` to match the operator overload signature. However, code like the following will not compile:

```
b = a * 2;
```

The thing is that the compiler treats operator overloads exactly as method overloads. It examines all the available overloads of a given operator to find the best match. The preceding statement requires the first parameter to be a `Vector` and the second parameter to be an integer, or something that an integer can be implicitly converted to. You have not provided such an overload. The compiler cannot start swapping the order of parameters, so the fact that you've provided an overload that takes a `double` followed by a `Vector` is not sufficient. You need to explicitly define an overload that takes a `Vector` followed by a `double` as well. There are two possible ways of implementing this. The first way involves breaking down the vector multiplication operation in the same way that you have done for all operators so far:

```
public static Vector operator * (Vector lhs, double rhs)
{
   return new Vector(rhs * lhs.x, rhs * lhs.y, rhs *lhs.z);
}
```

Given that you have already written code to implement essentially the same operation, however, you might prefer to reuse that code by writing:

```
public static Vector operator * (Vector lhs, double rhs)
{
   return rhs * lhs;
}
```

This code works by effectively telling the compiler that if it sees a multiplication of a `Vector` by a `double`, it can simply reverse the parameters and call the other operator overload. The sample code for this chapter uses the second version, because it looks neater and illustrates the idea in action. This version also makes for more maintainable code because it saves duplicating the code to perform the multiplication in two separate overloads.

Next, you need to overload the multiplication operator to support vector multiplication. Mathematics provides a couple of ways of multiplying vectors together, but the one we are interested in here is known as the *dot product* or *inner product,* which actually gives a scalar as a result. That's the reason for this example, to demonstrate that arithmetic operators don't have to return the same type as the class in which they are defined.

In mathematical terms, if you have two vectors `(x, y, z)` and `(X, Y, Z)`, then the inner product is defined to be the value of `x*X + y*Y + z*Z`. That might look like a strange way to multiply two things together, but it is actually very useful because it can be used to calculate various other quantities. Certainly, if you ever end up writing code that displays complex 3D graphics, for example using Direct3D or DirectDraw, you will almost certainly find your code needs to work out inner products of vectors quite often as an intermediate step in calculating where to place objects on the screen. What concerns us here is that we want people using your `Vector` to be able to write `double X = a*b` to calculate the inner product of two `Vector` objects (`a` and `b`). The relevant overload looks like this:

```
public static double operator * (Vector lhs, Vector rhs)
{
   return lhs.x * rhs.x + lhs.y * rhs.y + lhs.z * rhs.z;
}
```

Now that you understand the arithmetic operators, you can check that they work using a simple test method:

```
static void Main()
{
   // stuff to demonstrate arithmetic operations
   Vector vect1, vect2, vect3;
   vect1 = new Vector(1.0, 1.5, 2.0);
   vect2 = new Vector(0.0, 0.0, -10.0);

   vect3 = vect1 + vect2;

   Console.WriteLine("vect1 = " + vect1);
   Console.WriteLine("vect2 = " + vect2);
   Console.WriteLine("vect3 = vect1 + vect2 = " + vect3);
   Console.WriteLine("2*vect3 = " + 2*vect3);
   vect3 += vect2;

   Console.WriteLine("vect3+=vect2 gives " + vect3);

   vect3 = vect1*2;

   Console.WriteLine("Setting vect3=vect1*2 gives " + vect3);

   double dot = vect1*vect3;

   Console.WriteLine("vect1*vect3 = " + dot);
}
```

Running this code (`Vectors2.cs`) produces the following result:

VECTORS2

```
vect1 = ( 1, 1.5, 2 )
vect2 = ( 0, 0, -10 )
vect3 = vect1 + vect2 = ( 1, 1.5, -8 )
2*vect3 = ( 2, 3, -16 )
vect3+=vect2 gives ( 1, 1.5, -18 )
Setting vect3=vect1*2 gives ( 2, 3, 4 )
vect1*vect3 = 14.5
```

This shows that the operator overloads have given the correct results, but if you look at the test code closely, you might be surprised to notice that it actually used an operator that wasn't overloaded — the addition assignment operator, `+=`:

```
   vect3 += vect2;

   Console.WriteLine("vect3 += vect2 gives " + vect3);
```

Although `+=` normally counts as a single operator, it can be broken down into two steps: the addition and the assignment. Unlike the C++ language, C# will not actually allow you to overload the `=` operator, but if you overload `+`, the compiler will automatically use your overload of `+` to work out how to perform a `+=` operation. The same principle works for all the assignment operators such as `-=`, `*=`, `/=`, `&=`, and so on.

Overloading the Comparison Operators

C# has six comparison operators that we introduced earlier in this chapter (see the "Operators" section), and they come in three pairs:

- `==` and `!=`
- `>` and `<`
- `>=` and `<=`

The C# language requires that you overload these operators in pairs. That is, if you overload `==`, you must overload `!=` too; otherwise, you get a compiler error. In addition, the comparison operators must return a `bool`. This is the fundamental difference between these operators and the arithmetic operators. The result of adding or subtracting two quantities, for example, can theoretically be any type depending on the quantities. You have already seen that multiplying two `Vector` objects can be implemented to give a scalar. Another example involves the .NET base class `System.DateTime`. It's possible to subtract two `DateTime` instances, but the result is not a `DateTime`; instead it is a `System.TimeSpan` instance. By contrast, it doesn't really make much sense for a comparison to return anything other than a `bool`.

If you overload `==` and `!=`, you must also override the `Equals()` and `GetHashCode()` methods inherited from `System.Object`; otherwise, you'll get a compiler warning. The reasoning is that the `Equals()` method should implement the same kind of equality logic as the `==` operator.

Apart from these differences, overloading the comparison operators follows the same principles as overloading the arithmetic operators. However, comparing quantities isn't always as simple as you might think. For example, if you simply compare two object references, you will compare the memory address where the objects are stored. This is rarely the desired behavior of a comparison operator, and so you must code the operator to compare the value of the objects and return the appropriate Boolean response. The following example overrides the `==` and `!=` operators for the `Vector` struct. Here is the implementation of `==`:

```
public static bool operator == (Vector lhs, Vector rhs)
{
   if (lhs.x == rhs.x && lhs.y == rhs.y && lhs.z == rhs.z)
      return true;
   else
      return false;
}
```

This approach simply compares two `Vector` objects for equality based on the values of their components. For most structs, that is probably what you will want to do, though in some cases you may need to think carefully about what you mean by equality. For example, if there are embedded classes, should you simply compare whether the references point to the same object (*shallow comparison*) or whether the values of the objects are the same (*deep comparison*)?

A shallow comparison is where the objects point to the same point in memory, whereas deep comparisons are working with values and properties of the object to deem equality. You want to perform equality checks depending on the depth to help you decide what you want to verify.

You also need to override the `!=` operator. The simple way to do this is:

```
public static bool operator != (Vector lhs, Vector rhs)
{
   return ! (lhs == rhs);
}
```

As usual, you should quickly check that your override works with some test code. This time you'll define three `Vector` objects and compare them:

```
static void Main()
{
   Vector vect1, vect2, vect3;

   vect1 = new Vector(3.0, 3.0, -10.0);
   vect2 = new Vector(3.0, 3.0, -10.0);
   vect3 = new Vector(2.0, 3.0, 6.0);

   Console.WriteLine("vect1==vect2 returns  " + (vect1==vect2));
   Console.WriteLine("vect1==vect3 returns  " + (vect1==vect3));
   Console.WriteLine("vect2==vect3 returns  " + (vect2==vect3));

   Console.WriteLine();

   Console.WriteLine("vect1!=vect2 returns  " + (vect1!=vect2));
   Console.WriteLine("vect1!=vect3 returns  " + (vect1!=vect3));
   Console.WriteLine("vect2!=vect3 returns  " + (vect2!=vect3));
}
```

code snippet Vectors3.cs

Compiling this code (the `Vectors3.cs` sample in the code download) generates the following compiler warning because you haven't overridden `Equals()` for your `Vector`. For our purposes here, that does not matter, so we will ignore it.

```
Microsoft (R) Visual C# 2010 Compiler version 4.0.21006.1
for Microsoft (R) .NET Framework version 4.0
Copyright (C) Microsoft Corporation. All rights reserved.

Vectors3.cs(5,11): warning CS0660: 'Wrox.ProCSharp.OOCSharp.Vector' defines
        operator == or operator != but does not override Object.Equals(object o)
Vectors3.cs(5,11): warning CS0661: 'Wrox.ProCSharp.OOCSharp.Vector' defines
        operator == or operator != but does not override Object.GetHashCode()
```

Running the example produces these results at the command line:

VECTORS3

```
vect1==vect2 returns  True
vect1==vect3 returns  False
vect2==vect3 returns  False

vect1!=vect2 returns  False
vect1!=vect3 returns  True
vect2!=vect3 returns  True
```

Which Operators Can You Overload?

It is not possible to overload all the available operators. The operators that you can overload are listed in the following table.

CATEGORY	OPERATORS	RESTRICTIONS
Arithmetic binary	`+, *, /, −, %`	None.
Arithmetic unary	`+, −, ++, --`	None.
Bitwise binary	`&, |, ^, <<, >>`	None.
Bitwise unary	`!, ~true, false`	The `true` and `false` operators must be overloaded as a pair.
Comparison	`==, !=, >=, <=>, <,`	Comparison operators must be overloaded in pairs.
Assignment	`+=, −=, *=, /=, >>=, <<=, %=, &=, |=,  ^=`	You cannot explicitly overload these operators; they are overridden implicitly when you override the individual operators such as +, -, %, and so on.
Index	`[]`	You cannot overload the index operator directly. The indexer member type, discussed in Chapter 2, allows you to support the index operator on your classes and structs.
Cast	`()`	You cannot overload the cast operator directly. User-defined casts (discussed next) allow you to define custom cast behavior.

USER-DEFINED CASTS

Earlier in this chapter (see the "Explicit Conversions" section), you learned that you can convert values between predefined data types through a process of *casting*. You also saw that C# allows two different types of casts: implicit and explicit. This section looks at these types of casts.

For an explicit cast, you *explicitly* mark the cast in your code by writing the destination data type inside parentheses:

```
int I = 3;
long l = I;             // implicit
short s = (short)I;     // explicit
```

For the predefined data types, explicit casts are required where there is a risk that the cast might fail or some data might be lost. The following are some examples:

- When converting from an `int` to a `short`, the `short` might not be large enough to hold the value of the `int`.
- When converting from signed to unsigned data types, incorrect results will be returned if the signed variable holds a negative value.
- When converting from floating-point to integer data types, the fractional part of the number will be lost.
- When converting from a nullable type to a non-nullable type, a value of `null` will cause an exception.

By making the cast explicit in your code, C# forces you to affirm that you understand there is a risk of data loss, and therefore presumably you have written your code to take this into account.

Because C# allows you to define your own data types (structs and classes), it follows that you will need the facility to support casts to and from those data types. The mechanism is that you can define a cast as a member operator of one of the relevant classes. Your cast operator must be marked as either `implicit` or `explicit` to indicate how you are intending it to be used. The expectation is that you follow the same guidelines as for the predefined casts: if you know that the cast is always safe no matter what the value held by the source variable, then you define it as `implicit`. If, however, you know there is a risk of something going wrong for certain values — perhaps some loss of data or an exception being thrown — then you should define the cast as `explicit`.

The syntax for defining a cast is similar to that for overloading operators discussed earlier in this chapter. This is not a coincidence — a cast is regarded as an operator whose effect is to convert from the source type to the destination type. To illustrate the syntax, the following is taken from an example `struct` named `Currency`, which is introduced later in this section:

```
public static implicit operator float (Currency value)
{
   // processing
}
```

The return type of the operator defines the target type of the cast operation, and the single parameter is the source object for the conversion. The cast defined here allows you to implicitly convert the value of a `Currency` into a `float`. Note that if a conversion has been declared as `implicit`, the compiler will permit its use either implicitly or explicitly. If it has been declared as `explicit`, the compiler will only permit it to be used explicitly. In common with other operator overloads, casts must be declared as both `public` and `static`.

Implementing User-Defined Casts

This section illustrates the use of implicit and explicit user-defined casts in an example called `SimpleCurrency` (which, as usual, is available in the code download). In this example, you define a struct, `Currency`, which holds a positive USD ($) monetary value. C# provides the `decimal` type for this purpose, but it is possible you will still want to write your own struct or class to represent monetary values if you want to perform sophisticated financial processing and therefore want to implement specific methods on such a class.

The syntax for casting is the same for structs and classes. This example happens to be for a struct, but would work just as well if you declared `Currency` *as a class.*

Initially, the definition of the `Currency` struct is:

```
struct Currency
{
   public uint Dollars;
   public ushort Cents;

   public Currency(uint dollars, ushort cents)
   {
      this.Dollars = dollars;
      this.Cents = cents;
   }
```

```
      public override string ToString()
      {
         return string.Format("${0}.{1,-2:00}", Dollars,Cents);
      }
   }
```

code snippet SimpleCurrency/Program.cs

The use of unsigned data types for the `Dollar` and `Cents` fields ensures that a `Currency` instance can hold only positive values. It is restricted this way to illustrate some points about explicit casts later on. You might want to use a class like this to hold, for example, salary information for employees of a company (people's salaries tend not to be negative!). To keep the class simple, the fields are public, but usually you would make them `private` and define corresponding properties for the dollars and cents.

Start by assuming that you want to be able to convert `Currency` instances to `float` values, where the integer part of the `float` represents the dollars. In other words, you would like to be able to write code like this:

```
Currency balance = new Currency(10,50);
float f = balance; // We want f to be set to 10.5
```

To be able to do this, you need to define a cast. Hence, you add the following to your `Currency` definition:

```
   public static implicit operator float (Currency value)
   {
      return value.Dollars + (value.Cents/100.0f);
   }
```

The preceding cast is implicit. It is a sensible choice in this case because, as should be clear from the definition of `Currency`, any value that can be stored in the currency can also be stored in a `float`. There is no way that anything should ever go wrong in this cast.

However, if you have a `float` that you would like to be converted to a `Currency`, the conversion is not guaranteed to work. A `float` can store negative values, which `Currency` instances can't, and a `float` can store numbers of a far higher magnitude than can be stored in the (`uint`) `Dollar` field of `Currency`. Therefore, if a `float` contains an inappropriate value, converting it to a `Currency` could give unpredictable results. Because of this risk, the conversion from `float` to `Currency` should be defined as explicit. Here is the first attempt, which will not give quite the correct results, but it is instructive to examine why:

```
   public static explicit operator Currency (float value)
   {
      uint dollars = (uint)value;
      ushort cents = (ushort)((value-dollars)*100);
      return new Currency(dollars, cents);
   }
```

The following code will now successfully compile:

```
float amount = 45.63f;
Currency amount2 = (Currency)amount;
```

However, the following code, if you tried it, would generate a compilation error, because it attempts to use an explicit cast implicitly:

```
float amount = 45.63f;
Currency amount2 = amount;   // wrong
```

By making the cast explicit, you warn the developer to be careful because data loss might occur. However, as you will soon see, this is not how you want your `Currency` struct to behave. Try writing a test harness and running the sample. Here is the `Main()` method, which instantiates a `Currency` struct and attempts a few conversions. At the start of this code, you write out the value of `balance` in two different ways (this will be needed to illustrate something later in the example):

```
static void Main()
{
   try
   {
      Currency balance = new Currency(50,35);

      Console.WriteLine(balance);
      Console.WriteLine("balance is " + balance);
      Console.WriteLine("balance is (using ToString()) " + balance.ToString());

      float balance2= balance;

      Console.WriteLine("After converting to float, = " + balance2);

      balance = (Currency) balance2;

      Console.WriteLine("After converting back to Currency, = " + balance);
      Console.WriteLine("Now attempt to convert out of range value of " +
                        "-$50.50 to a Currency:");

      checked
      {
         balance = (Currency) (-50.50);
         Console.WriteLine("Result is " + balance.ToString());
      }
   }
   catch(Exception e)
   {
      Console.WriteLine("Exception occurred: " + e.Message);
   }
}
```

Notice that the entire code is placed in a `try` block to catch any exceptions that occur during your casts. In addition, the lines that test converting an out-of-range value to `Currency` are placed in a `checked` block in an attempt to trap negative values. Running this code gives this output:

SIMPLECURRENCY

```
50.35
Balance is $50.35
Balance is (using ToString()) $50.35
After converting to float, = 50.35
After converting back to Currency, = $50.34
Now attempt to convert out of range value of -$100.00 to a Currency:
Result is $4294967246.00
```

This output shows that the code did not quite work as expected. First, converting back from `float` to `Currency` gave a wrong result of `$50.34` instead of `$50.35`. Second, no exception was generated when you tried to convert an obviously out-of-range value.

The first problem is caused by rounding errors. If a cast is used to convert from a `float` to a `uint`, the computer will *truncate* the number rather than *rounding* it. The computer stores numbers in binary rather than decimal, and the fraction 0.35 cannot be exactly represented as a binary fraction (just as 1/3 cannot be represented exactly as a decimal fraction; it comes out as 0.3333 recurring). The computer ends up storing a value very slightly lower than 0.35 that can be represented exactly in binary format. Multiply by 100 and you get a number fractionally less than 35, which is truncated to 34 cents. Clearly, in this situation, such errors caused by truncation are serious, and the way to avoid them is to ensure that some intelligent rounding is performed in numerical conversions instead. Luckily, Microsoft has written a class that will do this: `System.Convert`. The `System.Convert` object contains a large number of static methods to perform various numerical conversions, and the one that we want is `Convert.ToUInt16()`. Note that the extra care taken by the `System.Convert` methods does come at a performance cost. You should use them only when you need them.

Let's examine the second problem — why the expected overflow exception wasn't thrown. The issue here is this: the place where the overflow really occurs isn't actually in the `Main()` routine at all — it is inside the code for the cast operator, which is called from the `Main()` method. The code in this method was not marked as `checked`.

The solution is to ensure that the cast itself is computed in a `checked` context too. With both this change and the fix for the first problem, the revised code for the conversion looks like the following:

```
public static explicit operator Currency (float value)
{
   checked
   {
      uint dollars = (uint)value;
      ushort cents = Convert.ToUInt16((value-dollars)*100);
      return new Currency(dollars, cents);
   }
}
```

Note that you use `Convert.ToUInt16()` to calculate the cents, as described earlier, but you do not use it for calculating the dollar part of the amount. `System.Convert` is not needed when working out the dollar amount because truncating the `float` value is what you want there.

You won't see a new set of results with this new `checked` cast just yet because you have some more modifications to make to the `SimpleCurrency` example later in this section.

Casts Between Classes

The `Currency` example involves only classes that convert to or from `float` — one of the predefined data types. However, it is not necessary to involve any of the simple data types. It is perfectly legitimate to define casts to convert between instances of different structs or classes that you have defined. You need to be aware of a couple of restrictions, however:

- You cannot define a cast if one of the classes is derived from the other (these types of casts already exist, as you will see).
- The cast must be defined inside the definition of either the source or the destination data type.

To illustrate these requirements, suppose that you have the class hierarchy shown in Figure 7-1.

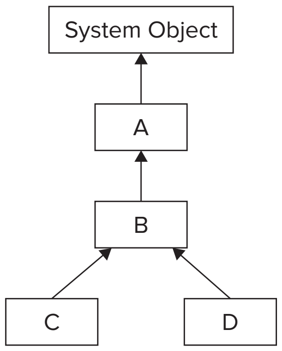

FIGURE 7-1

In other words, classes `C` and `D` are indirectly derived from `A`. In this case, the only legitimate user-defined cast between `A`, `B`, `C`, or `D` would be to convert between classes `C` and `D`, because these classes are not derived from each other. The code to do so might look like this (assuming that you want the casts to be explicit, which is usually the case when defining casts between user-defined classes):

```
public static explicit operator D(C value)
{
   // and so on
}
public static explicit operator C(D value)
{
   // and so on
}
```

For each of these casts, you have a choice of where you place the definitions — inside the class definition of `C` or inside the class definition of `D`, but not anywhere else. C# requires you to put the definition of a cast inside either the source class (or struct) or the destination class (or struct). A side effect of this is that you cannot define a cast between two classes unless you have access to edit the source code for at least one of them. This is sensible because it prevents third parties from introducing casts into your classes.

After you have defined a cast inside one of the classes, you cannot also define the same cast inside the other class. Obviously, there should be only one cast for each conversion — otherwise, the compiler would not know which one to pick.

Casts Between Base and Derived Classes

To see how these casts work, start by considering the case where the source and destination are both reference types, and consider two classes, `MyBase` and `MyDerived`, where `MyDerived` is derived directly or indirectly from `MyBase`.

First, from `MyDerived` to `MyBase`, it is always possible (assuming the constructors are available) to write:

```
MyDerived derivedObject = new MyDerived();
MyBase baseCopy = derivedObject;
```

In this case, you are casting implicitly from `MyDerived` to `MyBase`. This works because of the rule that any reference to a type `MyBase` is allowed to refer to objects of class `MyBase` or to objects of anything derived from `MyBase`. In OO programming, instances of a derived class are, in a real sense, instances of the base class, plus something extra. All the functions and fields defined on the base class are defined in the derived class too.

Alternatively, you can write:

```
MyBase derivedObject = new MyDerived();
MyBase baseObject = new MyBase();
MyDerived derivedCopy1 = (MyDerived) derivedObject;   // OK
MyDerived derivedCopy2 = (MyDerived) baseObject;      // Throws exception
```

This code is perfectly legal C# (in a syntactic sense, that is) and illustrates casting from a base class to a derived class. However, the final statement will throw an exception when executed. When you perform the cast, the object being referred to is examined. Because a base class reference can in principle refer to a derived class instance, it is possible that this object is actually an instance of the derived class that you are attempting to cast to. If that is the case, the cast succeeds, and the derived reference is set to refer to the object. If, however, the object in question is not an instance of the derived class (or of any class derived from it), the cast fails and an exception is thrown.

Notice that the casts that the compiler has supplied, which convert between base and derived class, do not actually do any data conversion on the object in question. All they do is set the new reference to refer to the object if it is legal for that conversion to occur. To that extent, these casts are very different in nature from the ones that you will normally define yourself. For example, in the `SimpleCurrency` example earlier, you defined casts that convert between a `Currency` struct and a `float`. In the `float`-to-`Currency` cast, you actually instantiated a new `Currency` struct and initialized it with the required values. The predefined casts between base and derived classes do not do this. If you actually want to convert a `MyBase` instance into a real `MyDerived` object with values based on the contents of the `MyBase` instance, you would not be able to use the cast syntax to do this. The most sensible option is usually to define a derived class constructor that takes a base class instance as a parameter and have this constructor perform the relevant initializations:

```
class DerivedClass: BaseClass
{
   public DerivedClass(BaseClass rhs)
   {
      // initialize object from the Base instance
   }
   // etc.
```

Boxing and Unboxing Casts

The previous discussion focused on casting between base and derived classes where both participants were reference types. Similar principles apply when casting value types, although in this case it is not possible to simply copy references — some copying of data must take place.

It is not, of course, possible to derive from structs or primitive value types. Casting between base and derived structs invariably means casting between a primitive type or a struct and `System.Object`. (Theoretically, it is possible to cast between a struct and `System.ValueType`, though it is hard to see why you would want to do this.)

The cast from any struct (or primitive type) to `object` is always available as an implicit cast — because it is a cast from a derived to a base type — and is just the familiar process of *boxing*. For example, with the `Currency` struct:

```
Currency balance = new Currency(40,0);
object baseCopy = balance;
```

When this implicit cast is executed, the contents of `balance` are copied onto the heap into a boxed object, and the `baseCopy` object reference is set to this object. What actually happens behind the scenes is this: When you originally defined the `Currency` struct, the .NET Framework implicitly supplied another (hidden) class, a boxed `Currency` class, which contains all the same fields as the `Currency` struct, but it is a reference type, stored on the heap. This happens whenever you define a value type — whether it is a `struct` or `enum`, and similar boxed reference types exist corresponding to all the primitive value types of `int`, `double`, `uint`, and so on. It is not possible, or necessary, to gain direct programmatic access to any of these boxed classes in source code, but they are the objects that are working behind the scenes whenever a value type is cast to `object`. When you implicitly cast `Currency` to `object`, a boxed `Currency` instance gets instantiated and initialized with all the data from the `Currency` struct. In the preceding code, it is this boxed `Currency` instance that `baseCopy` will refer to. By these means, it is possible for casting from derived to base type to work syntactically in the same way for value types as for reference types.

Casting the other way is known as *unboxing*. Just as for casting between a base reference type and a derived reference type, it is an explicit cast because an exception will be thrown if the object being cast is not of the correct type:

```
object derivedObject = new Currency(40,0);
object baseObject = new object();
Currency derivedCopy1 = (Currency)derivedObject;   // OK
Currency derivedCopy2 = (Currency)baseObject;      // Exception thrown
```

This code works in a way similar to the code presented earlier for reference types. Casting derivedObject to Currency works fine because derivedObject actually refers to a boxed Currency instance — the cast will be performed by copying the fields out of the boxed Currency object into a new Currency struct. The second cast fails because baseObject does not refer to a boxed Currency object.

When using boxing and unboxing, it is important to understand that both processes actually copy the data into the new boxed or unboxed object. Hence, manipulations on the boxed object, for example, will not affect the contents of the original value type.

Multiple Casting

One thing you will have to watch for when you are defining casts is that if the C# compiler is presented with a situation in which no direct cast is available to perform a requested conversion, it will attempt to find a way of combining casts to do the conversion. For example, with the Currency struct, suppose the compiler encounters a few lines of code like this:

```
Currency balance = new Currency(10,50);
long amount = (long)balance;
double amountD = balance;
```

You first initialize a Currency instance, and then you attempt to convert it to a long. The trouble is that you haven't defined the cast to do that. However, this code will still compile successfully. What will happen is that the compiler will realize that you have defined an implicit cast to get from Currency to float, and the compiler already knows how to explicitly cast a float to a long. Hence, it will compile that line of code into IL code that converts balance first to a float, and then converts that result to a long. The same thing happens in the final line of the code, when you convert balance to a double. However, because the cast from Currency to float and the predefined cast from float to double are both implicit, you can write this conversion in your code as an implicit cast. If you had preferred, you could have specified the casting route explicitly:

```
Currency balance = new Currency(10,50);
long amount = (long)(float)balance;
double amountD = (double)(float)balance;
```

However, in most cases, this would be seen as needlessly complicating your code. The following code, by contrast, would produce a compilation error:

```
Currency balance = new Currency(10,50);
long amount = balance;
```

The reason is that the best match for the conversion that the compiler can find is still to convert first to float then to long. The conversion from float to long needs to be specified explicitly, though.

Not all of this by itself should give you too much trouble. The rules are, after all, fairly intuitive and designed to prevent any data loss from occurring without the developer knowing about it. However, the problem is that if you are not careful when you define your casts, it is possible for the compiler to figure out a path that leads to unexpected results. For example, suppose that it occurs to someone else in the group writing the Currency struct that it would be useful to be able to convert a uint containing the total number of cents in an amount into a Currency (cents, not dollars, because the idea is not to lose the fractions of a dollar). Therefore, this cast might be written to try to achieve this:

```
public static implicit operator Currency (uint value)
{
   return new Currency(value/100u, (ushort)(value%100));
} // Do not do this!
```

Note the u after the first 100 in this code to ensure that value/100u is interpreted as a uint. If you had written value/100, the compiler would have interpreted this as an int, not a uint.

The code comment Do not do this is clearly commented in this code, and here is why. Look at the following code snippet; all it does is convert a uint containing 350 into a Currency and back again. What do you think bal2 will contain after executing this?

```
uint bal = 350;
Currency balance = bal;
uint bal2 = (uint)balance;
```

The answer is not 350 but 3! Moreover, it all follows logically. You convert 350 implicitly to a Currency, giving the result balance.Dollars = 3, balance.Cents = 50. Then the compiler does its usual figuring out of the best path for the conversion back. Balance ends up being implicitly converted to a float (value 3.5), and this is converted explicitly to a uint with value 3.

Of course, other instances exist in which converting to another data type and back again causes data loss. For example, converting a float containing 5.8 to an int and back to a float again will lose the fractional part, giving you a result of 5, but there is a slight difference in principle between losing the fractional part of a number and dividing an integer by more than 100. Currency has suddenly become a rather dangerous class that does strange things to integers!

The problem is that there is a conflict between how your casts interpret integers. The casts between Currency and float interpret an integer value of 1 as corresponding to one dollar, but the latest uint-to-Currency cast interprets this value as one cent. This is an example of very poor design. If you want your classes to be easy to use, you should make sure that all your casts behave in a way that is mutually compatible, in the sense that they intuitively give the same results. In this case, the solution is obviously to rewrite the uint-to-Currency cast so that it interprets an integer value of 1 as one dollar:

```
public static implicit operator Currency (uint value)
{
   return new Currency(value, 0);
}
```

Incidentally, you might wonder whether this new cast is necessary at all. The answer is that it could be useful. Without this cast, the only way for the compiler to carry out a uint-to-Currency conversion would be via a float. Converting directly is a lot more efficient in this case, so having this extra cast provides performance benefits, though you need to make sure it gives the same result as via a float, which you have now done. In other situations, you may also find that separately defining casts for different predefined data types allows more conversions to be implicit rather than explicit, though that is not the case here.

A good test of whether your casts are compatible is to ask whether a conversion will give the same results (other than perhaps a loss of accuracy as in float-to-int conversions), regardless of which path it takes. The Currency class provides a good example of this. Look at this code:

```
Currency balance = new Currency(50, 35);
ulong bal = (ulong) balance;
```

At present, there is only one way that the compiler can achieve this conversion: by converting the Currency to a float implicitly, then to a ulong explicitly. The float-to-ulong conversion requires an explicit conversion, but that is fine because you have specified one here.

Suppose, however, that you then added another cast, to convert implicitly from a Currency to a uint. You will actually do this by modifying the Currency struct by adding the casts both to and from uint. This code is available as the SimpleCurrency2 example:

```
      public static implicit operator Currency (uint value)
      {
         return new Currency(value, 0);
      }

      public static implicit operator uint (Currency value)
      {
         return value.Dollars;
      }
```

Now the compiler has another possible route to convert from Currency to ulong: to convert from Currency to uint implicitly, then to ulong implicitly. Which of these two routes will it take? C# has some precise rules about the best route for the compiler if there are several possibilities. (The rules are not detailed in this book, but if you are interested, details are in the MSDN documentation.) The best answer is that you should design your casts so that all routes give the same answer (other than possible loss of precision), in which case it doesn't really matter which one the compiler picks. (As it happens in this case, the compiler picks the `Currency`-to-`uint`-to-`ulong` route in preference to `Currency`-to-`float`-to-`ulong`.)

To test the `SimpleCurrency2` sample, add this code to the test code for `SimpleCurrency`:

```
try
{
   Currency balance = new Currency(50,35);

   Console.WriteLine(balance);
   Console.WriteLine("balance is " + balance);
   Console.WriteLine("balance is (using ToString()) " + balance.ToString());

   uint balance3 = (uint) balance;

   Console.WriteLine("Converting to uint gives " + balance3);
```

code snippet SimpleCurrency2/Program.cs

Running the sample now gives you these results:

SIMPLECURRENCY2

```
50
balance is $50.35
balance is (using ToString()) $50.35
Converting to uint gives 50
After converting to float, = 50.35
After converting back to Currency, = $50.34
Now attempt to convert out of range value of -$50.50 to a Currency:
Result is $4294967246.00
```

The output shows that the conversion to `uint` has been successful, though as expected, you have lost the cents part of the `Currency` in making this conversion. Casting a negative `float` to `Currency` has also produced the expected overflow exception now that the `float`-to-`Currency` cast itself defines a `checked` context.

However, the output also demonstrates one last potential problem that you need to be aware of when working with casts. The very first line of output has not displayed the balance correctly, displaying `50` instead of `$50.35`. Consider these lines:

```
Console.WriteLine(balance);
Console.WriteLine("balance is " + balance);
Console.WriteLine("balance is (using ToString()) " + balance.ToString());
```

Only the last two lines correctly display the `Currency` as a string. So what is going on? The problem here is that when you combine casts with method overloads, you get another source of unpredictability. We will look at these lines in reverse order.

The third `Console.WriteLine()` statement explicitly calls the `Currency.ToString()` method, ensuring that the `Currency` is displayed as a string. The second does not do so. However, the string literal `"balance is"` passed to `Console.WriteLine()` makes it clear to the compiler that the parameter is to be interpreted as a string. Hence, the `Currency.ToString()` method will be called implicitly.

The very first `Console.WriteLine()` method, however, simply passes a raw `Currency` struct to `Console.WriteLine()`. Now, `Console.WriteLine()` has many overloads, but none of them takes a `Currency` struct. So the compiler will start fishing around to see what it can cast the `Currency` to in order to make it match up with one of the overloads of `Console.WriteLine()`. As it happens, one of the `Console.WriteLine()` overloads is designed to display `uint`s quickly and efficiently, and it takes a `uint` as a parameter — you have now supplied a cast that converts `Currency` implicitly to `uint`.

In fact, `Console.WriteLine()` has another overload that takes a `double` as a parameter and displays the value of that `double`. If you look closely at the output from the first `SimpleCurrency` example, you will find the very first line of output displayed `Currency` as a `double`, using this overload. In that example, there wasn't a direct cast from `Currency` to `uint`, so the compiler picked `Currency`-to-`float`-to-`double` as its preferred way of matching up the available casts to the available `Console.WriteLine()` overloads. However, now that there is a direct cast to `uint` available in `SimpleCurrency2`, the compiler has opted for this route.

The upshot of this is that if you have a method call that takes several overloads, and you attempt to pass it a parameter whose data type doesn't match any of the overloads exactly, then you are forcing the compiler to decide not only what casts to use to perform the data conversion, but which overload, and hence which data conversion, to pick. The compiler always works logically and according to strict rules, but the results may not be what you expected. If there is any doubt, you are better off specifying which cast to use explicitly.

SUMMARY

This chapter looked at the standard operators provided by C#, described the mechanics of object equality, and examined how the compiler converts the standard data types from one to another. It also demonstrated how you can implement custom operator support on your data types using operator overloads. Finally, this chapter looked at a special type of operator overload, the cast operator, which allows you to specify how instances of your types are converted to other data types.

8 Delegates, Lambdas, and Events

WHAT'S IN THIS CHAPTER?

- ➤ Delegates
- ➤ Lambda expressions
- ➤ Events

Delegates are the .NET version of addresses to methods. Compare this to C++, where function pointers are nothing more than a pointer to a memory location that are not type-safe. You have no idea what a pointer is really pointing to, and items such as parameters and return types are not known. This is completely different with .NET; delegates are type-safe classes that define the return types and types of parameters. The delegate class not only contains a reference to a method, but can hold references to multiple methods.

Lambda expressions are directly related to delegates. When the parameter is a delegate type, you can use a Lambda expression to implement a method that's referenced from the delegate.

This chapter teaches you the basics of delegates and Lambda expressions, and shows you how to implement methods called by delegates with Lambda expressions. It also demonstrates how .NET uses delegates as the means of implementing events.

DELEGATES

Delegates exist for situations in which you want to pass methods around to other methods. To see what that means, consider this line of code:

```
int i = int.Parse("99");
```

You are so used to passing data to methods as parameters, as in this example, that you don't consciously think about it, and for this reason the idea of passing methods around instead of data might sound a little strange. However, there are cases in which you have a method that does something, and rather than operating on data, the method might need to do something that involves invoking another method. To complicate things further, you do not know at compile time what this second method is. That information is available only at runtime and hence will need to be passed in as a parameter to the first method. That might sound confusing but should become clearer with a couple of examples:

Starting threads and tasks — It is possible in C# to tell the computer to start some new sequence of execution in parallel with what it is currently doing. Such a sequence is known as a *thread*, and starting one up is done using the `Start()` method on an instance of one of the base classes, `System.Threading.Thread`. If you tell the computer to start a new sequence of execution, you have to tell it where to start that sequence. You have to supply it with the details of a method in which execution can start. In other words, the constructor of the `Thread` class takes a parameter that defines the method to be invoked by the thread.

- **Generic library classes** — Many libraries contain code to perform various standard tasks. It is usually possible for these libraries to be self-contained, in the sense that you know when you write to the library exactly how the task must be performed. However, sometimes the task contains some subtask, which only the individual client code that uses the library knows how to perform. For example, say that you want to write a class that takes an array of objects and sorts them into ascending order. Part of the sorting process involves repeatedly taking two of the objects in the array and comparing them to see which one should come first. If you want to make the class capable of sorting arrays of any object, there is no way that it can tell in advance how to do this comparison. The client code that hands your class the array of objects will also have to tell your class how to do this comparison for the particular objects it wants sorted. The client code has to pass your class details of an appropriate method that can be called and does the comparison.
- **Events** — The general idea here is that often you have code that needs to be informed when some event takes place. GUI programming is full of situations similar to this. When the event is raised, the runtime will need to know what method should be executed. This is done by passing the method that handles the event as a parameter to a delegate. This is discussed later in this chapter.

In C and C++, you can just take the address of a function and pass this as a parameter. There's no type safety with C. You can pass any function to a method where a function pointer is required. Unfortunately, this direct approach not only causes some problems with type safety but also neglects the fact that when you are doing object-oriented programming, methods rarely exist in isolation, but usually need to be associated with a class instance before they can be called. As a result of these problems, the .NET Framework does not syntactically permit this direct approach. Instead, if you want to pass methods around, you have to wrap up the details of the method in a new kind of object, a delegate. Delegates quite simply are a special type of object — special in the sense that, whereas all the objects defined up to now contain data, a delegate contains the address of a method, or the address of multiple methods.

Declaring Delegates

When you want to use a class in C#, you do so in two stages. First, you need to define the class — that is, you need to tell the compiler what fields and methods make up the class. Then (unless you are using only static methods), you instantiate an object of that class. With delegates it is the same process. You have to start by defining the delegates you want to use. Defining delegates means telling the compiler what kind of method a delegate of that type will represent. Then, you have to create one or more instances of that delegate. Behind the scenes, the compiler creates a class that represents the delegate.

The syntax for defining delegates looks like this:

```
delegate void IntMethodInvoker(int x);
```

In this case, you have defined a delegate called `IntMethodInvoker`, and you have indicated that each instance of this delegate can hold a reference to a method that takes one `int` parameter and returns `void`. The crucial point to understand about delegates is that they are type-safe. When you define the delegate, you have to give full details of the signature and the return type of the method that it is going to represent.

One good way of understanding delegates is by thinking of a delegate as something that gives a name to a method signature and the return type.

Suppose that you want to define a delegate called `TwoLongsOp` that will represent a method that takes two `long`s as its parameters and returns a `double`. You could do so like this:

```
delegate double TwoLongsOp(long first, long second);
```

Or, to define a delegate that will represent a method that takes no parameters and returns a `string`, you might write this:

```
delegate string GetAString();
```

The syntax is similar to that for a method definition, except that there is no method body and the definition is prefixed with the keyword `delegate`. Because what you are doing here is basically defining a new class, you can define a delegate in any of the same places that you would define a class — that is to say, either inside another class, outside of any class, or in a namespace as a top-level object. Depending on how visible you want your definition to be, and the scope of the delegate, you can apply any of the normal access modifiers to delegate definitions — `public`, `private`, `protected`, and so on:

```
public delegate string GetAString();
```

We really mean what we say when we describe defining a delegate as defining a new class. Delegates are implemented as classes derived from the class `System.MulticastDelegate`*, which is derived from the base class* `System.Delegate`*. The C# compiler is aware of this class and uses its delegate syntax to shield you from the details of the operation of this class. This is another good example of how C# works in conjunction with the base classes to make programming as easy as possible.*

After you have defined a delegate, you can create an instance of it so that you can use it to store details of a particular method.

There is an unfortunate problem with terminology here. With classes there are two distinct terms — class, *which indicates the broader definition, and* object, *which means an instance of the class. Unfortunately, with delegates there is only the one term;* delegate *can refer to both the class and the object. When you create an instance of a delegate, what you have created is also referred to as a delegate. You need to be aware of the context to know which meaning we are using when we talk about delegates.*

Using Delegates

The following code snippet demonstrates the use of a delegate. It is a rather long-winded way of calling the `ToString()` method on an `int`:

```
private delegate string GetAString();

static void Main()
{
   int x = 40;
   GetAString firstStringMethod = new GetAString(x.ToString);
   Console.WriteLine("String is {0}", firstStringMethod());
```

```
        // With firstStringMethod initialized to x.ToString(),
        // the above statement is equivalent to saying
        // Console.WriteLine("String is {0}", x.ToString());
    }
```

code snippet GetAStringDemo/Program.cs

In this code, you instantiate a delegate of type `GetAString`, and you initialize it so it refers to the `ToString()` method of the integer variable `x`. Delegates in C# always syntactically take a one-parameter constructor, the parameter being the method to which the delegate will refer. This method must match the signature with which you originally defined the delegate. So in this case, you would get a compilation error if you tried to initialize the variable `firstStringMethod` with any method that did not take any parameters and return a string. Notice that, because `int.ToString()` is an instance method (as opposed to a static one), you need to specify the instance (`x`) as well as the name of the method to initialize the delegate properly.

The next line actually uses the delegate to display the string. In any code, supplying the name of a delegate instance, followed by brackets containing any parameters, has exactly the same effect as calling the method wrapped by the delegate. Hence, in the preceding code snippet, the `Console.WriteLine()` statement is completely equivalent to the commented-out line.

In fact, supplying brackets to the delegate instance is the same as invoking the `Invoke()` method of the delegate class. Because `firstStringMethod` is a variable of a delegate type, the C# compiler replaces `firstStringMethod()` with `firstStringMethod.Invoke()`:

```
    firstStringMethod();
    firstStringMethod.Invoke();
```

For less typing, at every place where a delegate instance is needed, you can just pass the name of the address. This is known by the term *delegate inference*. This C# feature works as long as the compiler can resolve the delegate instance to a specific type. The example initialized the variable `firstStringMethod` of type `GetAString` with a new instance of the delegate `GetAString`:

```
        GetAString firstStringMethod = new GetAString(x.ToString);
```

You can write the same just by passing the method name with the variable `x` to the variable `firstStringMethod`:

```
        GetAString firstStringMethod = x.ToString;
```

The code that is created by the C# compiler is the same. The compiler detects that a delegate type is required with `firstStringMethod`, so it creates an instance of the delegate type `GetAString` and passes the address of the method with the object `x` to the constructor.

Be aware that you can't type the brackets to the method name as `x.ToString()` *and pass it to the delegate variable. This would be an invocation of the method. The invocation of* `x.ToString()` *returns a string object that can't be assigned to the delegate variable. You can only assign the address of a method to the delegate variable.*

Delegate inference can be used any place a delegate instance is required. Delegate inference can also be used with events because events are based on delegates (as you will see later in this chapter).

One feature of delegates is that they are type-safe to the extent that they ensure the signature of the method being called is correct. However, interestingly, they do not care what type of object the method is being called against or even whether the method is a static method or an instance method.

An instance of a given delegate can refer to any instance or static method on any object of any type, provided that the signature of the method matches the signature of the delegate.

To demonstrate this, the following example expands the previous code snippet so that it uses the `firstStringMethod` delegate to call a couple of other methods on another object — an instance method and a static method. For this, you use the `Currency` struct. The `Currency` struct has its own overload of `ToString()` and a static method with the same signature to `GetCurrencyUnit()`. This way the same delegate variable can be used to invoke these methods.

```
struct Currency
{
  public uint Dollars;
  public ushort Cents;

  public Currency(uint dollars, ushort cents)
  {
     this.Dollars = dollars;
     this.Cents = cents;
  }

  public override string ToString()
  {
     return string.Format("${0}.{1,2:00}", Dollars,Cents);
  }

  public static string GetCurrencyUnit()
  {
     return "Dollar";
  }

  public static explicit operator Currency (float value)
  {
     checked
     {
        uint dollars = (uint)value;
        ushort cents = (ushort)((value-dollars)*100);
        return new Currency(dollars, cents);
     }
  }

  public static implicit operator float (Currency value)
  {
     return value.Dollars + (value.Cents/100.0f);
  }

  public static implicit operator Currency (uint value)
  {
     return new Currency(value, 0);
  }

  public static implicit operator uint (Currency value)
  {
     return value.Dollars;
  }
}
```

code snippet GetAStringDemo/Currency.cs

Now you can use your `GetAString` instance as follows:

```
private delegate string GetAString();

static void Main()
{
   int x = 40;
   GetAString firstStringMethod = x.ToString;
   Console.WriteLine("String is {0}", firstStringMethod());

   Currency balance = new Currency(34, 50);

   // firstStringMethod references an instance method
   firstStringMethod = balance.ToString;
   Console.WriteLine("String is {0}", firstStringMethod());

   // firstStringMethod references a static method
   firstStringMethod = new GetAString(Currency.GetCurrencyUnit);
   Console.WriteLine("String is {0}", firstStringMethod());
}
```

This code shows how you can call a method via a delegate and subsequently reassign the delegate to refer to different methods on different instances of classes, even static methods or methods against instances of different types of class, provided that the signature of each method matches the delegate definition.

When you run the application, you get the output from the different methods that are referenced by the delegate:

```
String is 40
String is $34.50
String is Dollar
```

However, you still haven't seen the process of actually passing a delegate to another method. Nor have you actually achieved anything particularly useful yet. It is possible to call the `ToString()` method of `int` and `Currency` objects in a much more straightforward way than using delegates! Unfortunately, the nature of delegates requires a fairly complex example before you can really appreciate their usefulness. The next section presents two delegate examples. The first one simply uses delegates to call a couple of different operations. It illustrates how to pass delegates to methods and how you can use arrays of delegates — although arguably it still doesn't do much that you couldn't do a lot more simply without delegates. Then, a second, much more complex example of a `BubbleSorter` class is presented, which implements a method to sort out arrays of objects into increasing order. This class would be difficult to write without using delegates.

Simple Delegate Example

This example defines a `MathOperations` class that has a couple of static methods to perform two operations on doubles. Then you use delegates to call up these methods. The math class looks like this:

```
class MathOperations
{
   public static double MultiplyByTwo(double value)
   {
      return value * 2;
   }

   public static double Square(double value)
   {
      return value * value;
   }
}
```

code snippet SimpleDelegate/MathOperations.cs

You call up these methods like this:

```
using System;

namespace Wrox.ProCSharp.Delegates
{
   delegate double DoubleOp(double x);

   class Program
   {
      static void Main()
      {
         DoubleOp[] operations =
            {
               MathOperations.MultiplyByTwo,
               MathOperations.Square
            };

         for (int i=0; i < operations.Length; i++)
         {
            Console.WriteLine("Using operations[{0}]:", i);
            ProcessAndDisplayNumber(operations[i], 2.0);
            ProcessAndDisplayNumber(operations[i], 7.94);
            ProcessAndDisplayNumber(operations[i], 1.414);
            Console.WriteLine();
         }
      }

      static void ProcessAndDisplayNumber(DoubleOp action, double value)
      {
         double result = action(value);
         Console.WriteLine(
            "Value is {0}, result of operation is {1}", value, result);
      }
   }
}
```

code snippet SimpleDelegate/Program.cs

In this code, you instantiate an array of `DoubleOp` delegates (remember that after you have defined a delegate class, you can basically instantiate instances just as you can with normal classes, so putting some into an array is no problem). Each element of the array gets initialized to refer to a different operation implemented by the `MathOperations` class. Then, you loop through the array, applying each operation to three different values. This illustrates one way of using delegates — that you can group methods together into an array using them, so that you can call several methods in a loop.

The key lines in this code are the ones in which you actually pass each delegate to the `ProcessAndDisplayNumber()` method, for example:

```
            ProcessAndDisplayNumber(operations[i], 2.0);
```

Here, you are passing in the name of a delegate but without any parameters. Given that `operations[i]` is a delegate, syntactically:

- `operations[i]` means the *delegate* (that is, the method represented by the delegate).
- `operations[i](2.0)` means *actually call this method, passing in the value in parentheses.*

The `ProcessAndDisplayNumber()` method is defined to take a delegate as its first parameter:

```
      static void ProcessAndDisplayNumber(DoubleOp action, double value)
```

Then, when in this method, you call

```
        double result = action(value);
```

this actually causes the method that is wrapped up by the `action` delegate instance to be called and its return result stored in `Result`. Running this example gives you the following:

```
SimpleDelegate
Using operations[0]:
Value is 2, result of operation is 4
Value is 7.94, result of operation is 15.88
Value is 1.414, result of operation is 2.828

Using operations[1]:
Value is 2, result of operation is 4
Value is 7.94, result of operation is 63.0436
Value is 1.414, result of operation is 1.999396
```

Action<T> and Func<T> Delegates

Instead of defining a new delegate type with every parameter and return type, you can use the `Action<T>` and `Func<T>` delegates. The generic `Action<T>` delegate is meant to reference a method with `void` return. This delegate class exists in different variants so that you can pass up to 16 different parameter types. The `Action` class without the generic parameter is for calling methods without parameters. `Action<in T>` is to call a method with one parameter, `Action<in T1, in T2>` for a method with two parameters, and `Action<in T1, in T2, in T3, in T4, in T5, in T6, in T7, in T8>` for a method with eight parameters.

The `Func<T>` delegates can be used in a similar manner. `Func<T>` allows you to invoke methods with a return type. Similar to `Action<T>`, `Func<T>` is defined in different variants to pass up to 16 parameter types and a return type. `Func<out TResult>` is the delegate type to invoke a method with a return type and without parameters. `Func<in T, out TResult>` is for a method with one parameter, and `Func<in T1, in T2, in T3, in T4, out TResult>` is for a method with four parameters.

The example in the preceding section declared a delegate with `double` parameter and `double` return type:

```
delegate double DoubleOp(double x);
```

Instead of declaring the custom delegate `DoubleOp` you can use the `Func<in T, out TResult>` delegate. You can declare a variable of the delegate type, or as shown here an array of the delegate type:

```
        Func<double, double>[] operations =
           {
              MathOperations.MultiplyByTwo,
              MathOperations.Square
           };
```

and use it with the `ProcessAndDisplayNumber()` method as parameter:

```
     static void ProcessAndDisplayNumber(Func<double, double> action,
                                         double value)
     {
        double result = action(value);
        Console.WriteLine(
           "Value is {0}, result of operation is {1}", value, result);
     }
```

BubbleSorter Example

You are now ready for an example that will show the real usefulness of delegates. You are going to write a class called `BubbleSorter`. This class implements a static method, `Sort()`, which takes as its first parameter an array of objects, and rearranges this array into ascending order. For example, if you were to pass it this array of ints, {0, 5, 6, 2, 1}, it would rearrange this array into {0, 1, 2, 5, 6}.

The bubble-sorting algorithm is a well-known and very simple way of sorting numbers. It is best suited to small sets of numbers, because for larger sets of numbers (more than about 10) far more efficient algorithms are available. It works by repeatedly looping through the array, comparing each pair of numbers and, if necessary, swapping them, so that the largest numbers progressively move to the end of the array. For sorting ints, a method to do a bubble sort might look similar to this:

```
bool swapped = true;
do
{
    swapped = false;
    for (int i = 0; i < sortArray.Length — 1; i++)
    {
        if (sortArray[i] < sortArray[i+1])) // problem with this test
        {
            int temp = sortArray[i];
            sortArray[i] = sortArray[i + 1];
            sortArray[i + 1] = temp;
            swapped = true;
        }
    }
} while (swapped);
```

This is all very well for ints, but you want your Sort() method to be able to sort any object. In other words, if some client code hands you an array of Currency structs or any other class or struct that it may have defined, you need to be able to sort the array. This presents a problem with the line if(sortArray[i] < sortArray[i+1]) in the preceding code, because that requires you to compare two objects on the array to see which one is greater. You can do that for ints, but how are you to do it for some new class that doesn't implement the < operator? The answer is that the client code that knows about the class will have to pass in a delegate wrapping a method that will do the comparison. Also, instead of using an int type for the *temp* variable, a generic Sort() method can be implemented using a generic type.

With a generic Sort<T>() method accepting type T, a comparison method is needed that has two parameters of type T and a return type of type bool for the if comparison. This method can be referenced from a Func<T1, T2, TResult> delegate where T1 and T2 are the same type: Func<T, T, bool>.

This way you give your Sort<T> method this signature:

```
static public void Sort<T>(IList<T> sortArray, Func<T, T, bool> comparison)
```

The documentation for this method states that comparison must refer to a method that takes two arguments, and returns true if the value of the first argument is *smaller than* the second one.

Now you are all set. Here is the definition for the BubbleSorter class:

```
class BubbleSorter
{
    static public void Sort<T>(IList<T> sortArray, Func<T, T, bool> comparison)
    {
        bool swapped = true;
        do
        {
            swapped = false;
            for (int i = 0; i < sortArray.Count — 1; i++)
            {
                if (comparison(sortArray[i+1], sortArray[i]))
                {
                    T temp = sortArray[i];
                    sortArray[i] = sortArray[i + 1];
```

```
                        sortArray[i + 1] = temp;
                        swapped = true;
                    }
                }
            } while (swapped);
        }
    }
```

code snippet BubbleSorter/BubbleSorter.cs

To use this class, you need to define some other class, which you can use to set up an array that needs sorting. For this example, assume that the Mortimer Phones mobile phone company has a list of employees and wants them sorted according to salary. The employees are each represented by an instance of a class, `Employee`, which looks similar to this:

```
class Employee
{
   public Employee(string name, decimal salary)
   {
      this.Name = name;
      this.Salary = salary;
   }

   public string Name { get; private set; }
   public decimal Salary { get; private set; }

   public override string ToString()
   {
      return string.Format("{0}, {1:C}", Name, Salary);
   }

   public static bool CompareSalary(Employee e1, Employee e2)
   {
      return e1.Salary < e2.Salary;
   }
}
```

code snippet BubbleSorter/Employee.cs

Notice that to match the signature of the `Func<T, T, bool>` delegate, you have to define `CompareSalary` in this class as taking two `Employee` references and returning a Boolean. In the implementation the comparison based on salary is performed.

Now you are ready to write some client code to request a sort:

```
using System;

namespace Wrox.ProCSharp.Delegates
{
   class Program
   {
      static void Main()
      {
         Employee[] employees =
         {
              new Employee("Bugs Bunny", 20000),
              new Employee("Elmer Fudd", 10000),
              new Employee("Daffy Duck", 25000),
              new Employee("Wile Coyote", 1000000.38m),
              new Employee("Foghorn Leghorn", 23000),
              new Employee("RoadRunner", 50000)
         };
```

```
            BubbleSorter.Sort(employees, Employee.CompareSalary);

            foreach (var employee in employees)
            {
               Console.WriteLine(employee);
            }
         }
      }
   }
```

code snippet BubbleSorter/Program.cs

Running this code shows that the `Employees` are correctly sorted according to salary:

```
BubbleSorter
Elmer Fudd, $10,000.00
Bugs Bunny, $20,000.00
Foghorn Leghorn, $23,000.00
Daffy Duck, $25,000.00
RoadRunner, $50,000.00
Wile Coyote, $1,000,000.38
```

Multicast Delegates

So far, each of the delegates you have used wraps just one single method call. Calling the delegate amounts to calling that method. If you want to call more than one method, you need to make an explicit call through a delegate more than once. However, it is possible for a delegate to wrap more than one method. Such a delegate is known as a *multicast delegate*. If a multicast delegate is called, it will successively call each method in order. For this to make sense, the delegate signature should return a `void`; otherwise, you would only get the result of the last method that is invoked by the delegate.

With a `void` return type the `Action<double>` delegate can be used.

```
class Program
{
   static void Main()
   {
      Action<double> operations = MathOperations.MultiplyByTwo;
      operations += MathOperations.Square;
```

code snippet MulticastDelegates/Program.cs

In the earlier example, you wanted to store references to two methods, so you instantiated an array of delegates. Here, you simply add both operations into the same multicast delegate. Multicast delegates recognize the operators + and +=. Alternatively, you can also expand the last two lines of the preceding code, as in this snippet:

```
Action<double> operation1 = MathOperations.MultiplyByTwo;
Action<double> operation2 = MathOperations.Square;
Action<double> operations = operation1 + operation2;
```

Multicast delegates also recognize the operators – and `-=` to remove method calls from the delegate.

In terms of what's going on under the hood, a multicast delegate is a class derived from `System.MulticastDelegate`*, which in turn is derived from* `System.Delegate`. `System.MulticastDelegate`*, and has additional members to allow chaining of method calls together into a list.*

To illustrate the use of multicast delegates, the following code recasts the `SimpleDelegate` example into a new example, `MulticastDelegate`. Because you now need the delegate to refer to methods that return `void`, you have to rewrite the methods in the `MathOperations` class, so they display their results instead of returning them:

```
class MathOperations
{
   public static void MultiplyByTwo(double value)
   {
      double result = value * 2;
      Console.WriteLine("Multiplying by 2: {0} gives {1}", value, result);
   }

   public static void Square(double value)
   {
      double result = value * value;
      Console.WriteLine("Squaring: {0} gives {1}", value, result);
   }
}
```

code snippet MulticastDelegates/MathOperations.cs

To accommodate this change, you also have to rewrite `ProcessAndDisplayNumber`:

```
static void ProcessAndDisplayNumber(Action<double> action, double value)
{
   Console.WriteLine();
   Console.WriteLine("ProcessAndDisplayNumber called with value = {0}", value);
   action(value);
}
```

Now you can try out your multicast delegate like this:

```
static void Main()
{
   Action<double> operations = MathOperations.MultiplyByTwo;
   operations += MathOperations.Square;

   ProcessAndDisplayNumber(operations, 2.0);
   ProcessAndDisplayNumber(operations, 7.94);
   ProcessAndDisplayNumber(operations, 1.414);
   Console.WriteLine();
}
```

Now, each time `ProcessAndDisplayNumber` is called, it will display a message to say that it has been called. Then the following statement will cause each of the method calls in the `action` delegate instance to be called in succession:

```
action(value);
```

Running this code produces this result:

```
MulticastDelegate

ProcessAndDisplayNumber called with value = 2
Multiplying by 2: 2 gives 4
Squaring: 2 gives 4

ProcessAndDisplayNumber called with value = 7.94
Multiplying by 2: 7.94 gives 15.88
Squaring: 7.94 gives 63.0436
```

```
ProcessAndDisplayNumber called with value = 1.414
Multiplying by 2: 1.414 gives 2.828
Squaring: 1.414 gives 1.999396
```

If you are using multicast delegates, you should be aware that the order in which methods chained to the same delegate will be called is formally undefined. You should, therefore, avoid writing code that relies on such methods being called in any particular order.

Invoking multiple methods by one delegate might cause an even bigger problem. The multicast delegate contains a collection of delegates to invoke one after the other. If one of the methods invoked by a delegate throws an exception, the complete iteration stops. Have a look at the following `MulticastIteration` example. Here, the simple delegate `Action` that returns `void` without arguments is used. This delegate is meant to invoke the methods `One()` and `Two()` that fulfill the parameter and return type requirements of the delegate. Be aware that method `One()` throws an exception:

```
using System;

namespace Wrox.ProCSharp.Delegates
{
   class Program
   {
      static void One()
      {
         Console.WriteLine("One");
         throw new Exception("Error in one");
      }

      static void Two()
      {
         Console.WriteLine("Two");
      }
```

code snippet MulticastDelegateWithIteration/Program.cs

In the `Main()` method, delegate `d1` is created to reference method `One()`; next, the address of method `Two()` is added to the same delegate. `d1` is invoked to call both methods. The exception is caught in a `try`/`catch` block.

```
      static void Main()
      {
         Action d1 = One;
         d1 += Two;

         try
         {
            d1();
         }
         catch (Exception)
         {
            Console.WriteLine("Exception caught");
         }
      }
   }
}
```

Only the first method is invoked by the delegate. Because the first method throws an exception, iterating the delegates stops here and method `Two()` is never invoked. The result might differ because the order of calling the methods is not defined.

```
One
Exception Caught
```

In such a scenario, you can avoid the problem by iterating the list on your own. The `Delegate` class defines the method `GetInvocationList()` that returns an array of `Delegate` objects. You can now use this delegate to invoke the methods associated with them directly, catch exceptions, and continue with the next iteration:

```
static void Main()
{
   Action d1 = One;
   d1 += Two;

   Delegate[] delegates = d1.GetInvocationList();
   foreach (Action d in delegates)
   {
      try
      {
         d();
      }
      catch (Exception)
      {
         Console.WriteLine("Exception caught");
      }
   }
}
```

When you run the application with the code changes, you can see that the iteration continues with the next method after the exception is caught:

```
One
Exception caught
Two
```

Anonymous Methods

Up to this point, a method must already exist for the delegate to work (that is, the delegate is defined with the same signature as the method(s) it will be used with). However, there is another way to use delegates — with *anonymous methods*. An anonymous method is a block of code that is used as the parameter for the delegate.

The syntax for defining a delegate with an anonymous method doesn't change. It's when the delegate is instantiated that things change. The following is a very simple console application that shows how using an anonymous method can work:

```
using System;

namespace Wrox.ProCSharp.Delegates
{
  class Program
  {
    static void Main()
    {
      string mid = ", middle part,";

      Func<string, string> anonDel = delegate(string param)
      {
        param += mid;
        param += " and this was added to the string.";
        return param;
      };
      Console.WriteLine(anonDel("Start of string"));

    }
  }
}
```

code snippet AnonymousMethods/Program.cs

The delegate `Func<string, string>` takes a single string parameter and returns a string. `anonDel` is a variable of this delegate type. Instead of assigning the name of a method to this variable, a simple block of code is used, prefixed by the delegate keyword, followed by a string parameter.

As you can see, the block of code uses a method-level string variable, `mid`, which is defined outside of the anonymous method and adds it to the parameter that was passed in. The code then returns the string value. When the delegate is called, a string is passed in as the parameter and the returned string is output to the console.

The benefit of using anonymous methods is to reduce the amount of code you have to write. You don't have to define a method just to use it with a delegate. This becomes very evident when defining the delegate for an event. (Events are discussed later in this chapter.) This can help reduce the complexity of code, especially where there are several events defined. With anonymous methods, the code does not perform faster. The compiler still defines a method; the method just has an automatically assigned name that you don't need to know.

A couple of rules must be followed when using anonymous methods. You can't have a jump statement (`break`, `goto`, or `continue`) in an anonymous method that has a target outside of the anonymous method. The reverse is also true — a jump statement outside the anonymous method cannot have a target inside the anonymous method.

Unsafe code cannot be accessed inside an anonymous method. Also, `ref` and `out` parameters that are used outside of the anonymous method cannot be accessed. Other variables defined outside of the anonymous method can be used.

If you have to write the same functionality more than once, don't use anonymous methods. In this case, instead of duplicating the code, writing a named method is the preferred way. You only have to write it once and reference it by its name.

Beginning with C# 3.0, you can use Lambda expressions instead of writing anonymous methods.

LAMBDA EXPRESSIONS

Since C# 3.0, you can use a new syntax for assigning code implementation to delegates: *Lambda expressions*. Lambda expressions can be used whenever you have a delegate parameter type. The previous example using anonymous methods is changed here to use a Lambda expression.

```
using System;

namespace Wrox.ProCSharp.Delegates
{
  class Program
  {
        static void Main()
        {
          string mid = ", middle part,";

          Func<string, string> lambda = param =>
             {
                param += mid;
                param += " and this was added to the string.";
                return param;
             };

          Console.WriteLine(anonDel("Start of string"));
        }
      }
    }
```

code snippet LambdaExpressions/Program.cs

The left side of the Lambda operator => lists the parameters needed. The right side following the Lambda operator defines the implementation of the method that is assigned to the variable `lambda`.

Parameters

With Lambda expressions there are several ways to define parameters. If there's only one parameter, just the name of the parameter is enough. The following Lambda expression uses the parameter named *`s`*. Because the delegate type defines a `string` parameter, *`s`* is of type `string`. The implementation invokes the `String.Format()` method to return a string that is finally written to the console when the delegate is invoked: `change uppercase TEST`.

```
               Func<string, string> oneParam = s => String.Format(
                           "change uppercase {0}", s.ToUpper());
               Console.WriteLine(oneParam("test"));
```

If a delegate uses more than one parameter, you can combine the parameter names inside brackets. Here the parameters *x* and *y* are of type `double` as defined by the `Func<double, double, double>` delegate:

```
               Func<double, double, double> twoParams = (x, y) => x * y;
               Console.WriteLine(twoParams(3, 2));
```

For convenience, you can add the parameter types to the variable names inside the brackets:

```
               Func<double, double, double> twoParamsWithTypes =
                   (double x, double y) => x * y;
               Console.WriteLine(twoParamsWithTypes(4, 2));
```

Multiple Code Lines

If the Lambda expression consists of a single statement, a method block with curly brackets and a `return` statement is not needed. There's an implicit `return` added by the compiler:

```
    Func<double, double> square = x => x * x;
```

It's completely legal to add curly brackets, a `return` statement, and semicolons. Usually it's just easier to read without:

```
    Func<double, double> square = x =>
        {
            return x * x;
        }
```

However, if you need multiple statements in the implementation of the Lambda expression, curly brackets and the `return` statement are required:

```
Func<string, string> lambda = param =>
   {
      param += mid;
      param += " and this was added to the string.";
      return param;
   };
```

Variables Outside of the Lambda Expression

With Lambda expressions you can access variables outside the block of the Lambda expression. This is a great feature but can also be very dangerous if not used correctly.

In the example here, a Lambda expression of type `Func<int, int>` requires one `int` parameter and returns an `int`. The parameter for the Lambda expression is defined with the variable `x`. The implementation also accesses the variable `someVal` that is outside the Lambda expression. As long as you do not think that the Lambda expression creates a new method that is used later when `f` is invoked, this might not look confusing at all. Looking at this code block the returned value calling `f` should be the value from `x` plus 5, but this might not be the case:

```
int someVal = 5;
Func<int, int> f = x => x + someVal;
```

Assuming the variable `someVal` is later changed, and then the Lambda expression invoked, the new value of `someVal` is used. The result here invoking `f(3)` is `10`:

```
someVal = 7;
Console.WriteLine(f(3));
```

In particular, when the Lambda expression is invoked by a separate thread you might not know when the invocation happened and thus what value the outside variable currently has.

Now you might wonder how it is possible at all to access variables outside of the Lambda expression from within the Lambda expression. To understand this, look at what the compiler does when you define a Lambda expression. With the Lambda expression `x => x + someVal`, the compiler creates an anonymous class that has a constructor to pass the outer variable. The constructor depends on how many variables you access from the outside. With this simple example, the constructor accepts an `int`. The anonymous class contains an anonymous method that has the implementation as was defined by the Lambda expression, with the parameters and return type.

```
public class AnonymousClass
{
    private int someVal;
    public AnonymousClass(int someVal)
    {
        this.someVal = someVal;
    }
    public int AnonymousMethod(int x)
    {
        return x + someVal;
    }
}
```

Using the Lambda expression and invoking the method creates an instance of the anonymous class and passes the value of the variable from the time when the call is made.

Lambda expressions can be used any place where the type is a delegate. Another use of Lambda expressions is when the type is `Expression` *or* `Expression<T>`*. Here the compiler creates an expression tree. This feature is discussed in Chapter 11, "Language Integrated Query."*

EVENTS

Events are based on delegates and offer a publish/subscribe mechanism to delegates. You can find events everywhere across the framework. In Windows applications, the `Button` class offers the `Click` event. This type of event is a delegate. A handler method that is invoked when the `Click` event is fired needs to be defined, with the parameters as defined by the delegate type.

In the code example shown in this section, events are used to connect `CarDealer` and `Consumer` classes. The `CarDealer` offers an event when a new car arrives. The `Consumer` class subscribes to the event to get informed when a new car arrives.

Event Publisher

Start with a `CarDealer` class that offers a subscription based on events. `CarDealer` defines the event named `NewCarInfo` of type `EventHandler<CarInfoEventArgs>` with the `event` keyword. Inside the method `NewCar()` the event `NewCarInfo` is fired:

```
using System;

namespace Wrox.ProCSharp.Delegates
{
    public class CarInfoEventArgs: EventArgs
    {
        public CarInfoEventArgs(string car)
        {
            this.Car = car;
        }

        public string Car { get; private set; }
    }

    public class CarDealer
    {
        public event EventHandler<CarInfoEventArgs> NewCarInfo;

        public void NewCar(string car)
        {
            Console.WriteLine("CarDealer, new car {0}", car);
            if (NewCarInfo != null)
            {
                NewCarInfo(this, new CarInfoEventArgs(car));
            }
        }
    }
}
```

code snippet EventsSample/CarDealer.cs

The class `CarDealer` offers the event `NewCarInfo` of type `EventHandler<CarInfoEventArgs>`. As a convention, events typically use methods with two parameters where the first parameter is an object and contains the sender of the event, and the second parameter gives information about the event. The second parameter is different for various event types. .NET 1.0 defined several hundred delegates for events for all different data types. That's no longer necessary with the generic delegate `EventHandler<T>`. `EventHandler<TEventArgs>` defines a handler that returns `void` and accepts two parameters. With `EventHandler<TEventArgs>`, the first parameter needs to be of type `object`, and the second parameter is of type `T`. `EventHandler<TEventArgs>` also defines a constraint on `T;` it must derive from the base class `EventArgs`, which is the case with `CarInfoEventArgs`:

```
            public event EventHandler<CarInfoEventArgs> NewCarInfo;
```

The delegate `EventHandler<TEventArgs>` is defined as follows:

```
public delegate void EventHandler<TEventArgs>(object sender, TEventArgs e)
    where TEventArgs: EventArgs
```

Defining the event in one line is a C# shorthand notation. The compiler creates a variable of the delegate type `EventHandler<CarInfoEventArgs>` and adds methods to subscribe and unsubscribe from the delegate. The long form of the shorthand notation is shown next. This is very similar to auto-properties and full properties. With events, the `add` and `remove` keywords are used to add and remove a handler to the delegate:

```
private delegate EventHandler<CarInfoEventArgs> newCarInfo;
public event EventHandler<CarInfoEventArgs> NewCarInfo
{
    add
    {
        newCarInfo += value;
    }
    remove
    {
        newCarInfo = value;
    }
}
```

> *The long notation to define events is useful if more needs to be done than just adding and removing the event handler, for example, to add synchronization for multiple thread access. The WPF controls make use of the long notation to add bubbling and tunneling functionality with the events. You can read more about event bubbling and tunneling events in Chapter 27, "Core XAML."*

The class `CarDealer` fires the event in the method `NewCar`. Using `NewCarInfo` with brackets invokes all the handlers that are subscribed to the event. Remember, as was shown with multicast delegates, the order of the methods invoked is not guaranteed. To have more control over calling the handler methods you can use the `Delegate` class method `GetInvocationList()` to access every item in the delegate list and invoke each on its own, as shown earlier.

Before firing the event, it is necessary to check whether the delegate `NewCarInfo` is not `null`. If no one subscribed, the delegate is `null`:

```
        public void NewCar(string car)
        {
            Console.WriteLine("CarDealer, new car {0}", car);
            if (NewCarInfo != null)
            {
                NewCarInfo(this, new CarInfoEventArgs(car));
            }
        }
```

Event Listener

The class `Consumer` is used as the event listener. This class subscribes to the event of the `CarDealer` and defines the method `NewCarIsHere` that in turn fulfills the requirements of the `EventHandler<CarInfoEventArgs>` delegate with parameters of type `object` and `CarInfoEventArgs`:

```
using System;

namespace Wrox.ProCSharp.Delegates
```

```
{
    public class Consumer
    {
        private string name;

        public Consumer(string name)
        {
            this.name = name;
        }

        public void NewCarIsHere(object sender, CarInfoEventArgs e)
        {
            Console.WriteLine("{0}: car {1} is new", name, e.Car);
        }
    }
}
```

code snippet EventsSample/Consumer.cs

Now the event publisher and subscriber need to connect. This is done by using the `NewCarInfo` event of the `CarDealer` to create a subscription with `+=`. The consumer *michael* subscribes to the event, then the consumer *nick*, and next *michael* unsubscribes with `-=`:

```
namespace Wrox.ProCSharp.Delegates
{
    class Program
    {
        static void Main()
        {
            var dealer = new CarDealer();

            var michael = new Consumer("Michael");
            dealer.NewCarInfo += michael.NewCarIsHere;

            dealer.NewCar("Mercedes");

            var nick = new Consumer("Nick");
            dealer.NewCarInfo += nick.NewCarIsHere;

            dealer.NewCar("Ferrari");

            dealer.NewCarInfo = michael.NewCarIsHere;

            dealer.NewCar("Toyota");
        }
    }
}
```

code snippet EventsSample/Program.cs

Running the application, a Mercedes arrived and Michael was informed. Because after that Nick registers for the subscription as well, both Michael and Nick are informed about the new Ferrari. Then Michael unsubscribes and only Nick is informed about the Toyota:

```
CarDealer, new car Mercedes
Michael: car Mercedes is new
CarDealer, new car Ferrari
Michael: car Ferrari is new
Nick: car Ferrari is new
CarDealer, new car Toyota
Nick: car Toyota is new
```

Weak Events

With events, the publisher and listener are directly connected. This can be a problem with garbage collection. For example, if a listener is not directly referenced any more, there's still a reference from the publisher. The garbage collector cannot clean up memory from the listener, as the publisher still holds a reference and fires events to the listener.

This strong connection can be resolved by using the weak event pattern and using the `WeakEventManager` as an intermediate between the publisher and listeners.

The sample from before with the `CarDealer` as publisher and `Consumer` as listener is modified in the following section to use the weak event pattern.

Weak Event Manager

To use weak events you need to create a class that derives from `WeakEventManager`. `WeakEventManager` is defined in the namespace `System.Windows` in the assembly WindowsBase.

The class `WeakCarInfoEventManager` is the weak event manager class that manages the connection between the publisher and listener for the `NewCarInfo` event. This class implements a singleton pattern so that only one instance is created. The static property `CurrentManager` creates an object of type `WeakCarInfoEventManager` if it doesn't exist, and returns a reference to it. `WeakCarInfoEventManager.CurrentManager` is used to access the singleton object from the `WeakCarInfoEventManager`.

With the weak event pattern, the weak event manager class needs static methods `AddListener()` and `RemoveListener()`. The listener is connected and disconnected to the events of the publisher with these methods instead of using the events from the publisher directly. The listener also needs to implement the interface `IWeakEventListener` that is shown shortly. With the `AddListener()` and `RemoveListener()` methods, methods from the base class `WeakEventManager` are invoked to add and remove the listeners.

With the `WeakCarInfoEventManager` class you also need to override the `StartListening()` and `StopListening()` methods from the base class. `StartListening()` is called when the first listener is added, `StopListening()` when the last listener is removed. `StartListening()` and `StopListening()` subscribes and unsubscribes a method from the weak event manager to listen for the event from the publisher. In case the weak event manager class needs to connect to different publisher types, you can check the type information from the source object before doing the cast. The event is then forwarded to the listeners by calling the `DeliverEvent()` method from the base class, which in turn invokes the method `ReceiveWeakEvent()` from the `IWeakEventListener` interface in the listeners:

```
using System.Windows;

namespace Wrox.ProCSharp.Delegates
{
    public class WeakCarInfoEventManager: WeakEventManager
    {
        public static void AddListener(object source, IWeakEventListener listener)
        {
            CurrentManager.ProtectedAddListener(source, listener);
        }

        public static void RemoveListener(object source,
                                          IWeakEventListener listener)
        {
            CurrentManager.ProtectedRemoveListener(source, listener);
        }

        public static WeakCarInfoEventManager CurrentManager
        {
            get
            {
                WeakCarInfoEventManager manager =
                    GetCurrentManager(typeof(WeakCarInfoEventManager))
                      as WeakCarInfoEventManager;
                if (manager == null)
                {
                    manager = new WeakCarInfoEventManager();
                    SetCurrentManager(typeof(WeakCarInfoEventManager), manager);
                }
                return manager;
            }
        }

        protected override void StartListening(object source)
        {
            (source as CarDealer).NewCarInfo += CarDealer_NewCarInfo;
        }

        void CarDealer_NewCarInfo(object sender, CarInfoEventArgs e)
        {
            DeliverEvent(sender, e);
        }

        protected override void StopListening(object source)
        {
            (source as CarDealer).NewCarInfo = CarDealer_NewCarInfo;
        }
    }
}
```

code snippet WeakEventsSample/WeakCarInfoEventManager.cs

WPF makes use of the weak event pattern with the event manager classes `CollectionChangedEventManager`, `CurrentChangedEventManager`, `CurrentChangingEventManager`, `PropertyChangedEventManager`, `DataChangedEventManager`, *and* `LostFocusEventManager`.

With the publisher class `CarDealer` there's no need to change anything. It has the same implementation as before.

Event Listener

The listener needs to be changed to implement the interface `IWeakEventListener`. This interface defines the method `ReceiveWeakEvent()` that is called from the weak event manager when the event arrives. In the method implementation the method that should be invoked from the event is invoked, which is `NewCarIsHere()`.

```
using System;
using System.Windows;

namespace Wrox.ProCSharp.Delegates
{
 public class Consumer: IWeakEventListener
    {
        private string name;

        public Consumer(string name)
        {
            this.name = name;
        }
```

```
            public void NewCarIsHere(object sender, CarInfoEventArgs e)
            {
                Console.WriteLine("{0}: car {1} is new", name, e.Car);
            }

            bool IWeakEventListener.ReceiveWeakEvent(Type managerType, object sender,
                                                     EventArgs e)
            {
                  NewCarIsHere(sender, e as CarInfoEventArgs);
                  return true;
            }
        }
    }
```

code snippet WeakEventsSample/Consumer.cs

Inside the Main method where the publisher and listeners are connected, the connection is now done by using the static `AddListener()` and `RemoveListener()` methods from the `WeakCarInfoEventManager` class.

```
            static void Main()
            {
                var dealer = new CarDealer();

                var michael = new Consumer("Michael");
                WeakCarInfoEventManager.AddListener(dealer, michael);

                dealer.NewCar("Mercedes");

                var nick = new Consumer("Nick");
                WeakCarInfoEventManager.AddListener(dealer, nick);

                dealer.NewCar("Ferrari");

                WeakCarInfoEventManager.RemoveListener(dealer, michael);

                dealer.NewCar("Toyota");
            }
```

code snippet WeakEventsSample/Program.cs

With this additional work of implementing the weak event pattern, the publisher and listeners are no longer strongly connected. When a listener is not referenced anymore, it can be garbage collected.

SUMMARY

This chapter gave you the basics of delegates, Lambda expressions, and events. You learned how to declare a delegate and add methods to the delegate list. You learned how to implement methods called by delegates with Lambda expressions. You also learned the process of declaring event handlers to respond to an event, as well as how to create a custom event and use the patterns for raising the event.

As a .NET developer, you will be using delegates and events extensively, especially when developing Windows applications. Events are the means that the .NET developer has to monitor the various Windows messages that occur while the application is executing. Otherwise, you would have to monitor the WndProc and catch the `WM_MOUSEDOWN` message instead of getting the mouse `Click` event for a button.

The use of delegates and events in the design of a large application can reduce dependencies and the coupling of layers. This allows you to develop components that have a higher reusability factor.

Lambda expressions are C# language features on delegates. With these, you can reduce the amount of code you need to write. Lambda expressions are not used only with delegates, as you will see in Chapter 11.

The next chapter goes into the foundation of strings and regular expressions.

9 Strings and Regular Expressions

WHAT'S IN THIS CHAPTER?

- ➤ Building strings
- ➤ Formatting expressions
- ➤ Using regular expressions

Since the beginning of this book, you have been using strings almost constantly, and might not have realized that the stated mapping that the `string` keyword in C# actually refers to is the `System.String` .NET base class. `System.String` is a very powerful and versatile class, but it is by no means the only string-related class in the .NET armory. This chapter starts by reviewing the features of `System.String` and then looks at some nifty things you can do with strings using some of the other .NET classes — in particular those in the `System.Text` and `System.Text.RegularExpressions` namespaces. This chapter covers the following areas:

- ➤ **Building strings** — If you're performing repeated modifications on a string, for example, to build up a lengthy string prior to displaying it or passing it to some other method or application, the `String` class can be very inefficient. When you find yourself in this kind of situation, another class, `System.Text.StringBuilder`, is more suitable because it has been designed exactly for this situation.
- ➤ **Formatting expressions** — This chapter takes a closer look at those formatting expressions that have been used in the `Console.WriteLine()` method throughout the past few chapters. These formatting expressions are processed using a couple of useful interfaces, `IFormatProvider` and `IFormattable`. By implementing these interfaces on your own classes, you can actually define your own formatting sequences so that `Console.WriteLine()` and similar classes will display the values of your classes in whatever way you specify.
- ➤ **Regular expressions** — .NET also offers some very sophisticated classes that deal with situations in which you need to identify or extract substrings that satisfy certain fairly sophisticated criteria; for example, finding all occurrences within a string where a character or set of characters is repeated, finding all words that begin with "s" and contain at least one "n," or strings that adhere to an employee ID or a Social Security number construction. Although you can write methods to perform this kind of processing using the `String` class, such methods are cumbersome to write. Instead, you will find that some classes, specifically those from `System.Text.RegularExpressions`, are designed to perform this kind of processing.

EXAMINING SYSTEM.STRING

Before digging into the other string classes, this section quickly reviews some of the available methods in the `String` class itself.

`System.String` is a class specifically designed to store a string and allow a large number of operations on the string. In addition, due to the importance of this data type, C# has its own keyword and associated syntax to make it particularly easy to manipulate strings using this class.

You can concatenate strings using operator overloads:

```
string message1 = "Hello";  // returns "Hello"
message1 += ", There"; // returns "Hello, There"
string message2 = message1 + "!"; // returns "Hello, There!"
```

C# also allows extraction of a particular character using an indexer-like syntax:

```
string message = "Hello";
char char4 = message[4];   // returns 'o'. Note the string is zero-indexed
```

This enables you to perform such common tasks as replacing characters, removing whitespace, and capitalization. The following table introduces the key methods:

METHOD	PURPOSE
`Compare`	Compares the contents of strings, taking into account the culture (locale) in assessing equivalence between certain characters.
`CompareOrdinal`	Same as `Compare` but doesn't take culture into account.
`Concat`	Combines separate string instances into a single instance.
`CopyTo`	Copies a specific number of characters from the selected index to an entirely new instance of an array.
`Format`	Formats a string containing various values and specifiers for how each value should be formatted.
`IndexOf`	Locates the first occurrence of a given substring or character in the string.
`IndexOfAny`	Locates the first occurrence of any one of a set of characters in a string.
`Insert`	Inserts a string instance into another string instance at a specified index.
`Join`	Builds a new string by combining an array of strings.
`LastIndexOf`	Same as `IndexOf` but finds the last occurrence.
`LastIndexOfAny`	Same as `IndexOfAny` but finds the last occurrence.
`PadLeft`	Pads out the string by adding a specified repeated character to the left side of the string.
`PadRight`	Pads out the string by adding a specified repeated character to the right side of the string.
`Replace`	Replaces occurrences of a given character or substring in the string with another character or substring.
`Split`	Splits the string into an array of substrings; the breaks occur wherever a given character occurs.
`Substring`	Retrieves the substring starting at a specified position in a string.
`ToLower`	Converts string to lowercase.
`ToUpper`	Converts string to uppercase.
`Trim`	Removes leading and trailing whitespace.

Please note that this table is not comprehensive but is intended to give you an idea of the features offered by strings.

Building Strings

As you have seen, `String` is an extremely powerful class that implements a large number of very useful methods. However, the `String` class has a shortcoming that makes it very inefficient for making repeated modifications to a given string — it is actually an *immutable* data type, which means that after you initialize a string object, that string object can never change. The methods and operators that appear to modify the contents of a string actually create new strings, copying across the contents of the old string if necessary. For example, look at the following code:

```
string greetingText = "Hello from all the guys at Wrox Press. ";
greetingText += "We do hope you enjoy this book as much as we enjoyed writing it.";
```

What happens when this code executes is this: first, an object of type `System.String` is created and initialized to hold the text `Hello from all the guys at Wrox Press.` (Note the space *after* the period.) When this happens, the .NET runtime allocates just enough memory in the string to hold this text (39 chars), and the variable `greetingText` is set to refer to this string instance.

In the next line, syntactically it looks like more text is being added onto the string — though it is not. Instead, what happens is that a new string instance is created with just enough memory allocated to store the combined text — that's 103 characters in total. The original text, `Hello from all the people at Wrox Press.` , is copied into this new string instance along with the extra text: `We do hope you enjoy this book as much as we enjoyed writing it.` Then, the address stored in the variable `greetingText` is updated, so the variable correctly points to the new `String` object. The old `String` object is now unreferenced — there are no variables that refer to it — and so will be removed the next time the garbage collector comes along to clean out any unused objects in your application.

By itself, that does not look too bad, but suppose that you wanted to encode that string by replacing each letter (not the punctuation) with the character that has an ASCII code further on in the alphabet, as part of some extremely simple encryption scheme. This would change the string to `Ifmmp gspn bmm uif hvst bu Xspy Qsftt. Xf ep ipqf zpv fokpz uijt cppl bt nvdi bt xf fokpzfe xsjujoh ju.` Several ways of doing this exist, but the simplest and (if you are restricting yourself to using the `String` class) almost certainly the most efficient way is to use the `String.Replace()` method, which replaces all occurrences of a given substring in a string with another substring. Using `Replace()`, the code to encode the text looks like this:

```
string greetingText = "Hello from all the guys at Wrox Press. ";
greetingText += "We do hope you enjoy this book as much as we enjoyed writing it.";

for(int i = 'z'; i>= 'a'; i--)
{
   char old1 = (char)i;
   char new1 = (char)(i+1);
   greetingText = greetingText.Replace(old1, new1);
}

for(int i = 'Z'; i>='A'; i--)
{
   char old1 = (char)i;
   char new1 = (char)(i+1);
   greetingText = greetingText.Replace(old1, new1);
}

Console.WriteLine("Encoded:\n" + greetingText);
```

code snippet StringEncoder.cs

In this example, the `Replace()` method works in a fairly intelligent way, to the extent that it won't actually create a new string unless it actually makes changes to the old string. The original string contained 23 different lowercase characters and 3 different uppercase ones. The `Replace()` method will therefore have allocated a new string 26 times in total, with each new string storing 103 characters. That means that because of the encryption process, there will be string objects capable of storing a combined total of 2,678 characters now sitting on the heap waiting to be garbage-collected! Clearly, if you use strings to do text processing extensively, your applications will run into severe performance problems.

To address this kind of issue, Microsoft has supplied the `System.Text.StringBuilder` class. `StringBuilder` is not as powerful as `String` in terms of the number of methods it supports. The processing you can do on a `StringBuilder` is limited to substitutions and appending or removing text from strings. However, it works in a much more efficient way.

When you construct a string using the `String` class, just enough memory is allocated to hold the string. The `StringBuilder`, however, normally allocates more memory than is actually needed. You, as a developer, have the option to indicate how much memory the `StringBuilder` should allocate, but if you do not, the amount will default to some value that depends on the size of the string that the `StringBuilder` instance is initialized with. The `StringBuilder` class has two main properties:

- `Length`, which indicates the length of the string that it actually contains
- `Capacity`, which indicates the maximum length of the string in the memory allocation

Any modifications to the string take place within the block of memory assigned to the `StringBuilder` instance, which makes appending substrings and replacing individual characters within strings very efficient. Removing or inserting substrings is inevitably still inefficient because it means that the following part of the string has to be moved. Only if you perform some operation that exceeds the capacity of the string is it necessary to allocate new memory and possibly move the entire contained string. In adding extra capacity, based on our experiments the `StringBuilder` appears to double its capacity if it detects the capacity has been exceeded and no new value for the capacity has been set.

For example, if you use a `StringBuilder` object to construct the original greeting string, you might write this code:

```
StringBuilder greetingBuilder =
   new StringBuilder("Hello from all the guys at Wrox Press. ", 150);
greetingBuilder.AppendFormat("We do hope you enjoy this book as much as we enjoyed
                        writing it");
```

This code sets an initial capacity of `150` for the `StringBuilder`. It is always a good idea to set some capacity that covers the likely maximum length of a string, to ensure the `StringBuilder` does not need to relocate because its capacity was exceeded. By default, the capacity is set to 16. Theoretically, you can set as large a number as you can pass in an `int`, although the system will probably complain that it does not have enough memory if you actually try to allocate the maximum of two billion characters (this is the theoretical maximum that a `StringBuilder` instance is allowed to contain, in principle).

When the preceding code is executed, it first creates a `StringBuilder` object that looks like Figure 9-1.

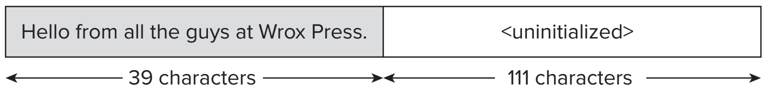

FIGURE 9-1

Then, on calling the `AppendFormat()` method, the remaining text is placed in the empty space, without the need for more memory allocation. However, the real efficiency gain from using a `StringBuilder` comes when you are making repeated text substitutions. For example, if you try to encrypt the text in the same way as before, you can perform the entire encryption without allocating any more memory whatsoever:

```
StringBuilder greetingBuilder =
   new StringBuilder("Hello from all the guys at Wrox Press. ", 150);
greetingBuilder.AppendFormat("We do hope you enjoy this book as much as we " +
   "enjoyed writing it");

Console.WriteLine("Not Encoded:\n" + greetingBuilder);

for(int i = 'z'; i>='a'; i--)
{
   char old1 = (char)i;
   char new1 = (char)(i+1);
   greetingBuilder = greetingBuilder.Replace(old1, new1);
}

for(int i = 'Z'; i>='A'; i--)
{
   char old1 = (char)i;
   char new1 = (char)(i+1);
   greetingBuilder = greetingBuilder.Replace(old1, new1);
}

Console.WriteLine("Encoded:\n" + greetingBuilder);
```

This code uses the `StringBuilder.Replace()` method, which does the same thing as `String.Replace()`, but without copying the string in the process. The total memory allocated to hold strings in the preceding code is 150 characters for the `StringBuilder` instance, as well as the memory allocated during the string operations performed internally in the final `Console.WriteLine()` statement.

Normally, you want to use `StringBuilder` to perform any manipulation of strings and `String` to store or display the final result.

StringBuilder Members

You have seen a demonstration of one constructor of `StringBuilder`, which takes an initial string and capacity as its parameters. There are others. For example, you can supply only a string:

```
StringBuilder sb = new StringBuilder("Hello");
```

Or you can create an empty `StringBuilder` with a given capacity:

```
StringBuilder sb = new StringBuilder(20);
```

Apart from the `Length` and `Capacity` properties, there is a read-only `MaxCapacity` property that indicates the limit to which a given `StringBuilder` instance is allowed to grow. By default, this is given by `int .MaxValue` (roughly two billion, as noted earlier), but you can set this value to something lower when you construct the `StringBuilder` object:

```
// This will both set initial capacity to 100, but the max will be 500.
// Hence, this StringBuilder can never grow to more than 500 characters,
// otherwise it will raise exception if you try to do that.
StringBuilder sb = new StringBuilder(100, 500);
```

You can also explicitly set the capacity at any time, though an exception will be raised if you set it to a value less than the current length of the string or a value that exceeds the maximum capacity:

```
StringBuilder sb = new StringBuilder("Hello");
sb.Capacity = 100;
```

The following table lists the main `StringBuilder` methods.

METHOD	PURPOSE
`Append()`	Appends a string to the current string.
`AppendFormat()`	Appends a string that has been worked out from a format specifier.
`Insert()`	Inserts a substring into the current string.
`Remove()`	Removes characters from the current string.
`Replace()`	Replaces all occurrences of a character with another character or a substring with another substring in the current string.
`ToString()`	Returns the current string cast to a `System.String` object (overridden from `System.Object`).

Several overloads of many of these methods exist.

There is no cast (either implicit or explicit) from `StringBuilder` to `String`. If you want to output the contents of a `StringBuilder` as a `String`, you must use the `ToString()` method.

Now that you have been introduced to the `StringBuilder` class and have learned some of the ways in which you can use it to increase performance, you should be aware that this class will not always give you the increased performance you are looking for. Basically, the `StringBuilder` class should be used when you are manipulating multiple strings. However, if you are just doing something as simple as concatenating two strings, you will find that `System.String` will be better-performing.

Format Strings

So far, a large number of classes and structs have been written for the code samples presented in this book, and they have normally implemented a `ToString()` method in order to display the contents of a given variable. However, quite often users might want the contents of a variable to be displayed in different, often culture- and locale-dependent ways. The .NET base class, `System.DateTime`, provides the most obvious example of this. For example, you might want to display the same date as 10 June 2010, 10 Jun 2010, 6/10/10 (USA), 10/6/10 (UK), or 10.06.2010 (Germany).

Similarly, the `Vector` struct in Chapter 7, "Operators and Casts," implements the `Vector.ToString()` method to display the vector in the format `(4, 56, 8)`. There is, however, another very common way of writing vectors, in which this vector would appear as `4i + 56j + 8k`. If you want the classes that you write to be user-friendly, they need to support the facility to display their string representations in any of the formats that users are likely to want to use. The .NET runtime defines a standard way in which this should be done: the `IFormattable` interface. Showing how to add this important feature to your classes and structs is the subject of this section.

As you probably know, you need to specify the format in which you want a variable displayed when you call `Console.WriteLine()`. Therefore, this section uses this method as an example, although most of the discussion applies to any situation in which you want to format a string. For example, if you want to display the value of a variable in a list box or text box, you will normally use the `String.Format()` method to obtain the appropriate string representation of the variable. However, the actual format specifiers you use to request a particular format are identical to those passed to `Console.WriteLine()`. Hence, you will focus on `Console.WriteLine()` as an example. You start by examining what actually happens when you supply a format string to a primitive type, and from this, you will see how you can plug format specifiers for your own classes and structs into the process.

Chapter 2, "Core C#," uses format strings in `Console.Write()` and `Console.WriteLine()` like this:

```
double d = 13.45;
int i = 45;
Console.WriteLine("The double is {0,10:E} and the int contains {1}", d, i);
```

The format string itself consists mostly of the text to be displayed, but wherever there is a variable to be formatted, its index in the parameter list appears in braces. You might also include other information inside the braces concerning the format of that item. For example, you can include:

➤ The number of characters to be occupied by the representation of the item, prefixed by a comma. A negative number indicates that the item should be left-justified, whereas a positive number indicates that it should be right-justified. If the item actually occupies more characters than have been requested, it will still appear in full.

➤ A format specifier, preceded by a colon. This indicates how you want the item to be formatted. For example, you can indicate whether you want a number to be formatted as a currency or displayed in scientific notation.

The following table lists the common format specifiers for the numeric types, which were briefly discussed in Chapter 2.

SPECIFIER	APPLIES TO	MEANING	EXAMPLE
`C`	Numeric types	Locale-specific monetary value	$4834.50 (USA) £4834.50 (UK)
`D`	Integer types only	General integer	4834
`E`	Numeric types	Scientific notation	4.834E+003
`F`	Numeric types	Fixed-point decimal	4384.50
`G`	Numeric types	General number	4384.5
`N`	Numeric types	Common locale-specific format for numbers	4,384.50 (UK/USA) 4 384,50 (continental Europe)
`P`	Numeric types	Percentage notation	432,000.00%
`X`	Integer types only	Hexadecimal format	1120 (If you want to display 0x1120, you will have to write out the 0x separately)

If you want an integer to be padded with zeros, you can use the format specifier `0` (zero) repeated as many times as the number length is required. For example, the format specifier `0000` will cause `3` to be displayed as `0003`, and `99` to be displayed as `0099`, and so on.

It is not possible to give a complete list, because other data types can add their own specifiers. Showing how to define your own specifiers for your own classes is the aim of this section.

How the String Is Formatted

As an example of how strings are formatted, if you execute the following statement:

```
Console.WriteLine("The double is {0,10:E} and the int contains {1}", d, i);
```

`Console.WriteLine()` just passes the entire set of parameters to the static method, `String.Format()`. This is the same method that you would call if you wanted to format these values for use in a string to be displayed in a text box, for example. The implementation of the three-parameter overload of `WriteLine()` basically does this:

```
// Likely implementation of Console.WriteLine()

public void WriteLine(string format, object arg0, object arg1)
{
   this.WriteLine(string.Format(this.FormatProvider, format,
      new object[]{arg0, arg1}));
}
```

The one-parameter overload of this method, which is in turn called in the preceding code sample, simply writes out the contents of the string it has been passed, without doing any further formatting on it.

`String.Format()` now needs to construct the final string by replacing each format specifier with a suitable string representation of the corresponding object. However, as you saw earlier, for this process of building up a string you need a `StringBuilder` instance rather than a `string` instance. In this example, a `StringBuilder` instance is created and initialized with the first known portion of the string, the text "`The double is`". Next, the `StringBuilder.AppendFormat()` method is called, passing in the first format specifier, `{0,10:E}`, as well as the associated object, `double`, to add the string representation of this object to the string object being constructed. This process continues with `StringBuilder.Append()` and `StringBuilder.AppendFormat()` being called repeatedly until the entire formatted string has been obtained.

Now comes the interesting part: `StringBuilder.AppendFormat()` has to figure out how to format the object. First, it probes the object to find out whether it implements an interface in the `System` namespace called `IFormattable`. You can determine this quite simply by trying to cast an object to this interface and seeing whether the cast succeeds, or by using the C# `is` keyword. If this test fails, `AppendFormat()` calls the object's `ToString()` method, which all objects either inherit from `System.Object` or override. This is exactly what happens here because none of the classes written so far has implemented this interface. That is why the overrides of `Object.ToString()` have been sufficient to allow the structs and classes from earlier chapters such as `Vector` to get displayed in `Console.WriteLine()` statements.

However, all the predefined primitive numeric types do implement this interface, which means that for those types, and in particular for `double` and `int` in the example, the basic `ToString()` method inherited from `System.Object` will not be called. To understand what happens instead, you need to examine the `IFormattable` interface.

`IFormattable` defines just one method, which is also called `ToString()`. However, this method takes two parameters as opposed to the `System.Object` version, which doesn't take any parameters. The following code shows the definition of `IFormattable`:

```
interface IFormattable
{
   string ToString(string format, IFormatProvider formatProvider);
}
```

The first parameter that this overload of `ToString()` expects is a string that specifies the requested format. In other words, it is the specifier portion of the string that appears inside the braces (`{}`) in the string originally passed to `Console.WriteLine()` or `String.Format()`. For example, in the example the original statement was:

```
Console.WriteLine("The double is {0,10:E} and the int contains {1}", d, i);
```

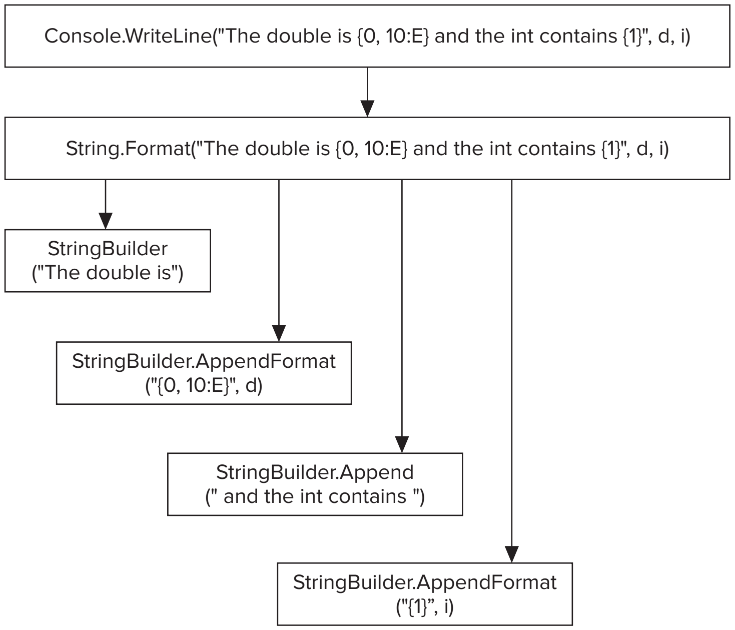
Hence, when evaluating the first specifier, `{0,10:E}`, this overload will be called against the `double` variable, `d`, and the first parameter passed to it will be `E`. `StringBuilder.AppendFormat()` will pass in here the text that appears after the colon in the appropriate format specifier from the original string.

We won't worry about the second `ToString()` parameter in this book. It is a reference to an object that implements the `IFormatProvider` interface. This interface gives further information that `ToString()` might need to consider when formatting the object, such as culture-specific details (a .NET culture is similar to a Windows locale; if you are formatting currencies or dates, you need this information). If you are calling this `ToString()` overload directly from your source code, you might want to supply such an object. However, `StringBuilder.AppendFormat()` passes in `null` for this parameter. If `formatProvider` is `null`, then `ToString()` is expected to use the culture specified in the system settings.

Getting back to the example, the first item you want to format is a `double`, for which you are requesting exponential notation, with the format specifier `E`. The `StringBuilder.AppendFormat()` method establishes that the `double` does implement `IFormattable`, and will therefore call the two-parameter `ToString()` overload, passing it the string `E` for the first parameter and `null` for the second parameter. It is now up to the `double`'s implementation of this method to return the string representation of the `double` in the appropriate format, taking into account the requested format and the current culture. `StringBuilder.AppendFormat()` will then sort out padding the returned string with spaces, if necessary, to fill the 10 characters the format string specified.

The next object to be formatted is an `int`, for which you are not requesting any particular format (the format specifier was simply `{1}`). With no format requested, `StringBuilder.AppendFormat()` passes in a null reference for the format string. The two-parameter overload of `int.ToString()` is expected to respond appropriately. No format has been specifically requested; therefore, it will call the no-parameter `ToString()` method.

This entire string formatting process is summarized in Figure 9-2.



Console.WriteLine("The double is {0, 10:E} and the int contains {1}", d, i)
String.Format("The double is {0, 10:E} and the int contains {1}", d, i)
StringBuilder ("The double is")
StringBuilder.AppendFormat ("{0, 10:E}", d)
StringBuilder.Append (" and the int contains ")
StringBuilder.AppendFormat ("{1}", i)

FIGURE 9-2

The FormattableVector Example

Now that you know how format strings are constructed, in this section you extend the `Vector` example from Chapter 7 so that you can format vectors in a variety of ways. You can download the code for this example from `www.wrox.com;` the filename is `FormattableVector.cs`. With your new knowledge of the principles involved now in hand, you will discover that the actual coding is quite simple. All you need to do is implement `IFormattable` and supply an implementation of the `ToString()` overload defined by that interface.

The format specifiers you are going to support are:

- `N` — Should be interpreted as a request to supply a quantity known as the `Norm` of the `Vector`. This is just the sum of squares of its components, which for mathematics buffs happens to be equal to the square of the length of the `Vector`, and is usually displayed between double vertical bars, like this: `||34.5||`.
- `VE` — Should be interpreted as a request to display each component in scientific format, just as the specifier `E` applied to a `double` indicates (`2.3E+01`, `4.5E+02`, `1.0E+00`).
- `IJK` — Should be interpreted as a request to display the vector in the form `23i + 450j + 1k`.
- Anything else should simply return the default representation of the `Vector (23, 450, 1.0)`.

To keep things simple, you are not going to implement any option to display the vector in combined `IJK` and scientific format. However, you will make sure to test the specifier in a case-insensitive way, so that you allow `ijk` instead of `IJK`. Note that it is entirely up to you which strings you use to indicate the format specifiers.

To achieve this, you first modify the declaration of `Vector` so it implements `IFormattable`:

```
struct Vector: IFormattable
{
   public double x, y, z;

   // Beginning part of Vector
```

Now you add your implementation of the two-parameter `ToString()` overload:

```
public string ToString(string format, IFormatProvider formatProvider)
{
   if (format == null)
   {
      return ToString();
   }

   string formatUpper = format.ToUpper();

   switch (formatUpper)
   {
      case "N":
         return "|| " + Norm().ToString() + " ||";
      case "VE":
         return String.Format("( {0:E}, {1:E}, {2:E} )", x, y, z);
      case "IJK":
         StringBuilder sb = new StringBuilder(x.ToString(), 30);
         sb.AppendFormat(" i + ");
         sb.AppendFormat(y.ToString());
         sb.AppendFormat(" j + ");
         sb.AppendFormat(z.ToString());
         sb.AppendFormat(" k");
         return sb.ToString();
      default:
         return ToString();
   }
}
```

That is all you have to do! Notice how you take the precaution of checking whether format is `null` before you call any methods against this parameter — you want this method to be as robust as reasonably possible. The format specifiers for all the primitive types are case-insensitive, so that is the behavior that other developers are going to expect from your class, too. For the format specifier `VE`, you need each component to be formatted in scientific notation, so you just use `String.Format()` again to achieve this. The fields `x`, `y`, and `z` are all `double`s. For the case of the `IJK` format specifier, there are quite a few substrings to be added to the string, so you use a `StringBuilder` object to improve performance.

For completeness, you also reproduce the no-parameter `ToString()` overload developed earlier:

```
public override string ToString()
{
   return "( " + x + ", " + y + ", " + z + " )";
}
```

Finally, you need to add a `Norm()` method that computes the square (norm) of the vector because you didn't actually supply this method when you developed the `Vector` struct:

```
public double Norm()
{
   return x*x + y*y + z*z;
}
```

Now you can try your formattable vector with some suitable test code:

```
static void Main()
{
   Vector v1 = new Vector(1,32,5);
   Vector v2 = new Vector(845.4, 54.3, -7.8);
   Console.WriteLine("\nIn IJK format,\nv1 is {0,30:IJK}\nv2 is {1,30:IJK}",
                     v1, v2);
   Console.WriteLine("\nIn default format,\nv1 is {0,30}\nv2 is {1,30}", v1, v2);
   Console.WriteLine("\nIn VE format\nv1 is {0,30:VE}\nv2 is {1,30:VE}", v1, v2);
   Console.WriteLine("\nNorms are:\nv1 is {0,20:N}\nv2 is {1,20:N}", v1, v2);
}
```

The result of running this sample is this:

```
FormattableVector
In IJK format,
v1 is               1 i + 32 j + 5 k
v2 is      845.4 i + 54.3 j + -7.8 k

In default format,
v1 is                 ( 1, 32, 5 )
v2 is        ( 845.4, 54.3, -7.8 )

In VE format
v1 is ( 1.000000E+000, 3.200000E+001, 5.000000E+000 )
v2 is ( 8.454000E+002, 5.430000E+001, -7.800000E+000 )

Norms are:
v1 is           || 1050 ||
v2 is      || 717710.49 ||
```

This shows that your custom specifiers are being picked up correctly.

REGULAR EXPRESSIONS

Regular expressions are part of those small technology areas that are incredibly useful in a wide range of programs, yet rarely used among developers. You can think of regular expressions as a mini-programming language with one specific purpose: to locate substrings within a large string expression. It is not a new technology; it originated in the UNIX environment and is commonly used with the Perl programming language.

Microsoft ported it onto Windows, where up until now it has been used mostly with scripting languages. Today, regular expressions are supported by a number of .NET classes in the namespace `System.Text.RegularExpressions`. You can also find the use of regular expressions in various parts of the .NET Framework. For instance, you will find that they are used within the ASP.NET Validation server controls.

If you are not familiar with the regular expressions language, this section introduces both regular expressions and their related .NET classes. If you are already familiar with regular expressions, you will probably want to just skim through this section to pick out the references to the .NET base classes. You might like to know that the .NET regular expression engine is designed to be mostly compatible with Perl 5 regular expressions, although it has a few extra features.

Introduction to Regular Expressions

The regular expressions language is designed specifically for string processing. It contains two features:

- A set of *escape codes* for identifying specific types of characters. You will be familiar with the use of the `*` character to represent any substring in DOS expressions. (For example, the DOS command `Dir Re*` lists the files with names beginning with `Re`.) Regular expressions use many sequences like this to represent items such as *any one character*, *a word break*, *one optional character*, and so on.
- A system for grouping parts of substrings and intermediate results during a search operation.

With regular expressions, you can perform quite sophisticated and high-level operations on strings. For example, you can:

- Identify (and perhaps either flag or remove) all repeated words in a string (for example, “The computer books books” to “The computer books”)
- Convert all words to title case (for example, “this is a Title” to “This Is A Title”)
- Convert all words longer than three characters to title case (for example, “this is a Title” to “This is a Title”)
- Ensure that sentences are properly capitalized
- Separate the various elements of a URI (for example, given `http://www.wrox.com`, extract the protocol, computer name, file name, and so on)

Of course, all these tasks can be performed in C# using the various methods on `System.String` and `System.Text.StringBuilder`. However, in some cases, this would require writing a fair amount of C# code. If you use regular expressions, this code can normally be compressed to just a couple of lines. Essentially, you instantiate a `System.Text.RegularExpressions.RegEx` object (or, even simpler, invoke a static `RegEx()` method), pass it the string to be processed, and pass in a regular expression (a string containing the instructions in the regular expressions language), and you’re done.

A regular expression string looks at first sight rather like a regular string, but interspersed with escape sequences and other characters that have a special meaning. For example, the sequence `\b` indicates the beginning or end of a word (a word boundary), so if you wanted to indicate you were looking for the characters `th` at the beginning of a word, you would search for the regular expression, `\bth` (that is, the sequence word boundary-`t`-`h`). If you wanted to search for all occurrences of `th` at the end of a word, you would write `th\b` (the sequence `t`-`h`-word boundary). However, regular expressions are much more sophisticated than that and include, for example, facilities to store portions of text that are found in a search operation. This section merely scratches the surface of the power of regular expressions.

Suppose your application needed to convert U.S. phone numbers to an international format. In the United States, the phone numbers have this format: 314-123-1234, which is often written as (314) 123-1234. When converting this national format to an international format you have to include +1 (the country code of the United States) and add brackets around the area code: +1 (314) 123-1234. As find-and-replace operations go, that is not too complicated. It would still require some coding effort if you were going to use the `String` class for this purpose (which would mean that you would have to write your code using the methods available from `System.String`). The regular expressions language allows you to construct a short string that achieves the same result.

This section is intended only as a very simple example, so it concentrates on searching strings to identify certain substrings, not on modifying them.

The RegularExpressionsPlayaround Example

For the rest of this section, you develop a short example, called `RegularExpressionsPlayaround`, that illustrates some of the features of regular expressions and how to use the .NET regular expressions engine in C# by performing and displaying the results of some searches. The text you are going to use as your sample document is an introduction to a Wrox Press book on ASP.NET (*Professional ASP.NET 4: in C# and VB,* Wiley Publishing, 2010, ISBN 978-0-4705-0220-4).

```
const string myText =
@"This comprehensive compendium provides a broad and thorough investigation of all
aspects of programming with ASP.NET. Entirely revised and updated for the fourth
release of .NET, this book will give you the information you need to
master ASP.NET and build a dynamic, successful, enterprise Web application.";
```

code snippet RegularExpressionsPlayaround.cs

This code is valid C# code, despite all the line breaks. It nicely illustrates the utility of verbatim strings that are prefixed by the @ symbol.

This text is referred to as the *input string*. To get your bearings and get used to the regular expressions of .NET classes, you start with a basic plain text search that does not feature any escape sequences or regular expression commands. Suppose that you want to find all occurrences of the string `ion`. This search string is referred to as the *pattern*. Using regular expressions and the `Text` variable declared previously, you could write this:

```
const string pattern = "ion";
MatchCollection myMatches = Regex.Matches(myText, pattern,
                                        RegexOptions.IgnoreCase |
                                        RegexOptions.ExplicitCapture);

foreach (Match nextMatch in myMatches)
{
   Console.WriteLine(nextMatch.Index);
}
```

This code uses the static method `Matches()` of the `Regex` class in the `System.Text.RegularExpressions` namespace. This method takes as parameters some input text, a pattern, and a set of optional flags taken from the `RegexOptions` enumeration. In this case, you have specified that all searching should be case-insensitive. The other flag, `ExplicitCapture`, modifies the way that the match is collected in a way that, for your purposes, makes the search a bit more efficient — you see why this is later (although it does have other uses that we won't explore here). `Matches()` returns a reference to a `MatchCollection` object. A *match* is the technical term for the results of finding an instance of the pattern in the expression. It is represented by the class `System.Text.RegularExpressions.Match`. Therefore, you return a `MatchCollection` that contains all the matches, each represented by a `Match` object. In the preceding code, you simply iterate over the collection and use the `Index` property of the `Match` class, which returns the index in the input text of where the match was found. Running this code results in three matches. The following table details some of the `RegexOptions` enumerations.

MEMBER NAME	DESCRIPTION
`CultureInvariant`	Specifies that the culture of the string is ignored.
`ExplicitCapture`	Modifies the way the match is collected by making sure that valid captures are the ones that are explicitly named.
`IgnoreCase`	Ignores the case of the string that is input.
`IgnorePatternWhitespace`	Removes unescaped whitespace from the string and enables comments that are specified with the pound or hash sign.
`Multiline`	Changes the characters ^ and $ so that they are applied to the beginning and end of each line and not just to the beginning and end of the entire string.
`RightToLeft`	Causes the inputted string to be read from right to left instead of the default left to right (ideal for some Asian and other languages that are read in this direction).
`Singleline`	Specifies a single-line mode where the meaning of the dot (.) is changed to match every character.

So far, nothing is new from the preceding example apart from some .NET base classes. However, the power of regular expressions really comes from that pattern string. The reason is that the pattern string does not have to contain only plain text. As hinted earlier, it can also contain what are known as *meta-characters,* which are special characters that give commands, as well as escape sequences, which work in much the same way as C# escape sequences. They are characters preceded by a backslash (`\`) and have special meanings.

For example, suppose that you wanted to find words beginning with `n`. You could use the escape sequence `\b`, which indicates a word boundary (a word boundary is just a point where an alphanumeric character precedes or follows a whitespace character or punctuation symbol). You would write this:

```
const string pattern = @"\bn";
MatchCollection myMatches = Regex.Matches(myText, pattern,
                                          RegexOptions.IgnoreCase |
                                          RegexOptions.ExplicitCapture);
```

Notice the `@` character in front of the string. You want the `\b` to be passed to the .NET regular expressions engine at runtime — you don't want the backslash intercepted by a well-meaning C# compiler that thinks it's an escape sequence intended for itself! If you want to find words ending with the sequence `ion`, you write this:

```
const string pattern = @"ion\b";
```

If you want to find all words beginning with the letter `a` and ending with the sequence `ion` (which has as its only match the word *application* in the example), you will have to put a bit more thought into your code. You clearly need a pattern that begins with `\ba` and ends with `ion\b`, but what goes in the middle? You need to somehow tell the application that between the `a` and the `ion` there can be any number of characters as long as none of them are whitespace. In fact, the correct pattern looks like this:

```
const string pattern = @"\ba\S*ion\b";
```

Eventually you will get used to seeing weird sequences of characters like this when working with regular expressions. It actually works quite logically. The escape sequence `\S` indicates any character that is not a whitespace character. The `*` is called a *quantifier.* It means that the preceding character can be repeated any number of times, including zero times. The sequence `\S*` means *any number of characters as long as they are not whitespace characters*. The preceding pattern will, therefore, match any single word that begins with `a` and ends with `ion`.

The following table lists some of the main special characters or escape sequences that you can use. It is not comprehensive, but a fuller list is available in the MSDN documentation.

SYMBOL	MEANING	EXAMPLE	MATCHES
`^`	Beginning of input text	`^B`	B, but only if first character in text
`$`	End of input text	`X$`	X, but only if last character in text
`.`	Any single character except the newline character (\ )	`i.ation`	`isation, ization`
`*`	Preceding character may be repeated zero or more times	`ra*t`	`rt, rat, raat, raaat,` and so on
`+`	Preceding character may be repeated one or more times	`ra+t`	`rat, raat, raaat` and so on, but not `rt`
`?`	Preceding character may be repeated zero or one time	`ra?t`	`rt` and `rat` only
`\s`	Any whitespace character	`\sa`	`[space]a, \ta, \na` (`\t` and `\n` have the same meanings as in C#)
`\S`	Any character that isn't whitespace	`\SF`	`aF, rF, cF`, but not `\tf`
`\b`	Word boundary	`ion\b`	Any word ending in `ion`
`\B`	Any position that isn't a word boundary	`\BX\B`	`Any X` in the middle of a word

If you want to search for one of the meta-characters, you can do so by escaping the corresponding character with a backslash. For example, `.` (a single period) means any single character other than the newline character, whereas `\.` means a dot.

You can request a match that contains alternative characters by enclosing them in square brackets. For example, `[1|c]` means one character that can be either `1` or `c`. If you wanted to search for any occurrence of the words `map` or `man`, you would use the sequence `ma[n|p]`. Within the square brackets, you can also indicate a range, for example `[a-z]`, to indicate any single lowercase letter, `[A-E]` to indicate any uppercase letter between `A` and `E` (including the letters `A` and `E` themselves), or `[0-9]` to represent a single digit. If you want to search for an integer (that is, a sequence that contains only the characters 0 through 9), you could write `[0-9]+`.

The use of the + character indicates there must be at least one such digit, but there may be more than one — so this would match 9, 83, 854, and so on.

Displaying Results

In this section, you code the `RegularExpressionsPlayaround` example, so you can get a feel for how the regular expressions work.

The core of the example is a method called `WriteMatches()`, which writes out all the matches from a `MatchCollection` in a more detailed format. For each match, it displays the index of where the match was found in the input string, the string of the match, and a slightly longer string, which consists of the match plus up to ten surrounding characters from the input text — up to five characters before the match and up to five afterward. (It is fewer than five characters if the match occurred within five characters of the beginning or end of the input text.) In other words, a match on the word `messaging` that occurs near the end of the input text quoted earlier would display `and messaging of d` (five characters before and after the match), but a match on the final word `data` would display `g of data.` (only one character after the match), because after that you get to the end of the string. This longer string lets you see more clearly where the regular expression locates the match:

```
static void WriteMatches(string text, MatchCollection matches)
{
   Console.WriteLine("Original text was: \n\n" + text + "\n");
   Console.WriteLine("No. of matches: " + matches.Count);

   foreach (Match nextMatch in matches)
   {
      int index = nextMatch.Index;
      string result = nextMatch.ToString();
      int charsBefore = (index < 5) ? index: 5;
      int fromEnd = text.Length-index-result.Length;
      int charsAfter = (fromEnd < 5) ? fromEnd: 5;
      int charsToDisplay = charsBefore + charsAfter + result.Length;

      Console.WriteLine("Index: {0}, \tString: {1}, \t{2}",
         index, result,
         text.Substring(index-charsBefore, charsToDisplay));
   }
}
```

The bulk of the processing in this method is devoted to the logic of figuring out how many characters in the longer substring it can display without overrunning the beginning or end of the input text. Note that you use another property on the `Match` object, `Value`, which contains the string identified for the match. Other than that, `RegularExpressionsPlayaround` simply contains a number of methods with names such as `Find1`, `Find2`, and so on, which perform some of the searches based on the examples in this section. For example, `Find2` looks for any string that contains `a` at the beginning of a word:

```
static void Find2()
{
   string text = @"This comprehensive compendium provides a broad and thorough
     investigation of all aspects of programming with ASP.NET. Entirely revised and
     updated for the 3.5 Release of .NET, this book will give you the information
     you need to master ASP.NET and build a dynamic, successful, enterprise Web
     application.";
   string pattern = @"\ba";
   MatchCollection matches = Regex.Matches(text, pattern,
     RegexOptions.IgnoreCase);
   WriteMatches(text, matches);
}
```

Along with this comes a simple `Main()` method that you can edit to select one of the `Find<n>()` methods:

```
static void Main()
{
   Find1();
   Console.ReadLine();
}
```

The code also needs to make use of the `RegularExpressions` namespace:

```
using System;
using System.Text.RegularExpressions;
```

Running the example with the `Find2()` method shown previously gives these results:

```
RegularExpressionsPlayaround
Original text was:

This comprehensive compendium provides a broad and thorough investigation of all
aspects of programming with ASP.NET. Entirely revised and updated for the 3.5
```

```
Release of .NET, this book will give you the information you need to master ASP.NET
and build a dynamic, successful, enterprise Web application.

No. of matches: 1
Index: 291,     String: application,     Web application.
```

Matches, Groups, and Captures

One nice feature of regular expressions is that you can group characters. It works the same way as compound statements in C#. In C#, you can group any number of statements by putting them in braces, and the result is treated as one compound statement. In regular expression patterns, you can group any characters (including meta-characters and escape sequences), and the result is treated as a single character. The only difference is that you use parentheses instead of braces. The resultant sequence is known as a *group*.

For example, the pattern `(an)+` locates any recurrences of the sequence `an`. The `+` quantifier applies only to the previous character, but because you have grouped the characters together, it now applies to repeats of `an` treated as a unit. This means that if you apply `(an)+` to the input text, `bananas came to Europe late in the annals of history`, the `anan` from `bananas` is identified. Yet, if you write `an+`, the program selects the `ann` from `annals`, as well as two separate sequences of `an` from `bananas`. The expression `(an)+` identifies occurrences of `an`, `anan`, `ananan`, and so on, whereas the expression `an+` identifies occurrences of `an`, `ann`, `annn`, and so on.

You might wonder why with the preceding example `(an)+` *picks out* `anan` *from the word banana but doesn't identify either of the two occurrences of* `an` *from the same word. The rule is that matches must not overlap. If there are a couple of possibilities that would overlap, then by default the longest possible sequence will be matched.*

However, groups are actually more powerful than that. By default, when you form part of the pattern into a group, you are also asking the regular expression engine to remember any matches against just that group, as well as any matches against the entire pattern. In other words, you are treating that group as a pattern to be matched and returned in its own right. This can actually be extremely useful if you want to break up strings into component parts.

For example, URIs have the format `<protocol>://<address>:<port>`, where the port is optional. An example of this is `http://www.wrox.com:4355`. Suppose that you want to extract the protocol, the address, and the port from a URI, where you know that there may or may not be whitespace (but no punctuation) immediately following the URI. You could do so using this expression:

```
\b(\S+)://([^:]+)(?::(\S+))?\b
```

Here is how this expression works: First, the leading and trailing `\b` sequences ensure that you consider only portions of text that are entire words. Within that, the first group, `(\S+)://`, identifies one or more characters that don't count as whitespace, and that are followed by:`//` — the `http://` at the start of an HTTP URI. The brackets cause the `http` to be stored as a group. Next, `([^:]+)` identifies the string `www.wrox.com` in the URI. This group will end either when it encounters the end of the word (the closing `\b`) or a colon (`:`) as marked by the next group.

The next group identifies the port (`:4355`). The following `?` indicates that this group is optional in the match — if there is no:`xxxx`, this won't prevent a match from being marked. This is very important because the port number is not always specified in a URI — in fact, it is absent most of the time. However, things are a bit more complicated than that. You want to indicate that the colon might or might not appear too, but you don't want to store this colon in the group. You've achieved this by having two nested groups. The inner `(\S+)` identifies anything that follows the colon (for example, `4355`). The outer group contains the inner group preceded by the colon, and this group in turn is preceded by the sequence `?:`. This sequence indicates that the group in question should not be saved (you only want to save `4355`; you don't need `:4355` as well!). Don't get confused by the two colons following each other — the first colon is part of the `?:` sequence that says "don't save this group," and the second is text to be searched for.

If you run this pattern on the following string, you'll get one match: `http://www.wrox.com`.

```
Hey I've just found this amazing URI at
http:// what was it --oh yes http://www.wrox.com
```

Within this match, you will find the three groups just mentioned as well as a fourth group, which represents the match itself. Theoretically, it is possible that each group itself might return no, one, or more than one match. Each of these individual matches is known as a *capture*. So, the first group, (`\S+`), has one capture, `http`. The second group also has one capture (`www.wrox.com`). The third group, however, has no captures, because there is no port number on this URI.

Notice that the string contains a second `http://`. Although this does match up to the first group, it will not be captured by the search because the entire search expression does not match this part of the text.

There isn't space to show examples of C# code that uses groups and captures, but you should know that the .NET `RegularExpressions` classes support groups and captures through classes known as `Group` and `Capture`. Also, the `GroupCollection` and `CaptureCollection` classes represent collections of groups and captures. The `Match` class exposes the `Groups` property, which returns the corresponding `GroupCollection` object. The `Group` class correspondingly implements the `Captures` property, which returns a `CaptureCollection`. The relationship between the objects is shown in Figure 9-3.

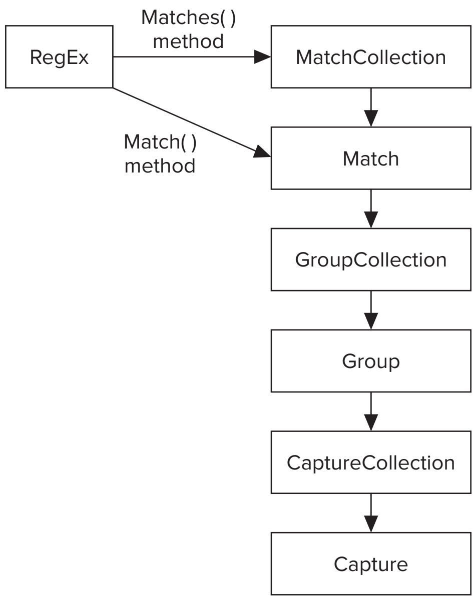


FIGURE 9-3

You might not want to return a `Group` object every time you just want to group some characters. A fair amount of overhead is involved in instantiating the object, which is not necessary if all you want is to group some characters as part of your search pattern. You can disable this by starting the group with the character sequence `?:` for an individual group, as was done for the URI example, or for all groups by specifying the `RegExOptions.ExplicitCaptures` flag on the `RegEx.Matches()` method, as was done in the earlier examples.

SUMMARY

You have quite a number of available data types at your disposal when working with the .NET Framework. One of the most used types in your applications (especially applications that focus on the submission and retrieval of data) is the `string` data type. The importance of `string` is the reason that this book has a complete chapter focused on how to use the `string` data type and manipulate it in your applications.

When working with strings in the past, it was quite common to just slice and dice the strings as needed using concatenation. With the .NET Framework, you can use the `StringBuilder` class to accomplish a lot of this task with better performance than before.

Last, but hardly least, advanced string manipulation using regular expressions is an excellent tool to search through and validate your strings.

10 Collections

WHAT'S IN THIS CHAPTER?

- ➤ Understanding collection interfaces and types
- ➤ Working with lists, queues, and stacks
- ➤ Working with linked and sorted lists
- ➤ Using dictionaries and sets
- ➤ Using bit arrays and bit vectors
- ➤ Evaluating performance

In Chapter 6, "Arrays and Tuples," you read about arrays and the interfaces implemented by the `Array` class. The size of arrays is fixed. If the number of elements is dynamic, you should use a collection class.

`List<T>` is a collection class that can be compared to arrays. But there are also other kinds of collections: queues, stacks, linked lists, and dictionaries.

> *Version 1 of the .NET Framework included non-generic collection classes such as* `ArrayList` *and* `HashTable`*. CLR 2.0 added support for generics and generic collection classes. The focus of this chapter is on the newer group of collection classes and mainly ignores the old ones, as they are rarely needed with new applications.*

COLLECTION INTERFACES AND TYPES

Most collection classes can be found in the `System.Collections` and `System.Collections.Generic` namespaces. Generic collection classes are located in the `System.Collections.Generic` namespace. Collection classes that are specialized for a specific type are located in the `System.Collections.Specialized` namespace. Thread-safe collection classes are in the `System.Collections.Concurrent` namespace.

Of course, there are also other ways to group collection classes. Collections can be grouped into lists, collections, and dictionaries based on the interfaces that are implemented by the collection class.

The following table describes interfaces implemented by collections and lists.

INTERFACE	DESCRIPTION
`IEnumerable<T>`	The interface `IEnumerable` is required by the `foreach` statement. This interface defines the method `GetEnumerator()` which returns an enumerator that implements the `IEnumerator` interface.
`ICollection<T>`	`ICollection<T>` is implemented by generic collection classes. With this you can get the number of items in the collection (`Count` property), and copy the collection to an array (`CopyTo`() method). You can also add and remove items from the collection (`Add(), Remove(), Clear()`).
`IList<T>`	The `IList<T>` interface is for lists where elements can be accessed from their position. This interface defines an indexer, as well as ways to insert or remove items from specific positions (`Insert()`, `RemoveAt()` methods). `IList`<T> derives from `ICollection<T>`.
`ISet<T>`	The `ISet<T>` interface is new with .NET 4. This interface is implemented by sets that allow combining different sets to a union, get the intersection of two sets, and check whether two sets overlap. `ISet<T>` derives from `ICollection<T>`.
`IDictionary<TKey, TValue>`	The interface `IDictionary<TKey, TValue>` is implemented by generic collection classes that have a key and a value. With this interface all the keys and values can be accessed, items can be accessed with an indexer of type key, and items can be added or removed.
`ILookup<TKey, TValue>`	Similar to the `IDictionary<TKey, TValue>` interface, lookups have keys and values. However, with lookups the collection can contain multiple values with one key.
`IComparer<T>`	The interface `IComparer<T>` is implemented by a comparer and used to sort elements inside a collection with the `Compare()` method.
`IEqualityComparer<T>`	`IEqualityComparer<T>` is implemented by a comparer that can be used for keys in a dictionary. With this interface the objects can be compared for equality. With .NET 4, this interface is also implemented by arrays and tuples.
`IProducerConsumerCollection<T>`	The interface `IProducerConsumerCollection<T>` is new with .NET 4 to support new thread-safe collection classes.

LISTS

For dynamic lists, the .NET Framework offers the generic class `List<T>`. This class implements the `IList`, `ICollection`, `IEnumerable`, `IList<T>`, `ICollection<T>`, and `IEnumerable<T>` interfaces.

The following examples use the members of the class Racer as elements to be added to the collection to represent a Formula-1 racer. This class has five properties: Id, FirstName, LastName, Country, and the number of Wins. With the constructor of the class, the name of the racer and the number of wins can be passed to set the members. The method ToString() is overridden to return the name of the racer. The class Racer also implements the generic interface IComparable<T> for sorting racer elements and IFormattable.

```
[Serializable]
public class Racer: IComparable<Racer>, IFormattable
{
    public int Id { get; private set; }
    public string FirstName { get; set; }
    public string LastName { get; set; }
    public string Country { get; set; }
    public int Wins { get; set; }
    public Racer(int id, string firstName, string lastName,
                 string country = null, int wins = 0)
    {
        this.Id = id;
        this.FirstName = firstName;
        this.LastName = lastName;
        this.Country = country;
        this.Wins = wins;
    }

    public override string ToString()
    {
        return String.Format("{0} {1}", FirstName, LastName);
    }

    public string ToString(string format, IFormatProvider formatProvider)
    {
        if (format == null) format = "N";
        switch (format.ToUpper())
        {
            case "N": // name
                return ToString();
            case "F": // first name
                return FirstName;
            case "L": // last name
                return LastName;
            case "W": // Wins
                return String.Format("{0}, Wins: {1}", ToString(), Wins);
            case "C": // Country
                return String.Format("{0}, Country: {1}", ToString(), Country);
            case "A": // All
                return String.Format("{0}, {1} Wins: {2}", ToString(), Country,
                                     Wins);
            default:
                throw new FormatException(String.Format(formatProvider,
                    "Format {0} is not supported", format));
        }
    }

    public string ToString(string format)
    {
        return ToString(format, null);
    }

    public int CompareTo(Racer other)
```

```
        {
            int compare = this.LastName.CompareTo(other.LastName);
            if (compare == 0)
                return this.FirstName.CompareTo(other.FirstName);
            return compare;
        }
    }
```

code snippet ListSamples/Racer.cs

Creating Lists

You can create list objects by invoking the default constructor. With the generic class `List<T>`, you must specify the type for the values of the list with the declaration. The code shows how to declare a `List<T>` with `int` and a list with `Racer` elements. `ArrayList` is a non-generic list that accepts any `Object` type for its elements.

Using the default constructor creates an empty list. As soon as elements are added to the list, the capacity of the list is extended to allow four elements. If the fifth element is added, the list is resized to allow eight elements. If eight elements are not enough, the list is resized again to contain 16 elements. With every resize the capacity of the list is doubled.

```
var intList = new List<int>();
var racers = new List<Racer>();
```

If the capacity of the list changes, the complete collection is reallocated to a new memory block. With the implementation of `List<T>`, an array of type `T` is used. With reallocation, a new array is created, and `Array.Copy()` copies the elements from the old to the new array. To save time, if you know the number of elements in advance, that should be in the list; you can define the capacity with the constructor. Here a collection with a capacity of 10 elements is created. If the capacity is not large enough for the elements added, the capacity is resized to 20 and 40 elements — doubled again.

```
List<int> intList = new List<int>(10);
```

You can get and set the capacity of a collection by using the `Capacity` property:

```
intList.Capacity = 20;
```

The capacity is not the same as the number of elements in the collection. The number of elements in the collection can be read with the `Count` property. Of course, the capacity is always larger or equal to the number of items. As long as no element was added to the list, the count is 0.

```
Console.WriteLine(intList.Count);
```

If you are finished adding elements to the list and don't want to add any more elements, you can get rid of the unneeded capacity by invoking the `TrimExcess()` method. However, because the relocation takes time, `TrimExcess()` does nothing if the item count is more than 90 percent of capacity.

```
intList.TrimExcess();
```

Collection Initializers

You can also assign values to collections using collection initializers. The syntax of collection initializers is similar to array initializers, which were explained in Chapter 6. With a collection initializer, values are assigned to the collection within curly brackets at the initialization of the collection:

```
var intList = new List<int>() {1, 2};
var stringList = new List<string>() {"one", "two"};
```

Collection initializers are not reflected within the IL code of the compiled assembly. The compiler converts the collection initializer to invoke the `Add()` *method for every item from the initializer list.*

Adding Elements

You can add elements to the list with the `Add()` method as shown. The generic instantiated type defines the parameter type of the `Add()` method.

```
var intList = new List<int>();
intList.Add(1);
intList.Add(2);

var stringList = new List<string>();
stringList.Add("one");
stringList.Add("two");
```

The variable `racers` is defined as type `List<Racer>`. With the `new` operator, a new object of the same type is created. Because the class `List<T>` was instantiated with the concrete class `Racer`, now only `Racer` objects can be added with the `Add()` method. In the following sample code, five Formula-1 racers are created and added to the collection. The first three are added using the collection initializer, and the last two are added by invoking the `Add()` method explicitly:

```
var graham = new Racer(7, "Graham", "Hill", "UK", 14);
var emerson = new Racer(13, "Emerson", "Fittipaldi", "Brazil", 14);
var mario = new Racer(16, "Mario", "Andretti", "USA", 12);

var racers = new List<Racer>(20) {graham, emerson, mario};

racers.Add(new Racer(24, "Michael", "Schumacher", "Germany", 91));
racers.Add(new Racer(27, "Mika", "Hakkinen", "Finland", 20));
```

code snippet ListSamples/Program.cs

With the `AddRange()` method of the `List<T>` class, you can add multiple elements to the collection at once. The method `AddRange()` accepts an object of type `IEnumerable<T>`, so you can also pass an array as shown:

```
racers.AddRange(new Racer[] {
      new Racer(14, "Niki", "Lauda", "Austria", 25),
      new Racer(21, "Alain", "Prost", "France", 51)});
```

The collection initializer can be used only during declaration of the collection. The `AddRange()` *method can be invoked after the collection is initialized.*

If you know some elements of the collection when instantiating the list, you can also pass any object that implements `IEnumerable<T>` to the constructor of the class. This is very similar to the `AddRange()` method:

```
var racers =
   new List<Racer>(new Racer[] {
      new Racer(12, "Jochen", "Rindt", "Austria", 6),
      new Racer(22, "Ayrton", "Senna", "Brazil", 41) });
```

Inserting Elements

You can insert elements at a specified position with the `Insert()` method:

```
racers.Insert(3, new Racer(6, "Phil", "Hill", "USA", 3));
```

The method `InsertRange()` offers the capability to insert a number of elements, similarly to the `AddRange()` method shown earlier.

If the index set is larger than the number of elements in the collection, an exception of type `ArgumentOutOfRangeException` is thrown.

Accessing Elements

All classes that implement the `IList` and `IList<T>` interface offer an indexer, so you can access the elements by using an indexer and passing the item number. The first item can be accessed with an index value 0. By specifying `racers[3]`, you will access the fourth element of the list:

```
Racer r1 = racers[3];
```

Getting the number of elements with the `Count` property, you can do a `for` loop to iterate through every item in the collection, and use the indexer to access every item:

```
for (int i = 0; i < racers.Count; i++)
{
   Console.WriteLine(racers[i]);
}
```

> *Indexed access to collection classes is available with* `ArrayList`, `StringCollection`, *and* `List<T>`.

Because `List<T>` implements the interface `IEnumerable`, you can iterate through the items in the collection using the `foreach` statement as well:

```
foreach (Racer r in racers)
{
   Console.WriteLine(r);
}
```

> *How the* `foreach` *statement is resolved by the compiler to make use of the* `IEnumerable` *and* `IEnumerator` *interfaces is explained in Chapter 6.*

Instead of using the `foreach` statement, the `List<T>` class also offers a `ForEach()` method that is declared with an `Action<T>` parameter:

```
public void ForEach(Action<T> action);
```

The implementation of `ForEach()` is shown next. `ForEach()` iterates through every item of the collection and invokes the method that is passed as parameter for every item.

```
public class List<T>: IList<T>
{
   private T[] items;

   //...

   public void ForEach(Action<T> action)
```

```
      {
         if (action == null) throw new ArgumentNullException("action");

         foreach (T item in items)
         {
            action(item);
         }
      }
      //...
   }
```

For passing a method with `ForEach`, `Action<T>` is declared as a delegate that defines a method with a `void` return type and parameter `T`:

```
public delegate void Action<T>(T obj);
```

With a list of `Racer` items, the handler for the `ForEach()` method must be declared with a `Racer` object as parameter and a `void` return type:

```
public void ActionHandler(Racer obj);
```

Because one overload of the `Console.WriteLine()` method accepts `Object` as parameter, you can pass the address of this method to the `ForEach()` method, and every racer of the collection is written to the console:

```
racers.ForEach(Console.WriteLine);
```

You can also write a Lambda expression that accepts a `Racer` object as parameter and does the `Console.WriteLine()` with the implementation. Here, the format `A` is used with the `ToString()` method of the `IFormattable` interface to display all information about the racer:

```
racers.ForEach(r => Console.WriteLine("{0:A}", r));
```

Lambda expressions are explained in Chapter 8, "Delegates, Lambdas, and Events."

Removing Elements

You can remove elements by index or pass the item that should be removed. Here, the fourth element is removed by passing 3 to `RemoveAt()`:

```
racers.RemoveAt(3);
```

You can also directly pass a `Racer` object to the `Remove()` method to remove this element. Removing by index is faster, because here the collection must be searched for the item to remove. The `Remove()` method first searches in the collection to get the index of the item with the `IndexOf()` method, and then uses the index to remove the item. `IndexOf()` first checks if the item type implements the interface `IEquatable<T>`. If it does, the `Equals()` method of this interface is invoked to find the item in the collection that is the same as the one passed to the method. If this interface is not implemented, the `Equals()` method of the `Object` class is used to compare the items. The default implementation of the `Equals()` method in the `Object` class does a bitwise compare with value types, but compares only references with reference types.

Chapter 7, "Operators and Casts," explains how you can override the `Equals()` *method.*

Here, the racer referenced by the variable `graham` is removed from the collection. The variable `graham` was created earlier when the collection was filled. Because the interface `IEquatable<T>` and the `Object.Equals()` method are not overridden with the `Racer` class, you cannot create a new object with the same content as the item that should be removed and pass it to the `Remove()` method.

```
if (!racers.Remove(graham))
{
   Console.WriteLine(
   "object not found in collection");
}
```

The method `RemoveRange()` removes a number of items from the collection. The first parameter specifies the index where the removal of items should begin; the second parameter specifies the number of items to be removed.

```
int index = 3;
int count = 5;
racers.RemoveRange(index, count);
```

To remove all items with some specific characteristics from the collection, you can use the `RemoveAll()` method. This method uses the `Predicate<T>` parameter when searching for elements, which is discussed next. For removing all elements from the collection, use the `Clear()` method defined with the `ICollection<T>` interface.

Searching

There are different ways to search for elements in the collection. You can get the index to the found item, or the item itself. You can use methods such as `IndexOf()`, `LastIndexOf()`, `FindIndex()`, `FindLastIndex()`, `Find()`, and `FindLast()`. And for just checking if an item exists, the `List<T>` class offers the `Exists()` method.

The method `IndexOf()` requires an object as parameter and returns the index of the item if it is found inside the collection. If the item is not found, –1 is returned. Remember that `IndexOf()` is using the `IEquatable<T>` interface to compare the elements.

```
int index1 = racers.IndexOf(mario);
```

With the `IndexOf()` method, you can also specify that the complete collection should not be searched, but rather specify an index where the search should start and the number of elements that should be iterated for the comparison.

Instead of searching a specific item with the `IndexOf()` method, you can search for an item that has some specific characteristics that you can define with the `FindIndex()` method. `FindIndex()` requires a parameter of type `Predicate`:

```
public int FindIndex(Predicate<T> match);
```

The `Predicate<T>` type is a delegate that returns a Boolean value and requires type `T` as parameter. This delegate can be used similarly to the `Action` delegate shown earlier with the `ForEach()` method. If the predicate returns `true`, there's a match and the element is found. If it returns `false`, the element is not found and the search continues.

```
public delegate bool Predicate<T>(T obj);
```

With the `List<T>` class that is using `Racer` objects for type `T`, you can pass the address of a method that returns a `bool` and defines a parameter of type `Racer` to the `FindIndex()` method. Finding the first racer of a specific country, you can create the `FindCountry` class as shown. The `FindCountryPredicate()` method has the signature and return type defined by the `Predicate<T>` delegate. The `Find()` method uses the variable `country` to search for a country that you can pass with the constructor of the class.

```
public class FindCountry
{
   public FindCountry(string country)
   {
      this.country = country;
   }
   private string country;

   public bool FindCountryPredicate(Racer racer)
   {
      if (racer == null) throw new ArgumentNullException("racer");

      return racer.Country == country;
   }
}
```

With the `FindIndex()` method, you can create a new instance of the `FindCountry()` class, pass a country string to the constructor, and pass the address of the `Find` method. After `FindIndex()` completes successfully, `index2` contains the index of the first item where the `Country` property of the racer is set to `Finland`.

```
int index2 = racers.FindIndex(new FindCountry("Finland").
                 FindCountryPredicate);
```

Instead of creating a class with a handler method, you can use a Lambda expression here as well. The result is exactly the same as before. Now the Lambda expression defines the implementation to search for an item where the `Country` property is set to `Finland`.

```
int index3 = racers.FindIndex(r => r.Country == "Finland");
```

Similar to the `IndexOf()` method, with the `FindIndex()` method, you can also specify the index where the search should start and the count of items that should be iterated through. To do a search for an index beginning from the last element in the collection, you can use the `FindLastIndex()` method.

The method `FindIndex()` returns the index of the found item. Instead of getting the index, you can also get directly to the item in the collection. The `Find()` method requires a parameter of type `Predicate<T>`, much as the `FindIndex()` method. The `Find()` method here is searching for the first racer in the list that has the `FirstName` property set to `Niki`. Of course, you can also do a `FindLast()` to find the last item that fulfills the predicate.

```
Racer racer = racers.Find(r => r.FirstName == "Niki");
```

To get not only one, but all items that fulfill the requirements of a predicate, you can use the `FindAll()` method. The `FindAll()` method uses the same `Predicate<T>` delegate as the `Find()` and `FindIndex()` methods. The `FindAll()` method does not stop when the first item is found but instead iterates through every item in the collection and returns all items where the predicate returns `true`.

With the `FindAll()` method invoked here, all racer items are returned where the property `Wins` is set to more than 20. All racers who won more than 20 races are referenced from the `bigWinners` list.

```
List<Racer> bigWinners = racers.FindAll(r => r.Wins > 20);
```

Iterating through the variable `bigWinners` with a `foreach` statement gives the following result:

```
foreach (Racer r in bigWinners)
{
      Console.WriteLine("{0:A}", r);
}
```

```
Michael Schumacher, Germany Wins: 91
Niki Lauda, Austria Wins: 25
Alain Prost, France Wins: 51
```

The result is not sorted, but this is done next.

Sorting

The `List<T>` class allows sorting its elements by using the `Sort()` method. `Sort()` uses the quick sort algorithm where all elements are compared until the complete list is sorted.

You can use several overloads of the `Sort()` method. The arguments that can be passed are a generic delegate `Comparison<T>`, the generic interface `IComparer<T>`, and a range together with the generic interface `IComparer<T>`:

```
public void List<T>.Sort();
public void List<T>.Sort(Comparison<T>);
public void List<T>.Sort(IComparer<T>);
public void List<T>.Sort(Int32, Int32, IComparer<T>);
```

Using the `Sort()` method without arguments is possible only if the elements in the collection implement the interface `IComparable`.

The class `Racer` implements the interface `IComparable<T>` to sort racers by the last name:

```
racers.Sort();
racers.ForEach(Console.WriteLine);
```

If you need to do a sort other than the default supported by the item types, you need to use other techniques, for example passing an object that implements the `IComparer<T>` interface.

The class `RacerComparer` implements the interface `IComparer<T>` for `Racer` types. This class allows you to sort either by the first name, last name, country, or number of wins. The kind of sort that should be done is defined with the inner enumeration type `CompareType`. The `CompareType` is set with the constructor of the class `RacerComparer`. The interface `IComparer<Racer>` defines the method `Compare` that is required for sorting. In the implementation of this method, the `CompareTo()` method of the `string` and `int` types is used.

```
public class RacerComparer: IComparer<Racer>
{
   public enum CompareType
   {
      FirstName,
      LastName,
      Country,
      Wins
   }

   private CompareType compareType;
   public RacerComparer(CompareType compareType)
   {
      this.compareType = compareType;
   }

   public int Compare(Racer x, Racer y)
   {
      if (x == null) throw new ArgumentNullException("x");
      if (y == null) throw new ArgumentNullException("y");

      int result;
      switch (compareType)
      {
         case CompareType.FirstName:
            return x.FirstName.CompareTo(y.FirstName);
         case CompareType.LastName:
            return x.LastName.CompareTo(y.LastName);
         case CompareType.Country:
            if ((result = x.Country.CompareTo(y.Country)) == 0)
               return x.LastName.CompareTo(y.LastName);
               else
                  return result;
            case CompareType.Wins:
               return x.Wins.CompareTo(y.Wins);
            default:
               throw new ArgumentException("Invalid Compare Type");
         }
      }
   }
```

code snippet ListSamples/RacerComparer.cs

An instance of the `RacerComparer` class can now be used with the `Sort()` method. Passing the enumeration `RacerComparer.CompareType.Country` sorts the collection by the property `Country`:

```
      racers.Sort(new RacerComparer(RacerComparer.CompareType.Country));
      racers.ForEach(Console.WriteLine);
```

Another way to do the sort is by using the overloaded `Sort()` method, which requires a `Comparison<T>` delegate:

```
public void List<T>.Sort(Comparison<T>);
```

`Comparison<T>` is a delegate to a method that has two parameters of type `T` and a return type `int`. If the parameter values are equal, the method must return `0`. If the first parameter is less than the second, a value less than zero must be returned; otherwise, a value greater than zero is returned:

```
public delegate int Comparison<T>(T x, T y);
```

Now you can pass a Lambda expression to the `Sort()` method to do a sort by the number of wins. The two parameters are of type `Racer`, and in the implementation the `Wins` properties are compared by using the `int` method `CompareTo()`. In the implementation, `r2` and `r1` are used in the reverse order, so the number of wins is sorted in descending order. After the method has been invoked, the complete racer list is sorted based on the number of wins of the racer:

```
   racers.Sort((r1, r2) => r2.Wins.CompareTo(r1.Wins));
```

You can also reverse the order of a complete collection by invoking the `Reverse()` method.

Type Conversion

With the `List<T>` method `ConvertAll<TOutput>()`, all types of a collection can be converted to a different type. The `ConvertAll<TOutput>()` method uses a `Converter` delegate that is defined like this:

```
public sealed delegate TOutput Converter<TInput, TOutput>(TInput from);
```

The generic types `TInput` and `TOutput` are used with the conversion. `TInput` is the argument of the delegate method, and `TOutput` is the return type.

In this example, all `Racer` types should be converted to `Person` types. Whereas the `Racer` type contains a `firstName`, `lastName`, `country`, and the number of `wins`, the `Person` type contains just a `name`. For the conversion, the country of the racer and race wins can be ignored, but the name must be converted:

```
[Serializable]
public class Person
{
   private string name;

   public Person(string name)
   {
      this.name = name;
      }

      public override string ToString()
      {
         return name;
      }
   }
```

The conversion happens by invoking the `racers.ConvertAll<Person>()` method. The argument of this method is defined as a Lambda expression with an argument of type `Racer` and a `Person` type that is returned. In the implementation of the Lambda expression, a new `Person` object is created and returned. For the `Person` object, the `FirstName` and `LastName` are passed to the constructor:

```
      List<Person> persons =
            racers.ConvertAll<Person>(
               r => new Person(r.FirstName + " " + r.LastName));
```

The result of the conversion is a list containing the converted `Person` objects: `persons` of type `List<Person>`.

Read-Only Collections

After collections are created they are read/write. Of course, they must be read/write; otherwise, you couldn't fill them with any values. However, after the collection is filled, you can create a read-only collection. The `List<T>` collection has the method `AsReadOnly()` that returns an object of type `ReadOnlyCollection<T>`. The class `ReadOnlyCollection<T>` implements the same interfaces as `List<T>`, but all methods and properties that change the collection throw a `NotSupportedException`.

QUEUE

A queue is a collection where elements are processed *first in, first out* (FIFO). The item that is put first in the queue is read first. Examples of queues are standing in the queue at the airport, a human resources queue to process employee applicants, print jobs waiting to be processed in a print queue, and a thread waiting for the CPU in a round-robin fashion. Often, there are queues where the elements processed differ in their priority. For example, in the queue at the airport, business passengers are processed before economy passengers. Here, multiple queues can be used, one queue for every priority. At the airport this can easily be found out, because there are separate check-in queues for business and economy passengers. The same is true for print queues and threads. You can have an array or a list of queues where one item in the array stands for a priority. Within every array item there's a queue, where processing happens with the FIFO principle.

Later in this chapter, a different implementation with a linked list is used to define a list of priorities.

A queue is implemented with the `Queue<T>` class in the namespace `System.Collections.Generic`. Internally, the `Queue<T>` class is using an array of type `T`, similar to the `List<T>` type. It implements the interfaces `IEnumerable<T>` and `ICollection`, but not `ICollection<T>`. `ICollection<T>` is not implemented because this interface defines `Add()` and `Remove()` methods which shouldn't be available for queues.

The `Queue<T>` class does not implement the interface `IList<T>`, so you cannot access the queue using an indexer. The queue just allows you to add an item to the queue, where the item is put at the end of the queue (with the `Enqueue()` method), and to get items from the head of the queue (with the `Dequeue()` method).

Figure 10-1 shows the items of the queue. The `Enqueue()` method adds items to one end of the queue; the items are read and removed at the other end of the queue with the `Dequeue()` method. Invoking the `Dequeue()` method once more removes the next item from the queue.

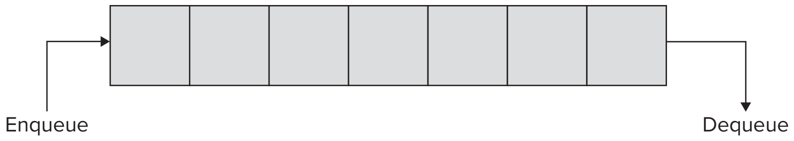

FIGURE 10-1

Methods of the `Queue<T>` class are described in the following table.

SELECTED QUEUE <T> MEMBERS	DESCRIPTION
`Count`	The property `Count` returns the number of items in the queue.
`Enqueue()`	The `Enqueue()` method adds an item to the end of the queue.
`Dequeue()`	The `Dequeue()` method reads and removes an item from the head of the queue. If there are no more items in the queue when the `Dequeue()` method is invoked, an exception of type `InvalidOperationException` is thrown.
`Peek()`	The `Peek()` method reads an item from the head of the queue but does not remove the item.
`TrimExcess()`	`TrimExcess()` resizes the capacity of the queue. The `Dequeue()` method removes items from the queue, but it doesn't resize the capacity of the queue. To get rid of the empty items at the beginning of the queue, use the `TrimExcess()` method.

When creating queues, you can use constructors similar to those used with the `List<T>` type. The default constructor creates an empty queue, but you can also use a constructor to specify the capacity. As items are added to the queue, the capacity is increased to hold 4, 8, 16, and 32 items if the capacity is not defined. Similarly to the `List<T>` class, the capacity is always doubled as required. The default constructor of the non-generic `Queue` class is different, because it creates an initial array of 32 empty items. With an overload of the constructor, you can also pass any other collection that implements the `IEnumerable<T>` interface that is copied to the queue.

The sample application that demonstrates the use of the `Queue<T>` class is a document management application. One thread is used to add documents to the queue, and another thread reads documents from the queue and processes them.

The items stored in the queue are of type `Document`. The `Document` class defines a title and content:

```
public class Document
{
   public string Title { get; private set; }
   public string Content { get; private set; }

   public Document(string title, string content)
   {
      this.Title = title;
      this.Content = content;
   }
}
```

code snippet QueueSample/Document.cs

The `DocumentManager` class is a thin layer around the `Queue<T>` class. The class `DocumentManager` defines how to handle documents: adding documents to the queue with the `AddDocument()` method, and getting documents from the queue with the `GetDocument()` method.

Inside the `AddDocument()` method, the document is added to the end of the queue by using the `Enqueue()` method. The first document from the queue is read with the `Dequeue()` method inside `GetDocument()`. Because multiple threads can access the `DocumentManager` concurrently, access to the queue is locked with the `lock` statement.

Threading and the `lock` *statement are discussed in Chapter 20, "Threads, Tasks, and Synchronization."*

`IsDocumentAvailable` is a read-only Boolean property that returns `true` if there are documents in the queue, and `false` if not:

```
public class DocumentManager
{
   private readonly Queue<Document> documentQueue = new Queue<Document>();

   public void AddDocument(Document doc)
   {
      lock (this)
      {
         documentQueue.Enqueue(doc);
      }
   }

   public Document GetDocument()
   {
      Document doc = null;
      lock (this)
      {
         doc = documentQueue.Dequeue();
      }
      return doc;
   }

   public bool IsDocumentAvailable
   {
      get
      {
         return documentQueue.Count > 0;
      }
   }
}
```

code snippet QueueSample/DocumentManager.cs

The class `ProcessDocuments` processes documents from the queue in a separate thread. The only method that can be accessed from the outside is `Start()`. In the `Start()` method, a new thread is instantiated. A `ProcessDocuments` object is created for starting the thread, and the `Run()` method is defined as the start method of the thread. `ThreadStart` is a delegate that references the method to be started by the thread. After creating the `Thread` object, the thread is started by calling the method `Thread.Start()`.

With the `Run()` method of the `ProcessDocuments` class, an endless loop is defined. Within this loop, the property `IsDocumentAvailable` is used to see if there is a document in the queue. If there is a document in the queue, the document is taken from the `DocumentManager` and processed. Processing here is writing information only to the console. In a real application, the document could be written to a file, written to the database, or sent across the network:

```
<public class ProcessDocuments
{
   public static void Start(DocumentManager dm)
   {
      new Thread(new ProcessDocuments(dm).Run).Start();
   }

   protected ProcessDocuments(DocumentManager dm)
   {
      documentManager = dm;
   }

   private DocumentManager documentManager;

   protected void Run()
   {
      while (true)
      {
         if (documentManager.IsDocumentAvailable)
         {
            Document doc = documentManager.GetDocument();
            Console.WriteLine("Processing document {0}", doc.Title);
         }
         Thread.Sleep(new Random().Next(20));
      }
   }
}
```

code snippet QueueSample/ProcessDocuments.cs

In the `Main()` method of the application, a `DocumentManager` object is instantiated, and the document processing thread is started. Then 1,000 documents are created and added to the `DocumentManager`:

```
class Program
{
   static void Main()
   {
      var dm = new DocumentManager();

      ProcessDocuments.Start(dm);

      // Create documents and add them to the DocumentManager
      for (int i = 0; i < 1000; i++)
      {
         Document doc = new Document("Doc " + i.ToString(), "content");
         dm.AddDocument(doc);
         Console.WriteLine("Added document {0}", doc.Title);
         Thread.Sleep(new Random().Next(20));
      }
   }
}
```

code snippet QueueSample/Program.cs

When you start the application, the documents are added to and removed from the queue, and you get output similar to the following:

```
Added document Doc 279
Processing document Doc 236
Added document Doc 280
Processing document Doc 237
Added document Doc 281
Processing document Doc 238
Processing document Doc 239
Processing document Doc 240
Processing document Doc 241
Added document Doc 282
Processing document Doc 242
Added document Doc 283
Processing document Doc 243
```

A real-life scenario doing the task described with the sample application can be an application that processes documents received with a Web service.

STACK

A stack is another container that is very similar to the queue. You just use different methods to access the stack. The item that is added last to the stack is read first. The stack is a *last in*, *first out* (LIFO) container.

Figure 10-2 shows the representation of a stack where the `Push()` method adds an item to the stack, and the `Pop()` method gets the item that was added last.

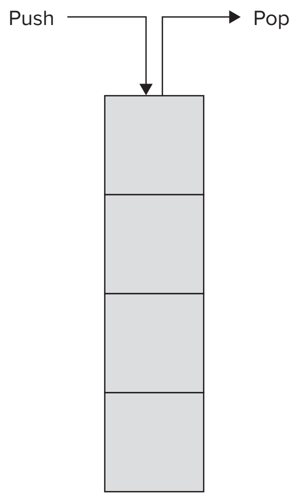

FIGURE 10-2

Similar to the `Queue<T>` class, the `Stack<T>` class implements the interfaces `IEnumerable<T>` and `ICollection`.

Members of the `Stack<T>` class are listed in the following table.

SELECTED STACK<T> MEMBERS	DESCRIPTION
`Count`	The property `Count` returns the number of items in the stack.
`Push()`	The `Push()` method adds an item on top of the stack.
`Pop()`	The `Pop()` method removes and returns an item from the top of the stack. If the stack is empty, an exception of type `InvalidOperation Exception` is thrown.
`Peek()`	The `Peek()` method returns an item from the top of the stack but does not remove the item.
`Contains()`	The `Contains()` method checks whether an item is in the stack and returns `true` if it is.

In this example, three items are added to the stack with the `Push()` method. With the `foreach` method, all items are iterated using the `IEnumerable` interface. The enumerator of the stack does not remove the items; it just returns item by item:

```
var alphabet = new Stack<char>();
alphabet.Push('A');
alphabet.Push('B');
alphabet.Push('C');

foreach (char item in alphabet)
```

```
            {
               Console.Write(item);
            }
            Console.WriteLine();
```

code snippet StackSample/Program.cs

Because the items are read in order from the last added to the first, the following result is produced:

```
CBA
```

Reading the items with the enumerator does not change the state of the items. With the `Pop()` method, every item that is read is also removed from the stack. This way you can iterate the collection using a `while` loop and verify the `Count` property if items still exist:

```
            var alphabet = new Stack<char>();
            alphabet.Push('A');
            alphabet.Push('B');
            alphabet.Push('C');

            Console.Write("First iteration: ");
            foreach (char item in alphabet)
            {
               Console.Write(item);
            }
            Console.WriteLine();

            Console.Write("Second iteration: ");
            while (alphabet.Count > 0)
            {
               Console.Write(alphabet.Pop());
            }
            Console.WriteLine();
```

The result gives CBA twice, once for each iteration. After the second iteration, the stack is empty because the second iteration used the `Pop()` method:

```
First iteration: CBA
Second iteration: CBA
```

LINKED LIST

`LinkedList<T>` is a doubly linked list, where one element references the next and the previous one, as shown in Figure 10-3.

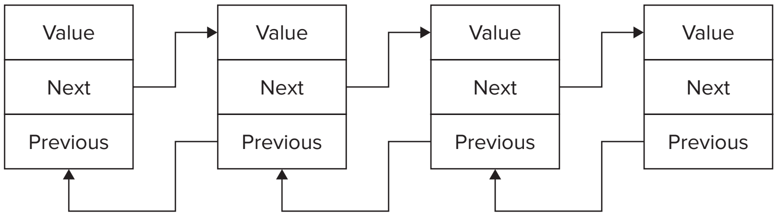

FIGURE 10-3

The advantage of a linked list is that if items are inserted in the middle of a list, the linked list is very fast. When an item is inserted, only the `Next` reference of the previous item and the `Previous` reference of the next item must be changed to reference the inserted item. With the `List<T>` class, when an element is inserted all following elements must be moved.

Of course, there's also a disadvantage with linked lists. Items of linked lists can be accessed only one after the other. It takes a long time to find an item that's somewhere in the middle or at the end of the list.

A linked list cannot just store the items inside the list; together with every item, the linked list must have information about the next and previous items. That's why the `LinkedList<T>` contains items of type `LinkedListNode<T>`. With the class `LinkedListNode<T>`, you can get to the next and previous items in the list. The `LinkedListNode<T>` class defines the properties `List`, `Next`, `Previous`, and `Value`. The `List` property returns the `LinkedList<T>` object that is associated with the node. `Next` and `Previous` are for iterating through the list and accessing the next or previous item. `Value` returns the item that is associated with the node. `Value` is of type `T`.

The `LinkedList<T>` class itself defines members to access the first (`First`) and last (`Last`) item of the list, to insert items at specific positions (`AddAfter()`, `AddBefore()`, `AddFirst()`, `AddLast()`), to remove items from specific positions (`Remove()`, `RemoveFirst()`, `RemoveLast()`), and to find elements where the search either starts from the begin (`Find()`) or the end (`FindLast()`) of the list.

The sample application to demonstrate linked lists uses a linked list together with a list. The linked list contains documents as in the queue example, but the documents have an additional priority associated with them. The documents will be sorted inside the linked list depending on the priority. If multiple documents have the same priority, the elements are sorted according to the time the document was inserted.

Figure 10-4 describes the collections of the sample application. `LinkedList<Document>` is the linked list containing all the `Document` objects. The figure shows the title and the priority of the documents. The title indicates when the document was added to the list: The first document added has the title `"One"`, the second document has the title `"Two"`, and so on. You can see that the documents `One` and `Four` have the same priority, 8, but because `One` was added before `Four`, it is earlier in the list.

When new documents are added to the linked list, they should be added after the last document that has the same priority. The `LinkedList<Document>` collection contains elements of type `LinkedListNode <Document>`. The class `LinkedListNode<T>` adds `Next` and `Previous` properties to walk from one node to the next. For referencing such elements, the `List<T>` is defined as `List<LinkedListNode<Document>>`. For fast access to the last document of every priority, the collection `List<LinkedListNode>` contains up to 10 elements, each referencing the last document of every priority. In the upcoming discussion, the reference to the last document of every priority is called the *priority node*.

From the previous example, the `Document` class is extended to contain the priority. The priority is set with the constructor of the class:

```
public class Document
{
   public string Title { get; private set; }
   public string Content { get; private set; }
   public byte Priority { get; private set; }

   public Document(string title, string content, byte priority = 0)
   {
      this.Title = title;
      this.Content = content;
      this.Priority = priority;
   }
}
```

code snippet LinkedListSample/Document.cs

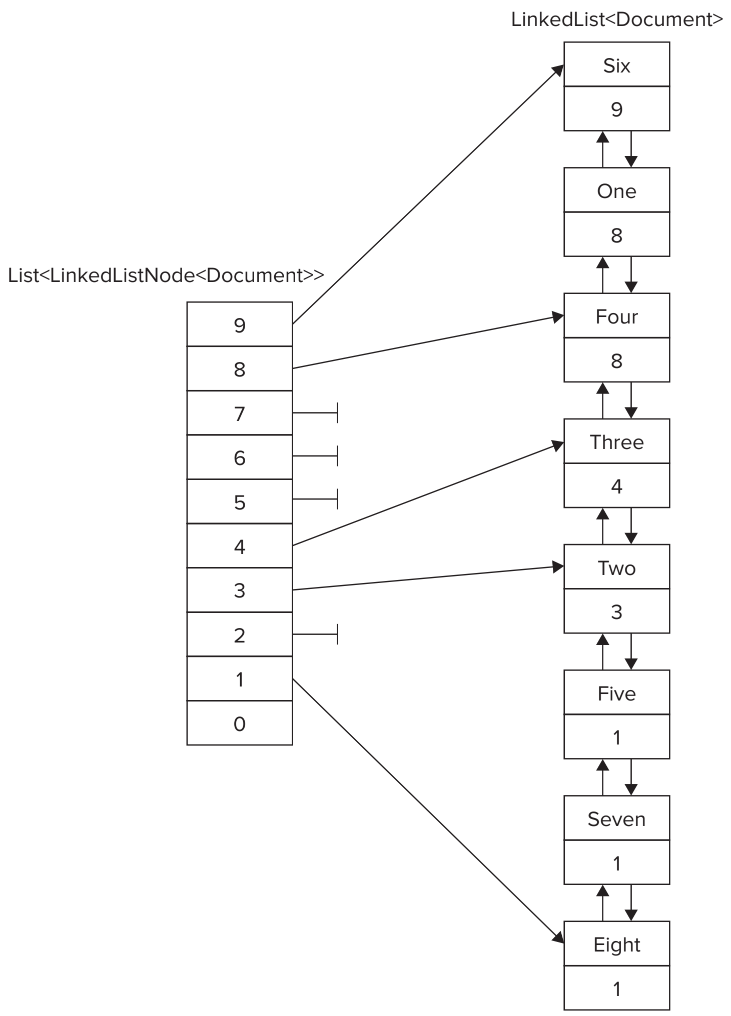

FIGURE 10-4

The heart of the solution is the `PriorityDocumentManager` class. This class is very easy to use. With the public interface of this class, new `Document` elements can be added to the linked list, the first document can be retrieved, and for testing purposes it also has a method to display all elements of the collection as they are linked in the list.

The class `PriorityDocumentManager` contains two collections. The collection of type `LinkedList<Document>` contains all documents. The collection of type `List<LinkedListNode <Document>>` contains references of up to 10 elements that are entry points for adding new documents with a specific priority. Both collection variables are initialized with the constructor of the class `PriorityDocumentManager`. The list collection is also initialized with `null`:

```
public class PriorityDocumentManager
{
  private readonly LinkedList<Document> documentList;
```

```
// priorities 0.9
private readonly List<LinkedListNode<Document>> priorityNodes;

public PriorityDocumentManager()
{
   documentList = new LinkedList<Document>();

   priorityNodes = new List<LinkedListNode<Document>>(10);
   for (int i = 0; i < 10; i++)
   {
      priorityNodes.Add(new LinkedListNode<Document>(null));
   }
}
```

code snippet LinkedListSample/PriorityDocumentManager.cs

Part of the public interface of the class is the method `AddDocument()`. `AddDocument()` does nothing more than call the private method `AddDocumentToPriorityNode()`. The reason for having the implementation inside a different method is that `AddDocumentToPriorityNode()` may be called recursively, as you will see soon:

```
public void AddDocument(Document d)
{
   if (d == null) throw new ArgumentNullException("d");

   AddDocumentToPriorityNode(d, d.Priority);
}
```

The first action that is done in the implementation of `AddDocumentToPriorityNode()` is a check to see if the priority fits in the allowed priority range. Here, the allowed range is between 0 and 9. If a wrong value is passed, an exception of type `ArgumentException` is thrown.

Next, you check if there's already a priority node with the same priority as the priority that was passed. If there's no such priority node in the list collection, `AddDocumentToPriorityNode()` is invoked recursively with the priority value decremented to check for a priority node with the next lower priority.

If there's no priority node with the same priority or any priority with a lower value, the document can be safely added to the end of the linked list by calling the method `AddLast()`. Also, the linked list node is referenced by the priority node that's responsible for the priority of the document.

If there's an existing priority node, you can get the position inside the linked list where the document should be inserted. Here, you must differentiate whether a priority node already exists with the correct priority, or if there's just a priority node that references a document with a lower priority. In the first case, you can just insert the new document after the position that's referenced by the priority node. Because the priority node always must reference the last document with a specific priority, the reference of the priority node must be set. It gets more complex if just a priority node referencing a document with a lower priority exists. Here, the document must be inserted before all documents with the same priority as the priority node. To get the first document of the same priority, a `while` loop iterates through all linked list nodes, using the `Previous` property, until a linked list node is reached that has a different priority. This way, you know the position where the document must be inserted, and the priority node can be set:

```
private void AddDocumentToPriorityNode(Document doc, int priority)
{
   if (priority > 9 || priority < 0)
      throw new ArgumentException("Priority must be between 0 and 9");

   if (priorityNodes[priority].Value == null)
   {
      --priority;
      if (priority >= 0)
```

```
            {
               // check for the next lower priority
               AddDocumentToPriorityNode(doc, priority);
            }
            else // now no priority node exists with the same priority or lower
                 // add the new document to the end
            {
               documentList.AddLast(doc);
               priorityNodes[doc.Priority] = documentList.Last;
            }
            return;
         }
         else // a priority node exists
         {
            LinkedListNode<Document> prioNode = priorityNodes[priority];
            if (priority == doc.Priority)
                  // priority node with the same priority exists
            {
               documentList.AddAfter(prioNode, doc);

               // set the priority node to the last document with the same priority
               priorityNodes[doc.Priority] = prioNode.Next;
            }
            else // only priority node with a lower priority exists
            {
               // get the first node of the lower priority
               LinkedListNode<Document> firstPrioNode = prioNode;

               while (firstPrioNode.Previous != null &&
                  firstPrioNode.Previous.Value.Priority == prioNode.Value.Priority)
               {
                  firstPrioNode = prioNode.Previous;
                  prioNode = firstPrioNode;
               }

               documentList.AddBefore(firstPrioNode, doc);

               // set the priority node to the new value
               priorityNodes[doc.Priority] = firstPrioNode.Previous;
            }
         }
      }
```

Now only simple methods are left for discussion. `DisplayAllNodes()` just does a `foreach` loop to display the priority and the title of every document to the console.

The method `GetDocument()` returns the first document (the document with the highest priority) from the linked list and removes it from the list:

```
      public void DisplayAllNodes()
      {
         foreach (Document doc in documentList)
         {
            Console.WriteLine("priority: {0}, title {1}", doc.Priority, doc.Title);
         }
      }

      // returns the document with the highest priority
      // (that's first in the linked list)
      public Document GetDocument()
      {
         Document doc = documentList.First.Value;
```

```
            documentList.RemoveFirst();
            return doc;
         }
      }
```

In the `Main()` method, the `PriorityDocumentManager` is used to demonstrate its functionality. Eight new documents with different priorities are added to the linked list, and then the complete list is displayed:

```
      static void Main()
      {
         PriorityDocumentManager pdm =  new PriorityDocumentManager();
         pdm.AddDocument(new Document("one", "Sample", 8));
         pdm.AddDocument(new Document("two", "Sample", 3));
         pdm.AddDocument(new Document("three", "Sample", 4));
         pdm.AddDocument(new Document("four", "Sample", 8));
         pdm.AddDocument(new Document("five", "Sample", 1));
         pdm.AddDocument(new Document("six", "Sample", 9));
         pdm.AddDocument(new Document("seven", "Sample", 1));
         pdm.AddDocument(new Document("eight", "Sample", 1));

         pdm.DisplayAllNodes();
      }
```

code snippet LinkedListSample/Program.cs

With the processed result, you can see that the documents are sorted first by the priority and second by when the document was added:

```
priority: 9, title six
priority: 8, title one
priority: 8, title four
priority: 4, title three
priority: 3, title two
priority: 1, title five
priority: 1, title seven
priority: 1, title eight
```

SORTED LIST

If the collection you need should be sorted based on a key, you can use `SortedList<TKey, TValue>`. This class sorts the elements based on a key. Not only can you use any type for the value, but also for the key.

The example creates a sorted list where both the key and the value are of type `string`. The default constructor creates an empty list, and then two books are added with the `Add()` method. With overloaded constructors, you can define the capacity of the list and also pass an object that implements the interface `IComparer<TKey>`, which is used to sort the elements in the list.

The first parameter of the `Add()` method is the key (the book title); the second parameter is the value (the ISBN number). Instead of using the `Add()` method, you can use the indexer to add elements to the list. The indexer requires the key as index parameter. If a key already exists, the `Add()` method throws an exception of type `ArgumentException`. If the same key is used with the indexer, the new value replaces the old value.

`SortedList<TKey, TValue>` *allows only one value per key. If you need multiple values per key you can use* `Lookup<TKey, TElement>`.

```
var books = new SortedList<string, string>();
books.Add("C# 2008 Wrox Box", "978-0-470-047205-7");
books.Add("Professional ASP.NET MVC 1.0", "978-0-470-38461-9");

books["Beginning Visual C# 2008"] = "978-0-470-19135-4";
books["Professional C# 2008"] = "978-0-470-19137-6";
```

code snippet SortedListSample/Program.cs

You can iterate through the list by using a `foreach` statement. Elements that are returned by the enumerator are of type `KeyValuePair<TKey, TValue>`, which contains both the key and the value. The key can be accessed with the `Key` property, and the value can be accessed with the `Value` property:

```
foreach (KeyValuePair<string, string> book in books)
{
   Console.WriteLine("{0}, {1}", book.Key, book.Value);
}
```

The iteration displays book titles and ISBN numbers ordered by the key:

```
Beginning Visual C# 2008, 978-0-470-19135-4
C# 2008 Wrox Box, 978-0-470-047205-7
Professional ASP.NET MVC 1.0, 978-0-470-38461-9
Professional C# 2008, 978-0-470-19137-6
```

You can also access the values and keys by using the `Values` and `Keys` properties. The `Values` property returns `IList<TValue>` and the `Keys` property returns `IList<TKey>`, so you can use these properties with a `foreach`:

```
foreach (string isbn in books.Values)
{
   Console.WriteLine(isbn);
}

foreach (string title in books.Keys)
{
   Console.WriteLine(title);
}
```

The first loop displays the values, and next the keys:

```
978-0-470-19135-4
978-0-470-047205-7
978-0-470-38461-9
978-0-470-19137-6
Beginning Visual C# 2008
C# 2008 Wrox Box
Professional ASP.NET MVC 1.0
Professional C# 2008
```

If you try to access an element with an indexer passing a key that does not exist, an exception of type `KeyNotFoundException` is thrown. To avoid that exception you can use the method `ContainsKey()` that returns `true` if the key passed exists in the collection, or you can invoke the method `TryGetValue()` that tries to get the value but doesn't throw an exception if the value is not here:

```
string isbn;
string title = "Professional C# 7.0";
if (!books.TryGetValue(title, out isbn))
{
    Console.WriteLine("{0} not found", title);
}
```

DICTIONARIES

Dictionaries represent a sophisticated data structure that allows you to access an element based on a key. Dictionaries are also known as hash tables or maps. The main feature of dictionaries is fast lookup based on keys. You can also add and remove items freely, a bit like a `List<T>`, but without the performance overhead of having to shift subsequent items in memory.

Figure 10-5 shows a simplified representation of a dictionary. Here `employee-ids` such as B4711 are the keys added to the dictionary. The key is transformed into a hash. With the hash a number is created to associate an index with the values. The index then contains a link to the value. The figure is simplified because it is possible that a single index entry can be associated with multiple values, and the index can be stored as a tree.

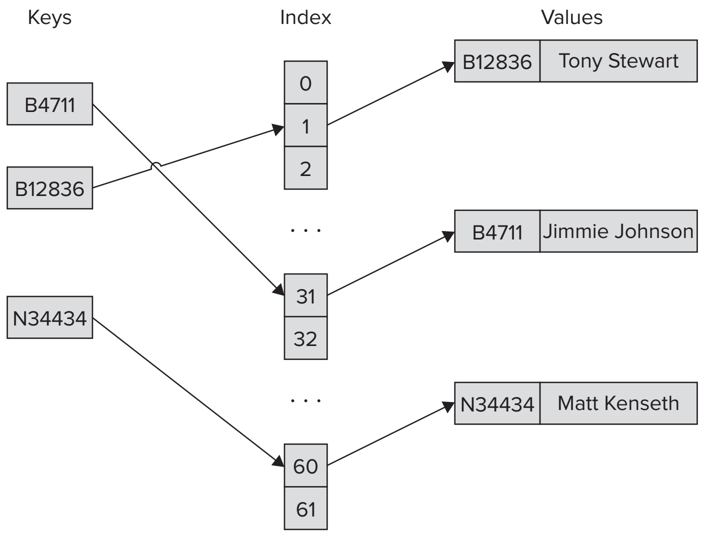

FIGURE 10-5

The .NET Framework offers several dictionary classes. The main class you can use is `Dictionary<TKey, TValue>`.

Key Type

A type that is used as a key in the dictionary must override the method `GetHashCode()` of the `Object` class. Whenever a dictionary class needs to work out where an item should be located, it calls the `GetHashCode()` method. The `int` that is returned by `GetHashCode()` is used by the dictionary to calculate an index of where to place the element. We don't go into this part of the algorithm. What you should know is that it involves prime numbers, so the capacity of a dictionary is a prime number.

The implementation of `GetHashCode()` must satisfy these requirements:

- The same object should always return the same value.
- Different objects can return the same value.
- It should execute as quickly as possible; it must be inexpensive to compute.
- It must not throw exceptions.
- It should use at least one instance field.

- The hash code value should be evenly distributed across the entire range of numbers that an `int` can store.
- The hash code should not change during the lifetime of the object.

> *A good performance of the dictionary is based on a good implementation of the method* `GetHashCode()`.

What's the reason for having hash code values evenly distributed across the range of integers? If two keys return hashes that give the same index, the dictionary class needs to start looking for the nearest available free location to store the second item — and will have to do some searching to retrieve this item later on. This is obviously going to hurt performance, and clearly, if lots of your keys are tending to give the same indexes for where they should be stored, this kind of clash becomes more likely. However, because of the way that Microsoft's part of the algorithm works, this risk is minimized when the calculated hash values are evenly distributed between `int.MinValue` and `int.MaxValue`.

Besides having an implementation of `GetHashCode()`, the key type also must implement the `IEquatable<T>.Equals()` method or override the `Equals()` method from the `Object` class. Because different key objects may return the same hash code, the method `Equals()` is used by the dictionary comparing keys. The dictionary examines if two keys `A` and `B` are equal; it invokes `A.Equals(B)`. This means that you must ensure that the following is always true:

If `A.Equals(B)` is true, then `A.GetHashCode()` and `B.GetHashCode()` must always return the same hash code.

This probably seems a fairly subtle point, but it is crucial. If you contrived some way of overriding these methods so that the preceding statement was not always true, a dictionary that uses instances of this class as its keys would simply not work properly. Instead, you'd find funny things happening. For example, you might place an object in the dictionary and then discover that you could never retrieve it, or you might try to retrieve an entry and have the wrong entry returned.

> *For this reason, the C# compiler will display a compilation warning if you supply an override for* `Equals()` *but don't supply an override for* `GetHashCode()`.

For `System.Object` this condition is true, because `Equals()` simply compares references, and `GetHashCode()` actually returns a hash that is based solely on the address of the object. This means that hash tables based on a key that doesn't override these methods will work correctly. However, the problem with this way of doing things is that keys are regarded as equal only if they are the same object. That means that when you place an object in the dictionary, you then have to hang onto the reference to the key. You can't simply instantiate another key object later with the same value. If you don't override `Equals()` and `GetHashCode()`, the type is not very convenient to use in a dictionary.

Incidentally, `System.String` implements the interface `IEquatable` and overloads `GetHashCode()` appropriately. `Equals()` provides value comparison, and `GetHashCode()` returns a hash based on the value of the string. Strings can be used conveniently as keys in dictionaries.

Number types such as `Int32` also implement the interface `IEquatable` and overload `GetHashCode()`. However, the hash code returned by these types simply maps to the value. If the number you would like to use as a key is not itself distributed around the possible values of an integer, using integers as keys doesn't fulfill the rule of evenly distributing key values to get the best performance. `Int32` is not meant to be used in a dictionary.

If you need to use a key type that does not implement `IEquatable` and override `GetHashCode` according to the key values you store in the dictionary, you can create a comparer implementing the interface `IEqualityComparer<T>`. `IEqualityComparer<T>` defines the methods `GetHashCode()` and `Equals()` with an argument of the object passed, so you can offer an implementation different from the object type itself. An overload of the `Dictionary<TKey, TValue>` constructor allows passing an object implementing `IEqualityComparer<T>`. If such an object is assigned to the dictionary, this class is used to generate the hash codes and compare the keys.

Dictionary Example

The dictionary example is a program that sets up a dictionary of employees. The dictionary is indexed by `EmployeeId` objects, and each item stored in the dictionary is an `Employee` object that stores details of an employee.

The struct `EmployeeId` is implemented to define a key to be used in a dictionary. The members of the class are a prefix character and a number for the employee. Both of these variables are read-only and can be initialized only in the constructor. A key within the dictionary shouldn't change, and this way that is guaranteed. The fields are filled within the constructor. The `ToString()` method is overloaded to get a string representation of the employee ID. As required for a key type, `EmployeeId` implements the interface `IEquatable` and overloads the method `GetHashCode()`.

```
[Serializable]
public class EmployeeIdException : Exception
{
    public EmployeeIdException(string message) : base(message)  { }
}

[Serializable]
public struct EmployeeId : IEquatable<EmployeeId>
{
    private readonly char prefix;
    private readonly int number;

    public EmployeeId(string id)
    {
        if (id == null) throw new ArgumentNullException("id");

        prefix = (id.ToUpper())[0];
        int numLength = id.Length  1;
        try
        {
            number = int.Parse(id.Substring(1, numLength > 6 ? 6 : numLength));
        }
        catch (FormatException)
        {
            throw new EmployeeIdException("Invalid EmployeeId format");
        }
    }

    public override string ToString()
    {
        return prefix.ToString() + string.Format("{0,6:000000}", number);
    }

    public override int GetHashCode()
    {
        return (number ^ number << 16) * 0x15051505;
    }

    public bool Equals(EmployeeId other)
```

```
            {
                if (other == null) return false;

                return (prefix == other.prefix && number == other.number);
            }

            public override bool Equals(object obj)
            {
                return Equals((EmployeeId)obj);
            }

            public static bool operator ==(EmployeeId left, EmployeeId right)
            {
                return left.Equals(right);
            }

            public static bool operator !=(EmployeeId left, EmployeeId right)
            {
                return !(left == right);
            }
        }
```

code snippet DictionarySample/EmployeeId.cs

The `Equals()` method that is defined by the `IEquatable<T>` interface compares the values of two `EmployeeId` objects and returns `true` if both values are the same. Instead of implementing the `Equals()` method from the `IEquatable<T>` interface, you can also override the `Equals()` method from the `Object` class:

```
public bool Equals(EmployeeId other)
{
   if (other == null) return false;
   return (prefix == other.prefix && number == other.number);
}
```

With the number variable, a value from 1 to around 190,000 is expected for the employees. This doesn't fill the range of an integer. The algorithm used by `GetHashCode()` shifts the number 16 bits to the left, then does an XOR with the original number, and finally multiplies the result by the hex value 15051505. The hash code is fairly distributed across the range of an integer:

```
public override int GetHashCode()
{
   return (number ^ number << 16) * 0x15051505;
}
```

On the Internet, you can find a lot more complex algorithms that have a better distribution across the integer range. You can also use the `GetHashCode()` *method of a string to return a hash.*

The `Employee` class is a simple entity class containing the name, salary, and ID of the employee. The constructor initializes all values, and the method `ToString()` returns a string representation of an instance. The implementation of `ToString()` uses a format string to create the string representation for performance reasons:

```
[Serializable]
public class Employee
{
   private string name;
   private decimal salary;
```

```
      private readonly EmployeeId id;

      public Employee(EmployeeId id, string name, decimal salary)
      {
         this.id = id;
         this.name = name;
         this.salary = salary;
      }

      public override string ToString()
      {
         return String.Format("{0}: {1, -20} {2:C}",
               id.ToString(), name, salary);
      }
   }
```

code snippet DictionarySample/Employee.cs

In the `Main()` method of the sample application, a new `Dictionary<TKey, TValue>` instance is created, where the key is of type `EmployeeId` and the value is of type `Employee`. The constructor allocates a capacity of 31 elements. Remember, the capacity is based on prime numbers. However, when you assign a value that is not a prime number, you don't need to worry. The `Dictionary<TKey, TValue>` class itself takes the next prime number that follows the integer passed to the constructor to allocate the capacity. The employee objects and IDs are created and added to the dictionary with the `Add()` method. Instead of using the `Add()` method, you can also use the indexer to add keys and values to the dictionary, as shown with the employees Dale and Jeff:

```
      static void Main()
      {
          var employees = new Dictionary<EmployeeId, Employee>(31);

          var idKyle = new EmployeeId("T3755");
          var kyle = new Employee(idKyle, "Kyle Bush", 5443890.00m);
          employees.Add(idKyle, kyle);
          Console.WriteLine(kyle);

          var idCarl = new EmployeeId("F3547");
          var carl = new Employee(idCarl, "Carl Edwards", 5597120.00m);
          employees.Add(idCarl, carl);
          Console.WriteLine(carl);

          var idJimmie = new EmployeeId("C3386");
          var jimmie = new Employee(idJimmie, "Jimmie Johnson", 5024710.00m);
          employees.Add(idJimmie, jimmie);
          Console.WriteLine(jimmie);

          var idDale = new EmployeeId("C3323");
          var dale = new Employee(idDale, "Dale Earnhardt Jr.", 3522740.00m);
          employees[idDale] = dale;
          Console.WriteLine(dale);

          var idJeff = new EmployeeId("C3234");
          var jeff = new Employee(idJeff, "Jeff Burton", 3879540.00m);
          employees[idJeff] = jeff;
          Console.WriteLine(jeff);
```

code snippet DictionarySample/Program.cs

After the entries are added to the dictionary, inside a `while` loop employees are read from the dictionary. The user is asked to enter an employee number to store in the variable `userInput`. The user can exit the application by entering X. If the key is in the dictionary, it is examined with the `TryGetValue()` method of the `Dictionary<TKey, TValue>` class. `TryGetValue()` returns `true` if the key is found and `false` otherwise. If the value is found, the value associated with the key is stored in the employee variable. This value is written to the console.

You can also use an indexer of the `Dictionary<TKey, TValue>` *class instead of* `TryGetValue()` *to access a value stored in the dictionary. However, if the key is not found, the indexer throws an exception of type* `KeyNotFoundException`.

```
            while (true)
            {
                Console.Write("Enter employee id (X to exit)> ");
                var userInput = Console.ReadLine();
                userInput = userInput.ToUpper();
                if (userInput == "X") break;

                EmployeeId id;
                try
                {
                    id = new EmployeeId(userInput);

                    Employee employee;
                    if (!employees.TryGetValue(id, out employee))
                    {
                        Console.WriteLine("Employee with id {0} does not exist",
                                          id);
                    }
                    else
                    {
                        Console.WriteLine(employee);
                    }
                }
                catch (EmployeeIdException ex)
                {
                    Console.WriteLine(ex.Message);
                }
            }
        }
    }
```

Running the application produces the following output:

```
Enter employee id (X to exit)> C3386
C003386: Jimmie Johnson       ? 5.024.710,00
Enter employee id (X to exit)> F3547
F003547: Carl Edwards         ? 5.597.120,00
Enter employee id (X to exit)> X
Press any key to continue …
```

Lookup

`Dictionary<TKey, TValue>` supports only one value per key. The class `Lookup<TKey, TElement>` resembles a `Dictionary<TKey, TValue>` but maps keys to a collection of values. This class is implemented in the assembly `System.Core` and defined with the namespace `System.Linq`.

`Lookup<TKey, TElement>` cannot be created as a normal dictionary. Instead, you have to invoke the method `ToLookup()` that returns a `Lookup<TKey, TElement>` object. The method `ToLookup()` is an extension method that is available with every class implementing `IEnumerable<T>`. In the following example, a list of `Racer` objects is filled. Because `List<T>` implements `IEnumerable<T>`, the `ToLookup()` method can be invoked on the racers list. This method requires a delegate of type `Func<TSource, TKey>` that defines the selector of the key. Here the racers are selected based on the country by using the Lambda expression `r => r.Country`. The `foreach` loop accesses only the racers from Australia by using the indexer.

You can read more about extension methods in Chapter 11, "Language Integrated Query." Lambda expressions are explained in Chapter 8.

```
var racers = new List<Racer>();
racers.Add(new Racer("Jacques", "Villeneuve", "Canada", 11));
racers.Add(new Racer("Alan", "Jones", "Australia", 12));
racers.Add(new Racer("Jackie", "Stewart", "United Kingdom", 27));
racers.Add(new Racer("James", "Hunt", "United Kingdom", 10));
racers.Add(new Racer("Jack", "Brabham", "Australia", 14));

var lookupRacers = racers.ToLookup(r => r.Country);

foreach (Racer r in lookupRacers["Australia"])
{
   Console.WriteLine(r);
}
```

code snippet LookupSample/Program.cs

The output shows the racers from Australia:

```
Alan Jones
Jack Brabham
```

Sorted Dictionary

`SortedDictionary<TKey, TValue>` is a binary search tree where the items are sorted based on the key. The key type must implement the interface `IComparable<TKey>`. If the key type is not sortable, you can also create a comparer implementing `IComparer<TKey>` and assign the comparer as a constructor argument of the sorted dictionary.

Earlier in this chapter you read about `SortedList<TKey, TValue>`. `SortedDictionary<TKey, TValue>` and `SortedList<TKey, TValue>` have similar functionalities. But because `SortedList<TKey, TValue>` is implemented as a list that is based on an array and `SortedDictionary<TKey, TValue>` is implemented as a dictionary, the classes have different characteristics:

- ➤ `SortedList<TKey, TValue>` uses less memory than `SortedDictionary<TKey, TValue>`.
- ➤ `SortedDictionary<TKey, TValue>` has faster insertion and removal of elements.
- ➤ When populating the collection with already sorted data, `SortedList<TKey, TValue>` is faster, if capacity changes are not needed.

SETS

A collection that contains only distinct items is known by the term *set*. .NET 4 includes two sets, HashSet<T> and SortedSet<T>, that both implement the interface ISet<T>. HashSet<T> contains an unordered list of distinct items; with SortedSet<T> the list is ordered.

The ISet<T> interface offers methods to create a union of multiple sets, an intersection of sets, or give information if one set is a super- or subset of another.

With the sample code, three new sets of type string are created and filled with Formula-1 cars. The HashSet<T> class implements the ICollection<T> interface. However, the Add() method is implemented explicitly and a different Add() method is offered by the class as you can see here. The Add() method differs by the return type; a Boolean value is returned to give the information if the element was added. If the element was already in the set, it is not added, and false is returned:

```
var companyTeams = new HashSet<string>()
      { "Ferrari", "McLaren", "Toyota", "BMW", "Renault" };
var traditionalTeams = new HashSet<string>()
      { "Ferrari", "McLaren" };
var privateTeams = new HashSet<string>()
      { "Red Bull", "Toro Rosso", "Force India", "Brawn GP" };

if (privateTeams.Add("Williams"))
   Console.WriteLine("Williams added");
if (!companyTeams.Add("McLaren"))
   Console.WriteLine("McLaren was already in this set");
```

code snippet SetSample/Program.cs

The result of these two Add() methods is written to the console:

```
Williams added
McLaren was already in this set
```

The methods IsSubsetOf() and IsSupersetOf() compare a set with a collection that implements the IEnumerable<T> interface and returns a Boolean result. Here, IsSubsetOf() verifies if every element in traditionalTeams is contained in companyTeams, which is the case; IsSupersetOf() verifies whether traditionalTeams has any additional elements compared to companyTeams:

```
if (traditionalTeams.IsSubsetOf(companyTeams))
{
   Console.WriteLine("traditionalTeams is subset of companyTeams");
}

if (companyTeams.IsSupersetOf(traditionalTeams))
{
   Console.WriteLine("companyTeams is a superset of traditionalTeams");
}
```

The output of this verification is shown here:

```
traditionalTeams is a subset of companyTeams
companyTeams is a superset of traditionalTeams
```

Williams is a traditional team as well, and that's why this team is added to the traditionalTeams collection:

```
traditionalTeams.Add("Williams");
if (privateTeams.Overlaps(traditionalTeams))
{
   Console.WriteLine("At least one team is the same with the " +
         "traditional and private teams");
}
```

Because there's an overlap, this is the result:

```
At least one team is the same with the traditional and private teams.
```

The variable `allTeams` that references a new `SortedSet<string>` is filled with a union of `companyTeams`, `privateTeams`, and `traditionalTeams` by calling the `UnionWith()` method:

```
         var allTeams = new SortedSet<string>(companyTeams);
         allTeams.UnionWith(privateTeams);
         allTeams.UnionWith(traditionalTeams);

         Console.WriteLine();
         Console.WriteLine("all teams");
         foreach (var team in allTeams)
         {
            Console.WriteLine(team);
         }
```

Here all teams are returned, but every team is listed just once because the set contains only unique values. Because the container is a `SortedSet<string>`, the result is ordered:

```
BMW
Brawn GP
Ferrari
Force India
McLaren
Red Bull
Renault
Toro Rosso
Toyota
Williams
```

The method `ExceptWith()` removes all private teams from the `allTeams` set:

```
         allTeams.ExceptWith(privateTeams);
         Console.WriteLine();
         Console.WriteLine("no private team left");
         foreach (var team in allTeams)
         {
            Console.WriteLine(team);
         }
```

The remaining elements in the collection do not contain any private team:

```
BMW
Ferrari
McLaren
Renault
Toyota
```

OBSERVABLE COLLECTION

In case you need information when items in the collection are removed or added, you can use the `ObservableCollection<T>` class. This class was defined for WPF so that the UI gets informed on collection changes, thus this class is defined in the assembly WindowsBase and you need to reference this assembly. The namespace of this class is `System.Collections.ObjectModel`.

`ObservableCollection<T>` derives from the base class `Collection<T>` that can be used to create custom collections and uses `List<T>` internal. From the base class the virtual method `SetItem()` and `RemoveItem()` is overridden to fire the `CollectionChanged` event. Clients of this class can register to this event by using the interface `INotifyCollectionChanged`.

The next sample shows using an `ObservableCollection<string>` where the method `Data_CollectionChanged` is registered to the `CollectionChanged` event. Two items are added to the end — one item is inserted, and one item is removed:

```
        var data = new ObservableCollection<string>();
        data.CollectionChanged += Data_CollectionChanged;
        data.Add("One");
        data.Add("Two");
        data.Insert(1, "Three");
        data.Remove("One");
```

code snippet ObservableCollectionSample/Program.cs

The method `Data_CollectionChanged` receives `NotifyCollectionChangedEventArgs` containing information about the changes of the collection. The `Action` property gives information if an item was added or removed. With removed items, the `OldItems` property is set and lists the removed items. With added items, the `NewItems` property is set and lists the new items:

```
    static void Data_CollectionChanged(object sender,
                                       NotifyCollectionChangedEventArgs e)
    {
        Console.WriteLine("action: {0}", e.Action.ToString());

        if (e.OldItems != null)
        {
            Console.WriteLine("starting index for old item(s): {0}",
                              e.OldStartingIndex);
            Console.WriteLine("old item(s):");
            foreach (var item in e.OldItems)
            {
                Console.WriteLine(item);
            }
        }
        if (e.NewItems != null)
        {
            Console.WriteLine("starting index for new item(s): {0}",
                              e.NewStartingIndex);
            Console.WriteLine("new item(s): ");
            foreach (var item in e.NewItems)
            {
                Console.WriteLine(item);
            }
        }
        Console.WriteLine();
    }
```

Running the application, you can see the output as follows. The first items `One` and `Two` are added to the collection and thus the `Add` action is shown with the index `0` and `1`. The third item `Three` is inserted on position 1 so it shows the action `Add` with index `1`. Finally, the item `One` is removed as shown with action `Remove` and index `0`:

```
action: Add
starting index for new item(s): 0
new item(s):
One

action: Add
starting index for new item(s): 1
new item(s):
Two

action: Add
```

```
starting index for new item(s): 1
new item(s):
Three

action: Remove
starting index for old item(s): 0
old item(s):
One
```

BIT ARRAYS

If you need to deal with a number of bits, you can use the class `BitArray` and the struct `BitVector32`. `BitArray` is located in the namespace `System.Collections`; `BitVector32` is in the namespace `System.Collections.Specialized`. The most important difference between these two types is that `BitArray` is resizable, which is useful if you don't know the number of bits needed in advance, and it can contain a large number of bits. `BitVector32` is stack-based and therefore faster. `BitVector32` contains only 32 bits, which are stored in an integer.

BitArray

The class `BitArray` is a reference type that contains an array of `int`s, where for every 32 bits a new integer is used. Members of this class are explained in the following table:

BITARRAY MEMBERS	DESCRIPTION
`Count Length`	The `get` accessor of both `Count` and `Length` return the number of bits in the array. With the `Length` property, you can also define a new size and resize the collection.
`Item Get() Set()`	You can use an indexer to read and write bits in the array. The indexer is of type `bool`. Instead of using the indexer, you can also use the `Get()` and `Set()` methods to access the bits in the array.
`SetAll()`	The method `SetAll()` sets the values of all bits according to the parameter passed to the method.
`Not()`	The method `Not()` generates the inverse of all bits of the array.
`And() Or() Xor()`	With the methods `And()`, `Or()`, and `Xor()`, you can combine two `BitArray` objects. The `And()` method does a binary AND, where the result bits are set only if the bits from both input arrays are set. The `Or()` method does a binary OR, where the result bits are set if one or both of the input arrays are set. The `Xor()` method is an exclusive OR, where the result is set if only one of the input bits is set.

The helper method `DisplayBits()` iterates through a `BitArray` and displays `1` or `0` to the console, depending on whether or not the bit is set:

```
static void DisplayBits(BitArray bits)
{
   foreach (bool bit in bits)
   {
      Console.Write(bit ? 1: 0);
   }
}
```

code snippet BitArraySample/Program.cs

The example to demonstrate the `BitArray` class creates a bit array with 8 bits, indexed from 0 to 7. The `SetAll()` method sets all 8 bits to `true`. Then the `Set()` method changes bit `1` to `false`. Instead of the `Set` method, you can also use an indexer, as shown with index `5` and `7`:

```
var bits1 = new BitArray(8);
bits1.SetAll(true);
bits1.Set(1, false);
bits1[5] = false;
bits1[7] = false;
Console.Write("initialized: ");
DisplayBits(bits1);
Console.WriteLine();
```

This is the displayed result of the initialized bits:

```
initialized: 10111010
```

The `Not()` method generates the inverse of the bits of the `BitArray`:

```
Console.Write(" not ");
DisplayBits(bits1);
bits1.Not();
Console.Write(" = ");
DisplayBits(bits1);
Console.WriteLine();
```

The result of `Not()` is all bits inversed. If the bit was `true`, it is `false`, and if it was `false`, it is `true`:

```
not 10111010 = 01000101
```

Here, a new `BitArray` is created. With the constructor, the variable `bits1` is used to initialize the array, so the new array has the same values. Then the values for bits 0, 1, and 4 are set to different values. Before the `Or()` method is used, the bit arrays `bits1` and `bits2` are displayed. The `Or()` method changes the values of `bits1`:

```
var bits2 = new BitArray(bits1);
bits2[0] = true;
bits2[1] = false;
bits2[4] = true;
DisplayBits(bits1);
Console.Write(" or ");
DisplayBits(bits2);
Console.Write(" = ");
bits1.Or(bits2);
DisplayBits(bits1);
Console.WriteLine();
```

With the `Or()` method, the set bits are taken from both input arrays. In the result, the bit is set if it was set with either the first or the second array:

```
01000101 or 10001101 = 11001101
```

Next, the `And()` method is used to operate on `bits2` and `bits1`:

```
DisplayBits(bits2);
Console.Write(" and ");
DisplayBits(bits1);
Console.Write(" = ");
bits2.And(bits1);
DisplayBits(bits2);
Console.WriteLine();
```

The result of the `And()` method only sets the bits where the bit was set in both input arrays:

```
10001101 and 11001101 = 10001101
```

Finally the `Xor()` method is used for an exclusive OR:

```
            DisplayBits(bits1);
            Console.Write(" xor ");
            DisplayBits(bits2);
            bits1.Xor(bits2);
            Console.Write(" = ");
            DisplayBits(bits1);
            Console.WriteLine();
```

With the `Xor()` method, the resultant bits are set only if the bit was set either in the first or the second input, but not both:

```
    11001101 xor 10001101 = 01000000
```

BitVector32

If you know the number of bits you need in advance, you can use the `BitVector32` structure instead of `BitArray`. `BitVector32` is more efficient because it is a value type and stores the bits on the stack inside an integer. With a single integer you have a place for 32 bits. If you need more bits, you can use multiple `BitVector32` values or the `BitArray`. The `BitArray` can grow as needed; this is not an option with `BitVector32`.

The next table shows the members of `BitVector` that are very different from `BitArray`:

BITVECTOR MEMBERS	DESCRIPTION
`Data`	The property `Data` returns the data behind the `BitVector32` as integer.
`Item`	The values for the `BitVector32` can be set using an indexer. The indexer is overloaded — you can get and set the values using a mask or a section of type `BitVector32.Section`.
`CreateMask()`	`CreateMask()` is a static method that you can use to create a mask for accessing specific bits in the `BitVector32`.
`CreateSection()`	`CreateSection()` is a static method that you can use to create several sections within the 32 bits.

The sample code creates a `BitVector32` with the default constructor, where all 32 bits are initialized to `false`. Then masks are created to access the bits inside the bit vector. The first call to `CreateMask()` creates a mask to access the first bit. After `CreateMask()` is invoked, `bit1` has a value of 1. Invoking `CreateMask()` once more and passing the first mask as a parameter to `CreateMask()` returns a mask to access the second bit, which is 2. `bit3` then has a value of 4 to access bit number 3. `bit4` has a value of 8 to access bit number 4.

Then the masks are used with the indexer to access the bits inside the bit vector and set fields accordingly:

```
            var bits1 = new BitVector32();
            int bit1 = BitVector32.CreateMask();
            int bit2 = BitVector32.CreateMask(bit1);
            int bit3 = BitVector32.CreateMask(bit2);
            int bit4 = BitVector32.CreateMask(bit3);
            int bit5 = BitVector32.CreateMask(bit4);

            bits1[bit1] = true;
            bits1[bit2] = false;
            bits1[bit3] = true;
            bits1[bit4] = true;
            bits1[bit5] = true;
            Console.WriteLine(bits1);
```

code snippet BitArraySample/Program.cs

The `BitVector32` has an overridden `ToString()` method that not only displays the name of the class but also 1 or 0 if the bits are set or not, respectively:

```
BitVector32{00000000000000000000000000011101}
```

Instead of creating a mask with the `CreateMask()` method, you can define the mask yourself; you can also set multiple bits at once. The hexadecimal value `abcdef` is the same as the binary value `1010 1011 1100 1101 1110 1111`. All the bits defined with this value are set:

```
bits1[0xabcdef] = true;
Console.WriteLine(bits1);
```

With the output shown you can verify the bits that are set:

```
BitVector32{00000000101010111100110111101111}
```

Separating the 32 bits to different sections can be extremely useful. For example, an IPv4 address is defined as a 4-byte number that is stored inside an integer. You can split the integer by defining four sections. With a multicast IP message, several 32-bit values are used. One of these 32-bit values is separated in these sections: 16 bits for the number of sources, 8 bits for a querier's query interval code, 3 bits for a querier's robustness variable, a 1-bit suppress flag, and 4 bits that are reserved. You can also define your own bit meanings to save memory.

The example simulates receiving the value `0x79abcdef` and passes this value to the constructor of `BitVector32`, so that the bits are set accordingly:

```
int received = 0x79abcdef;

BitVector32 bits2 = new BitVector32(received);
Console.WriteLine(bits2);
```

The bits are shown on the console as initialized:

```
BitVector32{01111001101010111100110111101111}
```

Then six sections are created. The first section requires 12 bits, as defined by the hexadecimal value `0xfff` (12 bits are set); section B requires 8 bits; section C, 4 bits; section D and E, 3 bits; and section F, 2 bits. The first call to `CreateSection()` just receives `0xfff` to allocate the first 12 bits. With the second call to `CreateSection()`, the first section is passed as an argument, so that the next section continues where the first section ended. `CreateSection()` returns a value of type `BitVector32.Section` that contains the offset and the mask for the section.

```
// sections: FF EEE DDD CCCC BBBBBBBB
// AAAAAAAAAAAA
BitVector32.Section sectionA = BitVector32.CreateSection(0xfff);
BitVector32.Section sectionB = BitVector32.CreateSection(0xff, sectionA);
BitVector32.Section sectionC = BitVector32.CreateSection(0xf, sectionB);
BitVector32.Section sectionD = BitVector32.CreateSection(0x7, sectionC);
BitVector32.Section sectionE = BitVector32.CreateSection(0x7, sectionD);
BitVector32.Section sectionF = BitVector32.CreateSection(0x3, sectionE);
```

Passing a `BitVector32.Section` to the indexer of the `BitVector32` returns an `int` just mapped to the section of the bit vector. Here, a helper method, `IntToBinaryString()`, retrieves a string representation of the `int` number:

```
Console.WriteLine("Section A: {0}",
                  IntToBinaryString(bits2[sectionA], true));
Console.WriteLine("Section B: {0}",
                  IntToBinaryString(bits2[sectionB], true));
Console.WriteLine("Section C: {0}",
                  IntToBinaryString(bits2[sectionC], true));
Console.WriteLine("Section D: {0}",
                  IntToBinaryString(bits2[sectionD], true));
Console.WriteLine("Section E: {0}",
                  IntToBinaryString(bits2[sectionE], true));
Console.WriteLine("Section F: {0}",
                  IntToBinaryString(bits2[sectionF], true));
```

The method `IntToBinaryString()` receives the bits in an integer and returns a string representation containing 0 and 1. With the implementation, 32 bits of the integer are iterated through. In the iteration, if the bit is set, 1 is appended to the `StringBuilder`; otherwise, 0 is appended. Within the loop, a bit shift happens to check if the next bit is set.

```
static string IntToBinaryString(int bits, bool removeTrailingZero)
{
   var sb = new StringBuilder(32);

   for (int i = 0; i < 32; i++)
   {
      if ((bits & 0x80000000) != 0)
      {
         sb.Append("1");
      }
      else
      {
         sb.Append("0");
      }
      bits = bits << 1;
   }
   string s = sb.ToString();
   if (removeTrailingZero)
   {
      return s.TrimStart('0');
   }
   else
   {
      return s;
   }
}
```

The result displays the bit representation of sections A to F, which you can now verify with the value that was passed into the bit vector:

```
Section A: 110111101111
Section B: 10111100
Section C: 1010
Section D: 1
Section E: 111
Section F: 1
```

CONCURRENT COLLECTIONS

.NET 4 contains the new namespace `System.Collections.Concurrent` with several new thread-safe collection classes. Thread-safe collections are guarded from multiple threads accessing the collections in conflicting ways.

For thread-safe access of collections the interface `IProducerConsumerCollection<T>` is defined. The most important methods of this interface are `TryAdd()` and `TryTake()`. `TryAdd()` tries to add an item to the collection, but this might fail if the collection is locked from adding items. To give this information, the method returns a Boolean value to inform about success or failure. `TryTake()` works the same way to inform the caller about success or failure and returns on success an item from the collection. The following list shows classes from the `System.Collections.Concurrent` namespace and its functionality:

- `ConcurrentQueue<T>` — This collection class is implemented with a lock-free algorithm and uses 32 item arrays that are combined in a linked list internally. Methods to access the elements of the queue are `Enqueue()`, `TryDequeue()`, and `TryPeek()`. The naming of these methods is very similar to the methods of `Queue<T>` that you know already, with the difference to the Try prefix where the method call might fail.

Because this class implements the interface `IProducerConsumerCollection<T>`, the methods `TryAdd()` and `TryTake()` just invoke `Enqueue()` and `TryDequeue()`.

- `ConcurrentStack<T>` — Very similar to `ConcurrentQueue<T>`, just with other item access methods, `ConcurrentStack<T>` defines the methods `Push()`, `PushRange()`, `TryPeek()`, `TryPop()`, and `TryPopRange()`. Internally this class uses a linked list of its items.
- `ConcurrentBag<T>` — This doesn't define any order to add or take items. This class uses a concept to map threads to arrays used internally and thus tries to reduce locks. The methods to access elements are `Add()`, `TryPeek()`, and `TryTake()`.
- `ConcurrentDictionary<TKey, TValue>` — This is a thread-safe collection of keys and values. `TryAdd()`, `TryGetValue()`, `TryRemove()`, and `TryUpdate()` are methods to access the members in a non-blocking fashion. Because the items are based on keys and values, `ConcurrentDictionary <TKey, TValue>` does not implement `IProducerConsumerCollection<T>`.
- The `ConcurrentXXX` — These collections are thread-safe in a way to return false if an action is not possible with the current state of threads. You always have to check if adding or taking the item was successful before moving on. You can't trust the collection to fulfill the task.
- `BlockingCollection<T>` — A collection that blocks and waits until it is possible to do the task by adding or taking the item, `BlockingCollection<T>` offers an interface to add and remove items with the `Add()` and `Take()` methods. These methods block the thread and wait until the task becomes possible.

  The `Add()` method has an overload where you also can pass a `CancellationToken`. This token allows cancelling a blocking call.

  If you do not want the thread to wait for an endless time, and do not want to cancel the call from the outside, the methods `TryAdd()` and `TryTake()` are offered as well, where you can also specify a timeout value for the maximum amount of time you would like to block the thread and wait before the call should fail.
- `BlockingCollection<T>` — This is a decorator to any class implementing the `IProducerConsumer Collection<T>` interface and by default uses `ConcurrentQueue<T>`. With the constructor you can also pass any other class that implements `IProducerConsumerCollection<T>`.

The following code example is a simple demonstration of using the `BlockingCollection<T>` class with multiple threads. One thread is the producer to write items in the collection with the `Add()` method, the other thread is the consumer to take items from the collection with the `Take()` method:

```
var sharedCollection = new BlockingCollection<int>();
var events = new ManualResetEventSlim[2];
var waits = new WaitHandle[2];
for (int i = 0; i < 2; i++)
{
    events[i] = new ManualResetEventSlim(false);
    waits[i] = events[i].WaitHandle;
}

var producer = new Thread(obj =>
{
    var state =
        (Tuple<BlockingCollection<int>, ManualResetEventSlim>)obj;
    var coll = state.Item1;
    var ev = state.Item2;
    var r = new Random();

    for (int i = 0; i < 300; i++)
    {
        coll.Add(r.Next(3000));
        }
        ev.Set();
    });
    producer.Start(
        Tuple.Create<BlockingCollection<int>, ManualResetEventSlim>(
            sharedCollection, events[0]));

    var consumer = new Thread(obj =>
    {
        var state =
            (Tuple<BlockingCollection<int>, ManualResetEventSlim>)obj;
        var coll = state.Item1;
        var ev = state.Item2;

        for (int i = 0; i < 300; i++)
        {
            int result = coll.Take();
        }
        ev.Set();
    });
    consumer.Start(
        Tuple.Create<BlockingCollection<int>, ManualResetEventSlim>(
            sharedCollection, events[1]));

    if (!WaitHandle.WaitAll(waits))
        Console.WriteLine("wait failed");
    else
        Console.WriteLine("reading/writing finished");
```

code snippet ConcurrentSample/Program.cs

Using the concurrent collections really gets interesting as soon as multiple threads come into play. This as well as the use of the `CancellationToken` *is shown in Chapter 20. The next chapter also gives information about using the concurrent collections with Parallel LINQ.*

PERFORMANCE

Many collection classes offer the same functionality as others; for example, `SortedList` offers nearly the same features as `SortedDictionary`. However, often there's a big difference in performance. Whereas one collection consumes less memory, the other collection class is faster with retrieval of elements. In the MSDN documentation, you often find performance hints with methods of the collection giving you information about the time the operation represents in *big-O* notation:

```
O(1)
O(log n)
O(n)
```

O(1) means that the time this operation needs is constant no matter how many items are in the collection. For example, the `ArrayList` has an `Add()` method with O(1) behavior. No matter how many elements are in the list, it always takes the same time when adding a new element to the end of the list. The `Count` property gives the number of items, so it is easy to find the end of the list.

O(n) means that for every element in the collection the same amount of additional time is needed. The `Add()` method of `ArrayList` can be an O(n) operation if a reallocation of the collection is required. Changing the capacity causes the copying of the list, and the time for the copy increases linearly with every element.

O(log n) means that the time needed for the operation increases with every element in the collection. But the increase of time for every element is not linear but logarithmic. `SortedDictionary<TKey,TValue>` has O(log n) behavior for inserting operations inside the collection; `SortedList<TKey,TValue>` has O(n) behavior for the same functionality. Here, `SortedDictionary<TKey,TValue>` is a lot faster because it is more efficient to insert elements into a tree structure than into a list.

The following table lists collection classes and their performance for different actions such as adding, inserting, and removing items. Using this table you can select the best collection class for the purpose of your use. The left column lists the collection class. The Add column gives timing information about adding items to the collection. The `List<T>` and the `HashSet<T>` classes define `Add` methods to add items to the collection. With other collection classes, there's a different method to add elements to the collection; for example, the `Stack<T>` class defines a `Push()` method, and the `Queue<T>` class defines an `Enqueue()` method. You can find this information in the table as well.

If there are multiple big-O values in a cell, the reason is that if a collection needs to be resized, resizing takes a while. For example, with the `List<T>` class, adding items needs O(1). If the capacity of the collection is not large enough and the collection needs to be resized, the resize requires O(n) time. The larger the collection is, the longer the resize operation takes. It's best to avoid resizes by setting the capacity of the collection to a value that can hold all elements.

If the cell content is *na,* this means that this operation is *not applicable* with this collection type.

COLLECTION	ADD	INSERT	REMOVE	ITEM	SORT	FIND
`List<T>`	O(1) or O(n) if the collection must be resized	O(n)	O(n)	O(1)	O (n log n), worst case O (n ^ 2)	O(n)
`Stack<T>`	`Push()`, O(1) or O(n) if the stack must be resized	na	`Pop()`, O(1)	na	na	na
`Queue<T>`	`Enqueue()`, O(1) or O(n) if the queue must be resized	na	`Dequeue()`, O(1)	na	na	na
`HashSet<T>`	O(1) or O(n) if the set must be resized	`Add()` O(1) or O(n)	O(1)	na	na	na

SUMMARY

This chapter took a look at working with different kinds of collections. Arrays are fixed in size, but you can use lists for dynamically growing collections. For accessing elements on a first-in, first-out basis, there's a queue, and there's a stack for last-in, first-out operations. Linked lists allow for fast inserting and removing of elements but are slow for searching. With keys and value, you can use dictionaries, which are fast for searching and inserting elements. Sets are for unique items and can be ordered (`SortedSet<T>`) or not ordered (`HashSet<T>`). `ObservableCollection<T>` gives events when items change in the list.

In this chapter, you've seen a lot of interfaces and classes and their use for accessing and sorting collections. You've also seen some specialized collections, such as `BitArray` and `BitVector32`, which are optimized for working with a collection of bits.

Chapter 11 gives you details about Language Integrated Query (LINQ).

11

Language Integrated Query

WHAT'S IN THIS CHAPTER?

- ➤ Traditional queries across objects using `List<T>`
- ➤ Extension methods
- ➤ LINQ query operators
- ➤ Parallel LINQ
- ➤ Expression trees

LINQ (Language Integrated Query) integrates query syntax inside the C# programming language and makes it possible to access different data sources with the same syntax. LINQ makes this possible by offering an abstraction layer.

This chapter gives you the core foundation of LINQ and the language extensions for C# that make the new features possible.

For using LINQ across the database you should read Chapter 31, "ADO.NET Entity Framework." To query XML data, read Chapter 33, "Manipulating XML," after reading this chapter.

LINQ OVERVIEW

This chapter starts with a simple LINQ query before diving into the full potential of LINQ. The C# language offers integrated query language that is converted to method calls. This section shows you what the conversion looks like so you can use all the possibilities of LINQ.

Lists and Entities

The LINQ queries in this chapter will be done on a collection containing Formula-1 champions from 1950 to 2008. This data needs to be prepared with entity classes and lists.

For the entities, the type `Racer` is defined. `Racer` defines several properties and an overloaded `ToString()` method to display a racer in a string format. This class implements the interface

IFormattable to support different variants of format strings, and the interface IComparable<Racer>, which can be used to sort a list of racers based on the LastName. For doing more advanced queries, the class Racer contains not only single value properties such as FirstName, LastName, Wins, Country, and Starts, but also multivalue properties such as Cars and Years. The Years property lists all the years of the championship title. Some racers have won more than one title. The Cars property is used to list all the cars that have been used by the driver during the title years.

```
using System;
using System.Text;

namespace Wrox.ProCSharp.LINQ
{
    [Serializable]
    public class Racer: IComparable<Racer>, IFormattable
    {
        public Racer(string firstName = null, string lastName = null,
                string country = null, int starts = 0, int wins = 0,
                IEnumerable<int> years = null, IEnumerable<string> cars = null)
        {
            this.FirstName = firstName;
            this.LastName = lastName;
            this.Country = country;
                        this.Starts = starts;
            this.Wins = wins;

            var yearsList = new List<int>();
            foreach (var year in years)
            {
                yearsList.Add(year);
            }
            this.Years = yearsList.ToArray();
            var carList = new List<string>();
            foreach (var car in cars)
            {
                carList.Add(car);
            }
            this.Cars = carList.ToArray();

        }

        public string FirstName {get; set;}
        public string LastName {get; set;}
        public int Wins {get; set;}
        public string Country {get; set;}
        public int Starts {get; set;}
        public string[] Cars { get; private set; }
        public int[] Years { get; private set; }

        public override string ToString()
        {
            return String.Format("{0} {1}", FirstName, LastName);
        }

        public int CompareTo(Racer other)
        {
            if (other == null) throw new ArgumentNullException("other");

            return this.LastName.CompareTo(other.LastName);
        }

        public string ToString(string format)
        {
            return ToString(format, null);
        }

        public string ToString(string format, IFormatProvider formatProvider)
        {
            switch (format)
            {
                case null:
                case "N":
                    return ToString();
                case "F":
                    return FirstName;
                case "L":
                return LastName;
                case "C":
                    return Country;
                case "S":
                   return Starts.ToString();
                case "W":
                    return Wins.ToString();
                case "A":
                    return String.Format("{0} {1}, {2}; starts: {3}, wins: {4}",
                        FirstName, LastName, Country, Starts, Wins);
                default:
                    throw new FormatException(String.Format(
                        "Format {0} not supported", format));
            }
        }
    }
}
```

code snippet DataLib/Racer.cs

A second entity class is `Team`. This class just contains the name and an array of years for constructor championships.

```
    [Serializable]
    public class Team
    {
        public Team(string name, params int[] years)
        {
            this.Name = name;
            this.Years = years;
        }
        public string Name { get; private set; }
        public int[] Years { get; private set; }
    }
```

code snippet DataLib/Team.cs

The class `Formula1` returns a list of racers in the method `GetChampions()`. The list is filled with all Formula-1 champions from the years 1950 to 2008:

```
using System.Collections.Generic;

namespace Wrox.ProCSharp.LINQ
{
    public static class Formula1
```

```
        {
            private static List<Racer> racers;

            public static IList<Racer> GetChampions()
            {
                if (racers == null)
                {
                    racers = new List<Racer>(40);
                    racers.Add(new Racer("Nino", "Farina", "Italy", 33, 5,
                                         new int[] { 1950 },
                                         new string[] { "Alfa Romeo" }));
                    racers.Add(new Racer("Alberto", "Ascari", "Italy", 32, 10,
                                         new int[] { 1952, 1953 },
                                         new string[] { "Ferrari" }));
                    racers.Add(new Racer("Juan Manuel", "Fangio", "Argentina", 51, 24,
                                         new int[] { 1951, 1954, 1955, 1956, 1957 },
                                         new string[] { "Alfa Romeo", "Maserati",
                                                        "Mercedes", "Ferrari" }));
                    racers.Add(new Racer("Mike", "Hawthorn", "UK", 45, 3,
                                         new int[] { 1958 },
                                         new string[] { "Ferrari" }));
                    racers.Add(new Racer("Phil", "Hill", "USA", 48, 3,
                                         new int[] { 1961 },
                                         new string[] { "Ferrari" }));
                    racers.Add(new Racer("John", "Surtees", "UK", 111, 6,
                                         new int[] { 1964 },
                                         new string[] { "Ferrari" }));
                    racers.Add(new Racer("Jim", "Clark", "UK", 72, 25,
                                         new int[] { 1963, 1965 },
                                         new string[] { "Lotus" }));
                    racers.Add(new Racer("Jack", "Brabham", "Australia", 125, 14,
                                         new int[] { 1959, 1960, 1966 },
                                         new string[] { "Cooper", "Brabham" }));
                    racers.Add(new Racer("Denny", "Hulme", "New Zealand", 112, 8,
                                         new int[] { 1967 },
                                         new string[] { "Brabham" }));
                    racers.Add(new Racer("Graham", "Hill", "UK", 176, 14,
                                         new int[] { 1962, 1968 },
                                         new string[] { "BRM", "Lotus" }));
                    racers.Add(new Racer("Jochen", "Rindt", "Austria", 60, 6,
                                         new int[] { 1970 },
                                         new string[] { "Lotus" }));
                    racers.Add(new Racer("Jackie", "Stewart", "UK", 99, 27,
                                         new int[] { 1969, 1971, 1973 },
                                         new string[] { "Matra", "Tyrrell" }));
                    //...

                return racers;
            }
        }
    }
```

code snippet DataLib/Formula1.cs

Where queries are done across multiple lists, the `GetConstructorChampions()` method that follows returns the list of all constructor championships. Constructor championships have been around since 1958.

```
            private static List<Team> teams;
            public static IList<Team> GetContructorChampions()
            {
                if (teams == null)
            {
                teams = new List<Team>()
                {
                    new Team("Vanwall", 1958),
                    new Team("Cooper", 1959, 1960),
                    new Team("Ferrari", 1961, 1964, 1975, 1976, 1977, 1979, 1982,
                             1983, 1999, 2000, 2001, 2002, 2003, 2004, 2007, 2008),
                    new Team("BRM", 1962),
                    new Team("Lotus", 1963, 1965, 1968, 1970, 1972, 1973, 1978),
                    new Team("Brabham", 1966, 1967),
                    new Team("Matra", 1969),
                    new Team("Tyrrell", 1971),
                    new Team("McLaren", 1974, 1984, 1985, 1988, 1989, 1990, 1991,
                             1998),
                    new Team("Williams", 1980, 1981, 1986, 1987, 1992, 1993, 1994,
                             1996, 1997),
                    new Team("Benetton", 1995),
                    new Team("Renault", 2005, 2006 )
                };
            }
            return teams;
        }
```

LINQ Query

Using these prepared lists and entities, you can do a LINQ query, for example, a query to get all world champions from Brazil sorted by the highest number of wins. To accomplish this you could use methods of the `List<T>` class; e.g. the `FindAll()` and `Sort()` methods. However, using LINQ there's a simpler syntax as soon as you're used to it:

```
private static void LinqQuery()
{
   var query = from r in Formula1.GetChampions()
               where r.Country == "Brazil"
               orderby r.Wins descending
               select r;

   foreach (Racer r in query)
   {
      Console.WriteLine("{0:A}", r);
   }
}
```

code snippet LINQIntro/Program.cs

The result of this query shows world champions from Brazil ordered:

```
Ayrton Senna, Brazil; starts: 161, wins: 41
Nelson Piquet, Brazil; starts: 204, wins: 23
Emerson Fittipaldi, Brazil; starts: 143, wins: 14
```

The statement

```
from r in Formula1.GetChampions()
where r.Country == "Brazil"
orderby r.Wins descending
select r;
```

is a LINQ query. The clauses `from`, `where`, `orderby`, `descending`, and `select` are predefined keywords in this query.

The query expression must begin with a `from` clause and end with a `select` or `group` clause. In between you can optionally use `where`, `orderby`, `join`, `let`, and additional `from` clauses.

Extension Methods

The compiler modifies the LINQ query to invoke methods instead. LINQ offers various extension methods for the `IEnumerable<T>` interface so you can use the LINQ query across any collection that implements this interface.

Extension methods make it possible to write a method to a class that doesn't offer the method at first. You can also add a method to any class that implements a specific interface, so multiple classes can make use of the same implementation.

For example, wouldn't you like to have a `Foo()` method with the `String` class? The `String` class is sealed, so it is not possible to inherit from this class. You can do an extension method, as shown in the following code:

```
public static class StringExtension
{
    public static void Foo(this string s)
    {
        Console.WriteLine("Foo invoked for {0}", s);
    }
}
```

An *extension method* is defined as a static method where the first parameter defines the type it extends and it is declared in a static class. The `Foo()` method extends the `string` class, as is defined with the first parameter. For differentiating extension methods from normal static methods, the extension method also requires the `this` keyword with the first parameter.

Indeed, it is now possible to use the `Foo()` method with the `string` type:

```
string s = "Hello";
s.Foo();
```

The result shows `Foo invoked for Hello` in the console, because `Hello` is the string passed to the `Foo()` method.

This might appear to be breaking object-oriented rules because a new method is defined for a type without changing the type or deriving from it. However, this is not the case. The extension method cannot access private members of the type it extends. Calling an extension method is just a new syntax of invoking a static method. With the string you can get the same result by calling the method `Foo()` this way:

```
string s = "Hello";
StringExtension.Foo(s);
```

To invoke the static method, write the class name followed by the method name. Extension methods are a different way to invoke static methods. You don't have to supply the name of the class where the static method is defined. Instead, the static method is taken because of the parameter type. You just have to import the namespace that contains the class to get the `Foo()` extension method in the scope of the `String` class.

One of the classes that define LINQ extension methods is `Enumerable` in the namespace `System.Linq`. You just have to import the namespace to open the scope of the extension methods of this class. A sample implementation of the `Where()` extension method is shown in the following code. The first parameter of the `Where()` method that includes the `this` keyword is of type `IEnumerable<T>`. This way the `Where()` method can be used with every type that implements `IEnumerable<T>`. A few examples of types that implement this interface are arrays and `List<T>`. The second parameter is a `Func<T, bool>` delegate that references a method that returns a Boolean value and requires a parameter of type `T`. This predicate is invoked within the implementation to examine if the item from the `IEnumerable<T>` source should go into the destination collection. If the method is referenced by the delegate, the `yield return` statement returns the item from the source to the destination:

```
public static IEnumerable<TSource> Where<TSource>(
        this IEnumerable<TSource> source,
        Func<TSource, bool> predicate)
{
    foreach (TSource item in source)
        if (predicate(item))
            yield return item;
}
```

Because `Where()` is implemented as a generic method, it works with any type that is contained in a collection. Any collection implementing `IEnumerable<T>` is supported.

Now it's possible to use the extension methods `Where()`, `OrderByDescending()`, and `Select()` from the class `Enumerable`. Because each of these methods returns `IEnumerable<TSource>`, it is possible to invoke one method after the other by using the previous result. With the arguments of the extension methods, anonymous methods that define the implementation for the delegate parameters are used:

```
static void ExtensionMethods()
{
    var champions = new List<Racer>(Formula1.GetChampions());
    IEnumerable<Racer> brazilChampions =
        champions.Where(r => r.Country == "Brazil").
                OrderByDescending(r => r.Wins).
                Select(r => r);

    foreach (Racer r in brazilChampions)
    {
        Console.WriteLine("{0:A}", r);
    }
}
```

code snippet LINQIntro/Program.cs

Deferred Query Execution

When the query expression is defined during runtime, the query does not run. The query runs when the items are iterated.

Let's have a look once more at the extension method `Where()`. This extension method makes use of the `yield return` statement to return the elements where the predicate is true. Because the `yield return` statement is used, the compiler creates an enumerator and returns the items as soon as they are accessed from the enumeration:

```
public static IEnumerable<T> Where<T>(this IEnumerable<T> source,
Func<T, bool> predicate)
{
        foreach (T item in source)
           if (predicate(item))
              yield return item;
    }
```

This has a very interesting and important effect. With the following example a collection of `String` elements is created and filled with the name `arr`. Next, a query is defined to get all names from the collection where the item starts with the letter `J`. The collection should also be sorted. The iteration does not happen when the query is defined. Instead, the iteration happens with the `foreach` statement, where all items are iterated. Only one element of the collection fulfills the requirements of the `where` expression by starting with the letter J: `Juan`. After the iteration is done and `Juan` is written to the console, four new names are added to the collection. Then the iteration is done again:

```
var names = new List<string> { "Nino", "Alberto", "Juan", "Mike", "Phil" };

var namesWithJ = from n in names
                 where n.StartsWith("J")
                 orderby n
                 select n;

Console.WriteLine("First iteration");
foreach (string name in namesWithJ)
{
   Console.WriteLine(name);
}
Console.WriteLine();

names.Add("John");
names.Add("Jim");
names.Add("Jack");
names.Add("Denny");

Console.WriteLine("Second iteration");
foreach (string name in namesWithJ)
{
   Console.WriteLine(name);
}
```

Because the iteration does not happen when the query is defined, but it does happen with every `foreach`, changes can be seen, as the output from the application demonstrates:

```
First iteration
Juan

Second iteration
Jack
Jim
John
Juan
```

Of course, you also must be aware that the extension methods are invoked every time the query is used within an iteration. Most of the time this is very practical, because you can detect changes in the source data. However, there are situations where this is impractical. You can change this behavior by invoking the extension methods `ToArray()`, `ToEnumerable()`, `ToList()`, and the like. In the example, you can see that `ToList` iterates through the collection immediately and returns a collection implementing `IList<string>`. The returned list is then iterated through twice; in between iterations, the data source gets new names:

```
var names = new List<string>
                { "Nino", "Alberto", "Juan", "Mike", "Phil" };
var namesWithJ = (from n in names
                        where n.StartsWith("J")
                        orderby n
                        select n).ToList();

    Console.WriteLine("First iteration");
    foreach (string name in namesWithJ)
    {
       Console.WriteLine(name);
    }
    Console.WriteLine();

    names.Add("John");
    names.Add("Jim");
    names.Add("Jack");
    names.Add("Denny");

    Console.WriteLine("Second iteration");
    foreach (string name in namesWithJ)
    {
       Console.WriteLine(name);
    }
```

In the result, you can see that in between the iterations the output stays the same although the collection values have changed:

```
First iteration
Juan

Second iteration
Juan

STANDARD QUERY OPERATORS

`Where`, `OrderByDescending`, and `Select` are only a few of the query operators defined by LINQ. The LINQ query defines a declarative syntax for the most common operators. There are many more query operators available with the `Enumerable` class.

The following table lists the standard query operators defined by the `Enumerable` class:

STANDARD QUERY OPERATORS	DESCRIPTION
`Where OfType<TResult>`	*Filtering* operators define a restriction to the elements returned. With the `Where` query operator you can use a predicate, for example, defined by a Lambda expression that returns a bool. `OfType<TResult>` filters the elements based on the type and returns only the elements of the type `TResult`.
`Select SelectMany`	*Projection* operators are used to transform an object into a new object of a different type. `Select` and `SelectMany` define a projection to select values of the result based on a selector function.
`OrderBy ThenBy OrderByDescending ThenByDescending Reverse`	*Sorting* operators change the order of elements returned. `OrderBy` sorts values in ascending order; `OrderByDescending` sorts values in descending order. `ThenBy` and `ThenByDescending` operators are used for a secondary sort if the first sort gives similar results. `Reverse` reverses the elements in the collection.

continues

(continued)

STANDARD QUERY OPERATORS	DESCRIPTION
`Join GroupJoin`	*Join* operators are used to combine collections that might not be directly related to each other. With the `Join` operator a join of two collections based on key selector functions can be done. This is similar to the JOIN you know from SQL. The `GroupJoin` operator joins two collections and groups the results.
`GroupBy ToLookup`	*Grouping* operators put the data into groups. The `GroupBy` operator groups elements with a common key. `ToLookup` groups the elements by creating a one-to-many dictionary.
`Any All Contains`	*Quantifier* operators return a Boolean value if elements of the sequence satisfy a specific condition. `Any`, `All`, and `Contains` are quantifier operators. `Any` determines if any element in the collection satisfies a predicate function; `All` determines if all elements in the collection satisfy a predicate. `Contains` checks whether a specific element is in the collection. These operators return a Boolean value.
`Take Skip TakeWhile SkipWhile`	*Partitioning* operators return a subset of the collection. `Take`, `Skip`, `TakeWhile`, and `SkipWhile` are partitioning operators. With these, you get a partial result. With `Take`, you have to specify the number of elements to take from the collection; `Skip` ignores the specified number of elements and takes the rest. `TakeWhile` takes the elements as long as a condition is true.
`Distinct Union Intersect Except Zip`	*Set* operators return a collection set. `Distinct` removes duplicates from a collection. With the exception of `Distinct`, the other set operators require two collections. `Union` returns unique elements that appear in either of the two collections. `Intersect` returns elements that appear in both collections. `Except` returns elements that appear in just one collection. `Zip` is new with .NET 4 and combines two collections into one.
`First FirstOrDefault Last LastOrDefault ElementAt ElementAtOrDefault Single SingleOrDefault`	*Element* operators return just one element. `First` returns the first element that satisfies a condition. `FirstOrDefault` is similar to `First`, but it returns a default value of the type if the element is not found. `Last` returns the last element that satisfies a condition. With `ElementAt`, you specify the position of the element to return. `Single` returns only the one element that satisfies a condition. If more than one element satisfies the condition, an exception is thrown.
`Count Sum Min Max Average Aggregate`	*Aggregate* operators compute a single value from a collection. With aggregate operators, you can get the sum of all values, the number of all elements, the element with the lowest or highest value, an average number, and so on.
`ToArray AsEnumerable ToList ToDictionary Cast<TResult>`	*Conversion* operators convert the collection to an array: `IEnumerable`, `IList`, `IDictionary`, and so on.
`Empty Range Repeat`	*Generation* operators return a new sequence. The collection is empty using the `Empty` operator; `Range` returns a sequence of numbers, and `Repeat` returns a collection with one repeated value.

The following sections are examples of using these operators.

Filtering

Have a look at some examples for a query.

With the `where` clause, you can combine multiple expressions; for example, get only the racers from Brazil and Austria who won more than 15 races. The result type of the expression passed to the `where` clause just needs to be of type bool:

```
var racers = from r in Formula1.GetChampions()
             where r.Wins > 15 &&
                 (r.Country == "Brazil" || r.Country == "Austria")
             select r;

foreach (var r in racers)
{
   Console.WriteLine("{0:A}", r);
}
```

code snippet Enumerablesample/Program.cs

Starting the program with this LINQ query returns Niki Lauda, Nelson Piquet, and Ayrton Senna as shown:

```
Niki Lauda, Austria, Starts: 173, Wins: 25
Nelson Piquet, Brazil, Starts: 204, Wins: 23
Ayrton Senna, Brazil, Starts: 161, Wins: 41
```

Not all queries can be done with the LINQ query. Not all extension methods are mapped to LINQ query clauses. Advanced queries require using extension methods. To better understand complex queries with extension methods, it's good to see how simple queries are mapped. Using the extension methods `Where()` and `Select()` produces a query very similar to the LINQ query done before:

```
var racers = Formula1.GetChampions().
    Where(r => r.Wins > 15 &&
          (r.Country == "Brazil" || r.Country == "Austria")).
    Select(r => r);
```

Filtering with Index

One example where you can't use the LINQ query is an overload of the `Where()` method. With an overload of the `Where()` method you can pass a second parameter that is the index. The index is a counter for every result returned from the filter. You can use the index within the expression to do some calculation based on the index. Here the index is used within the code that is called by the `Where()` extension method to return only racers whose last name starts with `A` if the index is even:

```
var racers = Formula1.GetChampions().
   Where((r, index) => r.LastName.StartsWith("A") && index % 2 != 0);
foreach (var r in racers)
{
   Console.WriteLine("{0:A}", r);
}
```

All the racers with last names beginning with the letter A are Alberto Ascari, Mario Andretti, and Fernando Alonso. Because Mario Andretti is positioned within an index that is odd, he is not in the result:

```
Alberto Ascari, Italy; starts: 32, wins: 10
Fernando Alonso, Spain; starts: 132, wins: 21
```

Type Filtering

For filtering based on a type you can use the `OfType()` extension method. Here the array data contains both `string` and `int` objects. Using the extension method `OfType()`, passing the string class to the generic parameter returns only the strings from the collection:

```
object[] data = { "one", 2, 3, "four", "five", 6 };
var query = data.OfType<string>();
foreach (var s in query)
{
   Console.WriteLine(s);
}
```

Running this code, the strings one, four, and five are displayed:

```
one
four
five
```

Compound from

If you need to do a filter based on a member of the object that itself is a sequence, you can use a compound `from`. The `Racer` class defines a property `Cars` where `Cars` is a string array. For a filter of all racers who were champions with a Ferrari, you can use the LINQ query as shown. The first `from` clause accesses the `Racer` objects returned from `Formula1.GetChampions()`. The second `from` clause accesses the `Cars` property of the `Racer` class to return all cars of type `string`. Next the cars are used with the `where` clause to filter only the racers who were champions with a Ferrari:

```
var ferrariDrivers = from r in Formula1.GetChampions()
                     from c in r.Cars
                     where c == "Ferrari"
                     orderby r.LastName
                     select r.FirstName + " " + r.LastName;
```

If you are curious about the result of this query, all Formula-1 champions driving a Ferrari are:

```
Alberto Ascari
Juan Manuel Fangio
Mike Hawthorn
Phil Hill
Niki Lauda
Kimi Räikkönen
Jody Scheckter
Michael Schumacher
John Surtees
```

The C# compiler converts a compound `from` clause with a LINQ query to the `SelectMany()` extension method. `SelectMany()` can be used to iterate a sequence of a sequence. The overload of the `SelectMany` method that is used with the example is shown here:

```
public static IEnumerable<TResult> SelectMany<TSource, TCollection, TResult> (
      this IEnumerable<TSource> source,
      Func<TSource,
      IEnumerable<TCollection>> collectionSelector,
      Func<TSource, TCollection, TResult>
         resultSelector);
```

The first parameter is the implicit parameter that receives the sequence of `Racer` objects from the `GetChampions()` method. The second parameter is the `collectionSelector` delegate where the inner sequence is defined. With the Lambda expression `r => r.Cars` the collection of cars should be returned. The third parameter is a delegate that is now invoked for every car and receives the `Racer` and `Car` objects. The Lambda expression creates an anonymous type with a `Racer` and a `Car` property. As a result of this

SelectMany() method, the hierarchy of racers and cars is flattened and a collection of new objects of an anonymous type for every car is returned.

This new collection is passed to the Where() method so that only the racers driving a Ferrari are filtered. Finally, the OrderBy() and Select() methods are invoked:

```
            var ferrariDrivers = Formula1.GetChampions().
                SelectMany(
                  r => r.Cars,
                  (r, c) => new { Racer = r, Car = c }).
                  Where(r => r.Car == "Ferrari").
                  OrderBy(r => r.Racer.LastName).
                  Select(r => r.Racer.FirstName + " " + r.Racer.LastName);
```

Resolving the generic SelectMany() method to the types that are used here, the types are resolved as follows. In this case the source is of type Racer, the filtered collection is a string array, and of course the name of the anonymous type that is returned is not known and is shown here as TResult:

```
    public static IEnumerable<TResult> SelectMany<Racer, string, TResult> (
          this IEnumerable<Racer> source,
          Func<Racer, IEnumerable<string>> collectionSelector,
          Func<Racer, string, TResult> resultSelector);
```

Because the query was just converted from a LINQ query to extension methods, the result is the same as before.

Sorting

For sorting a sequence, the orderby clause was used already. Let's review the example from before with the orderby descending clause. Here the racers are sorted based on the number of wins as specified by the key selector in descending order:

```
            var racers = from r in Formula1.GetChampions()
                         where r.Country == "Brazil"
                         orderby r.Wins descending
                         select r;
```

code snippet EnumerableSample/Program.cs

The orderby clause is resolved to the OrderBy() method, and the orderby descending clause is resolved to the OrderByDescending() method:

```
            var racers = Formula1.GetChampions().
               Where(r => r.Country == "Brazil").
               OrderByDescending(r => r.Wins).
               Select(r => r);
```

The OrderBy() and OrderByDescending() methods return IOrderedEnumerable<TSource>. This interface derives from the interface IEnumerable<TSource> but contains an additional method CreateOrderedEnumerable<TSource>(). This method is used for further ordering of the sequence. If two items are the same based on the key selector, ordering can continue with the ThenBy() and ThenByDescending() methods. These methods require an IOrderedEnumerable<TSource> to work on, but return this interface as well. So, you can add any number of ThenBy() and ThenByDescending() to sort the collection.

Using the LINQ query you just have to add all the different keys (with commas) for sorting to the orderby clause. Here the sort of all racers is done first based on the country, next on the last name, and finally on the first name. The Take() extension method that is added to the result of the LINQ query is used to take the first 10 results:

```
            var racers = (from r in Formula1.GetChampions()
                          orderby r.Country, r.LastName, r.FirstName
                          select r).Take(10);
```

The sorted result is shown here:

```
Argentina: Fangio, Juan Manuel
Australia: Brabham, Jack
Australia: Jones, Alan
Austria: Lauda, Niki
Austria: Rindt, Jochen
Brazil: Fittipaldi, Emerson
Brazil: Piquet, Nelson
Brazil: Senna, Ayrton
Canada: Villeneuve, Jacques
Finland: Hakkinen, Mika
```

Doing the same with extension methods makes use of the `OrderBy()` and `ThenBy()` methods:

```
      var racers = Formula1.GetChampions().
         OrderBy(r => r.Country).
         ThenBy(r => r.LastName).
         ThenBy(r => r.FirstName).
         Take(10);
```

Grouping

To group query results based on a key value, the `group` clause can be used. Now the Formula-1 champions should be grouped by the country, and the number of champions within a country should be listed. The clause `group r by r.Country into g` groups all the racers based on the `Country` property and defines a new identifier `g` that can be used later to access the group result information. The result from the `group` clause is ordered based on the extension method `Count()` that is applied on the group result, and if the count is the same, the ordering is done based on the key. This is the country because this was the key used for grouping. The `where` clause filters the results based on groups that have at least two items, and the `select` clause creates an anonymous type with `Country` and `Count` properties:

```
      var countries = from r in Formula1.GetChampions()
                      group r by r.Country into g
                      orderby g.Count() descending, g.Key
                      where g.Count() >= 2
                      select new {
                                   Country = g.Key,
                                   Count = g.Count()
                                 };

      foreach (var item in countries)
      {
         Console.WriteLine("{0, -10} {1}", item.Country, item.Count);
      }
```

The result displays the collection of objects with the `Country` and `Count` property:

```
UK         9
Brazil     3
Australia  2
Austria    2
Finland    2
Italy      2
USA        2
```

Doing the same with extension methods, the `groupby` clause is resolved to the `GroupBy()` method. What's interesting with the declaration of the `GroupBy()` method is that it returns an enumeration of objects implementing the `IGrouping` interface. The `IGrouping` interface defines the `Key` property, so you can access the key of the group after defining the call to this method:

```
public static IEnumerable<IGrouping<TKey, TSource>> GroupBy<TSource, TKey>(
      this IEnumerable<TSource> source, Func<TSource, TKey> keySelector);
```

The `group r by r.Country into g` clause is resolved to `GroupBy(r => r.Country)` and returns the group sequence. The group sequence is first ordered by the `OrderByDecending()` method, then by the `ThenBy()` method. Next the `Where()` and `Select()` methods that you already know are invoked:

```
var countries = Formula1.GetChampions().
    GroupBy(r => r.Country).
    OrderByDescending(g => g.Count()).
    ThenBy(g => g.Key).
    Where(g => g.Count() >= 2).
    Select(g => new { Country = g.Key,
                      Count = g.Count() });
```

Grouping with Nested Objects

If the grouped objects should contain nested sequences, you can do that by changing the anonymous type created by the `select` clause. With this example the returned countries should contain not only the properties for the name of the country and the number of racers, but also a sequence of the names of the racers. This sequence is assigned by using an inner `from`/`in` clause assigned to the `Racers` property. The inner `from` clause is using the `g` group to get all racers from the group, order them by last name, and create a new string based on the first and last name:

```
var countries = from r in Formula1.GetChampions()
                group r by r.Country into g
                orderby g.Count() descending, g.Key
                where g.Count() >= 2
                select new
                {
                    Country = g.Key,
                    Count = g.Count(),
                    Racers = from r1 in g
                             orderby r1.LastName
                             select r1.FirstName + " " + r1.LastName
                };
foreach (var item in countries)
{
   Console.WriteLine("{0, -10} {1}", item.Country, item.Count);
   foreach (var name in item.Racers)
   {
      Console.Write("{0}; ", name);
   }
   Console.WriteLine();
}
```

code snippet EnumerableSample/Program.cs

The output now lists all champions from the specified countries:

```
UK         9
Jim Clark; Lewis Hamilton; Mike Hawthorn; Graham Hill; Damon Hill; James Hunt;
Nigel Mansell; Jackie Stewart; John Surtees;
Brazil     3
Emerson Fittipaldi; Nelson Piquet; Ayrton Senna;
Australia  2
Jack Brabham; Alan Jones;
Austria    2
Niki Lauda; Jochen Rindt;
Finland    3
Mika Hakkinen; Kimi Raikkonen; Keke Rosberg;
Italy      2
Alberto Ascari; Nino Farina;
USA        2
Mario Andretti; Phil Hill;
```

Join

You can use the `join` clause to combine two sources based on specific criteria. But first, let's get two lists that should be joined. With Formula-1, there's a drivers and a constructors championship. The drivers are returned from the method `GetChampions()`, and the constructors are returned from the method `GetConstructorChampions()`. Now it would be interesting to get a list by year where every year lists the driver and the constructor champion.

For doing this, the first two queries for the racers and the teams are defined:

```
var racers = from r in Formula1.GetChampions()
             from y in r.Years
             where y > 2003
             select new
             {
                Year = y,
                Name = r.FirstName + " " + r.LastName
             };

var teams = from t in
            Formula1.GetContructorChampions()
            from y in t.Years
            where y > 2003
            select new
            {
                Year = y,
                Name = t.Name
            };
```

Using these two queries, a join is done based on the year of the driver champion and the year of the team champion with the clause `join t in teams on r.Year equals t.Year`. The `select` clause defines a new anonymous type containing `Year`, `Racer`, and `Team` properties:

```
var racersAndTeams =
      from r in racers
      join t in teams on r.Year equals t.Year
      select new
      {
         Year = r.Year,
         Racer = r.Name,
         Team = t.Name
      };
Console.WriteLine("Year  Champion " + "Constructor Title");
foreach (var item in racersAndTeams)
{
   Console.WriteLine("{0}: {1,-20} {2}",
      item.Year, item.Racer, item.Team);
}
```

Of course you can also combine this to one LINQ query, but that's a matter of taste:

```
int year = 2003;
var racersAndTeams =
    from r in
       from r1 in Formula1.GetChampions()
       from yr in r1.Years
       where yr > year
       select new
       {
          Year = yr,
          Name = r1.FirstName + " " + r1.LastName
       }
```

```
                join t in
                   from t1 in
                      Formula1.GetContructorChampions()
                   from yt in t1.Years
                   where yt > year
                   select new
                   {
                       Year = yt,
                       Name = t1.Name
                   }
                on r.Year equals t.Year
                select new
                {
                   Year = r.Year,
                   Racer = r.Name,
                   Team = t.Name
                };
```

The output displays data from the anonymous type:

```
Year   Champion             Constructor Title
2004   Michael Schumacher   Ferrari
2005   Fernando Alonso      Renault
2006   Fernando Alonso      Renault
2007   Kimi Räikkönen       Ferrari
2008   Lewis Hamilton       Ferrari
```

Set Operations

The extension methods `Distinct()`, `Union()`, `Intersect()`, and `Except()` are set operations. Let's create a sequence of Formula-1 champions driving a Ferrari and another sequence of Formula-1 champions driving a McLaren, and then let's find out if any driver has been a champion driving both of these cars. Of course, that's where the `Intersect()` extension method can help.

First get all champions driving a Ferrari. This is just using a simple LINQ query with a compound `from` to access the property `Cars` that's returning a sequence of string objects:

```
            var ferrariDrivers = from r in
                                 Formula1.GetChampions()
                                 from c in r.Cars
                                 where c == "Ferrari"
                                 orderby r.LastName
                                 select r;
```

code snippet EnumerableSample/Program.cs

Now the same query with a different parameter of the `where` clause would be needed to get all McLaren racers. It's not a good idea to write the same query another time. You have one option to create a method where you can pass the parameter `car`:

```
         private static IEnumerable<Racer>GetRacersByCar(string car)
         {
            return from r in Formula1.GetChampions()
                   from c in r.Cars
                   where c == car
                   orderby r.LastName
                   select r;
         }
```

However, because the method wouldn't be needed in other places, defining a variable of a delegate type to hold the LINQ query is a good approach. The variable `racersByCar` needs to be of a delegate type that requires a string parameter and returns IEnumerable<Racer>, similar to the method that was implemented before. For doing this, several generic Func<> delegates are defined, so you do not need to declare your own delegate. A Lambda expression is assigned to the variable racersByCar. The left side of the Lambda expression defines a car variable of the type that is the first generic parameter of the Func delegate (a string). The right side defines the LINQ query that uses the parameter with the where clause:

```
Func<string, IEnumerable<Racer>> racersByCar =
      car => from r in Formula1.GetChampions()
             from c in r.Cars
             where c == car
             orderby r.LastName
             select r;
```

Now you can use the Intersect() extension method to get all racers that won the championship with a Ferrari and a McLaren:

```
Console.WriteLine("World champion with Ferrari and McLaren");
foreach (var racer in racersByCar("Ferrari").Intersect(
                          racersByCar("McLaren")))
{
   Console.WriteLine(racer);
}
```

The result is just one racer, Niki Lauda:

```
World champion with Ferrari and McLaren
Niki Lauda
```

The Set operations compares the objects by invoking the GetHashCode() *and* Equals()*method of the entity class. For custom comparision, you can also pass an object that implements the interface* IEqualityComparer<T>. *In the sample here, the* GetChampions() *method always returns the same objects and thus the default comparison works.*

Zip

The Zip() method is new with .NET 4 and enables you to merge two related sequences into one with a predicate function.

First, two related sequences are created, both with the same filtering (country Italy) and ordering. For merging this is important, as item 1 from the first collection is merged with item 1 from the second collection, item 2 with item 2, and so on. In case the count of the two sequences is different, Zip() just stops when the end of the smaller collection is reached.

The items in the first collection have a Name property and the items in the second collection have LastName and Starts properties.

Using the Zip() method on the collection racerNames requires the second collection racerNamesAndStarts as the first parameter. The second parameter is of type Func<TFirst, TSecond, TResult>. This parameter is implemented as a Lambda expression and receives the elements of the first collection with the parameter first, and the elements of the second collection with the parameter second. The implementation creates and returns a string containing the Name property of the first element and the Starts property of the second element:

```
var racerNames = from r in Formula1.GetChampions()
                 where r.Country == "Italy"
                 orderby r.Wins descending
                 select new
```

```
                  {
                      Name = r.FirstName + " " + r.LastName
                  };

         var racerNamesAndStarts = from r in Formula1.GetChampions()
                                   where r.Country == "Italy"
                                   orderby r.Wins descending
                                   select new
                                   {
                                       LastName = r.LastName,
                                       Starts = r.Starts
                                   };

         var racers = racerNames.Zip(racerNamesAndStarts,
                 (first, second) => first.Name + ", starts: " + second.Starts);
         foreach (var r in racers)
         {
             Console.WriteLine(r);
         }
```

The result of this merge is shown here:

```
Alberto Ascari, starts: 32
Nino Farina, starts: 33
```

Partitioning

Partitioning operations such as the extension methods `Take()` and `Skip()` can be used for easily paging, for example, to display 5 by 5 racers.

With the LINQ query shown here, the extension methods `Skip()` and `Take()` are added to the end of the query. The `Skip()` method first ignores a number of items calculated based on the page size and the actual page number; the `Take()` method then takes a number of items based on the page size:

```
int pageSize = 5;

int numberPages = (int)Math.Ceiling(Formula1.GetChampions().Count() /
      (double)pageSize);

for (int page = 0; page < numberPages; page++)
{
   Console.WriteLine("Page {0}", page);

   var racers =
      (from r in Formula1.GetChampions()
       orderby r.LastName
       select r.FirstName + " " + r.LastName).
      Skip(page * pageSize).Take(pageSize);

   foreach (var name in racers)
   {
      Console.WriteLine(name);
   }
   Console.WriteLine();
}
```

Here is the output of the first three pages:

```
Page 0
Fernando Alonso
Mario Andretti
Alberto Ascari
Jack Brabham
```

```
Jim Clark

Page 1
Juan Manuel Fangio
Nino Farina
Emerson Fittipaldi
Mika Hakkinen
Lewis Hamilton

Page 2
Mike Hawthorn
Phil Hill
Graham Hill
Damon Hill
Denny Hulme
```

Paging can be extremely useful with Windows or web applications showing the user only a part of the data.

An important behavior of this paging mechanism that you will notice: because the query is done with every page, changing the underlying data affects the results. New objects are shown as paging continues. Depending on your scenario this can be advantageous to your application. If this behavior is not what you need, you can do the paging not over the original data source, but by using a cache that maps to the original data.

With the `TakeWhile()` and `SkipWhile()` extension methods you can also pass a predicate to take or skip items based on the result of the predicate.

Aggregate Operators

The aggregate operators such as `Count()`, `Sum()`, `Min()`, `Max()`, `Average()`, and `Aggregate()` do not return a sequence but a single value instead.

The `Count()` extension method returns the number of items in the collection. Here the `Count()` method is applied to the `Years` property of a `Racer` to filter the racers and return only the ones who won more than three championships:

```
var query = from r in Formula1.GetChampions()
            where r.Years.Count() > 3
            orderby r.Years.Count() descending
            select new
            {
               Name = r.FirstName + " " + r.LastName,
               TimesChampion = r.Years.Count()
            };

foreach (var r in query)
{
   Console.WriteLine("{0} {1}", r.Name, r.TimesChampion);
}
```

The result is shown here:

```
Michael Schumacher 7
Juan Manuel Fangio 5
Alain Prost 4
```

The `Sum()` method summarizes all numbers of a sequence and returns the result. Here, `Sum()` is used to calculate the sum of all race wins for a country. First the racers are grouped based on the country, then with the new anonymous type created, the `Wins` property is assigned to the sum of all wins from a single country:

```
var countries =
   (from c in
       from r in Formula1.GetChampions()
       group r by r.Country into c
       select new
       {
          Country = c.Key,
          Wins = (from r1 in c
                  select r1.Wins).Sum()
       }
       orderby c.Wins descending, c.Country
       select c).Take(5);

foreach (var country in countries)
{
   Console.WriteLine("{0} {1}", country.Country, country.Wins);
}
```

The most successful countries based on the Formula-1 race champions are as follows:

```
UK 147
Germany 91
Brazil 78
France 51
Finland 42
```

The methods `Min()`, `Max()`, `Average()`, and `Aggregate()` are used in the same way as `Count()` and `Sum()`. `Min()` returns the minimum number of the values in the collection, and `Max()` returns the maximum number. `Average()` calculates the average number. With the `Aggregate()` method you can pass a Lambda expression that should do an aggregation with all the values.

Conversion

In this chapter you've already seen that the query execution is deferred until the items are accessed. Using the query within an iteration, the query is executed. With a conversion operator, the query is executed immediately and you get the result in an array, a list, or a dictionary.

In this example the `ToList()` extension method is invoked to immediately execute the query and get the result into a `List<T>`:

```
List<Racer> racers =
   (from r in Formula1.GetChampions()
    where r.Starts > 150
    orderby r.Starts descending
    select r).ToList();
foreach (var racer in racers)
{
   Console.WriteLine("{0} {0:S}", racer);
}
```

code snippet EnumerableSample/Program.cs

It's not that simple to just get the returned objects to the list. For example, for fast access from a car to a racer within a collection class, you can use the new class `Lookup<TKey, TElement>`.

The `Dictionary<TKey, TValue>` *supports only a single value for a key. With the class* `Lookup<TKey TElement>` *from the namespace* `System.Linq` *you can have multiple values for a single key. These classes are covered in detail in Chapter 10, "Collections."*

Using the compound from query, the sequence of racers and cars is flattened, and an anonymous type with the properties Car and Racer gets created. With the lookup that is returned, the key should be of type string referencing the car, and the value should be of type Racer. To make this selection, you can pass a key and an element selector to one overload of the ToLookup() method. The key selector references the Car property, and the element selector references the Racer property:

```
var racers = (from r in Formula1.GetChampions()
              from c in r.Cars
              select new
              {
                  Car = c,
                  Racer = r
              }).ToLookup(cr => cr.Car, cr => cr.Racer);
if (racers.Contains("Williams"))
{
   foreach (var williamsRacer in
      racers["Williams"])
   {
      Console.WriteLine(williamsRacer);
   }
}
```

The result of all "Williams" champions that are accessed using the indexer of the Lookup class is shown here:

```
Alan Jones
Keke Rosberg
Nigel Mansell
Alain Prost
Damon Hill
Jacques Villeneuve
```

In case you need to use a LINQ query over an untyped collection, for example the ArrayList, you can use the Cast() method. With the following sample, an ArrayList collection that is based on the Object type is filled with Racer objects. To make it possible to define a strongly typed query, you can use the Cast() method:

```
var list = new System.Collections.ArrayList(Formula1.GetChampions()
        as System.Collections.ICollection);

var query = from r in list.Cast<Racer>()
            where r.Country == "USA"
            orderby r.Wins descending
            select r;
foreach (var racer in query)
{
   Console.WriteLine("{0:A}", racer);
}
```

Generation Operators

The generation operators Range(), Empty(), and Repeat() are not extension methods but normal static methods that return sequences. With LINQ to objects, these methods are available with the Enumerable class.

Have you ever needed a range of numbers filled? Nothing is easier than with the Range() method. This method receives the start value with the first parameter and the number of items with the second parameter:

```
var values = Enumerable.Range(1, 20);
foreach (var item in values)
{
   Console.Write("{0} ", item);
}
```

```
            Console.WriteLine();
```

Of course the result now looks like this:

```
1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18 19 20
```

You can combine the result with other extension methods to get a different result — for example, using the `Select()` extension method:

```
            var values = Enumerable.Range(1, 20).Select(n => n * 3);
```

The `Empty()` method returns an iterator that does not return values. This can be used for parameters that require a collection where you can pass an empty collection.

The `Repeat()` method returns an iterator that returns the same value a specific number of times.

PARALLEL LINQ

.NET 4 contains a new class `ParallelEnumerable` in the `System.Linq` namespace to split the work of queries across multiple threads. Although the `Enumerable` class defines extension methods to the `IEnumerable<T>` interface, most extension methods of the `ParallelEnumerable` class are extensions for the class `ParallelQuery<TSource>`. One important exception is the `AsParallel()` method that extends `IEnumerable<TSource>` and returns `ParallelQuery<TSource>`, so a normal collection class can be queried in a parallel manner.

Parallel Queries

To dmonstrate Parallel LINQ, a large collection is needed. With small collections you will not see any effect when the collection fits inside the CPU's cache. In the following code, a large `int` array is filled with random values:

```
const int arraySize = 100000000;
var data = new int[arraySize];
var r = new Random();
for (int i = 0; i < arraySize; i++)
{
    data[i] = r.Next(40);
}
```

code snippet ParallelLinqSample/Program.cs

Now you can use a LINQ query to filter the data and get a sum of the filtered data. The query defines a filter with the `where` clause to summarize only the items with values `< 20`, and then the aggregation function sum is invoked. The only difference to the LINQ queries you've seen so far is the call to the `AsParallel()` method.

```
var sum = (from x in data.AsParallel()
           where x < 20
           select x).Sum();
```

As with the LINQ queries you've seen so far, the compiler changes the syntax to invoke the methods `AsParallel()`, `Where()`, `Select()`, and `Sum()`. `AsParallel()` is defined with the `ParallelEnumerable` class to extend the `IEnumerable<T>` interface, so it can be called with a simple array. `AsParallel()`

returns `ParallelQuery<TSource>`. Because of the returned type, the `Where()` method that is chosen by the compiler is `ParallelEnumerable.Where()` instead of `Enumerable.Where()`. In the following code, the `Select()` and `Sum()` methods are from `ParallelEnumerable` as well. In contrast to the implementation of the `Enumerable` class, with the `ParallelEnumerable` class the query is *partitioned* so that multiple threads can work on the query. The array can be split into multiple parts where different threads work on every part to filter the remaining items. After the partitioned work is completed, *merging* needs to take place to get the summary result of all parts.

```
var sum = data.AsParallel().Where(x => x < 20).Select(x => x).Sum();
```

Running this code starts the task manager so you can see that all CPUs of your system are busy. If you remove the `AsParallel()` method, multiple CPUs might not be used. Of course if you do not have multiple CPUs on your system, then don't expect to see an improvement with the parallel version.

Partitioners

The `AsParallel()` method is an extension not only to the `IEnumerable<T>` interface, but also to the `Partitioner` class. With this you can influence the partitions to be created.

The `Partitioner` class is defined with the namespace `System.Collections.Concurrent` and has different variants. The `Create()` method accepts arrays or objects implementing `IList<T>`. Depending on that, as well as on the parameter `loadBalance` that is of type Boolean and available with some overloads of the method, a different partitioner type is returned. For arrays, .NET 4 includes `DynamicPartitionerFor Array<TSource>` and `StaticPartitionerForArray<TSource>` that both derive from the abstract base class `OrderablePartitioner<TSource>`.

The code from the "Parallel Queries" section is changed to manually create a partitioner instead of relying on the default one:

```
var sum = (from x in Partitioner.Create(data, true).AsParallel()
           where x < 20
           select x).Sum();
```

You can also influence the parallelism by invoking the methods `WithExecutionMode()` and `WithDegreeOfParallelism()`. With `WithExecutionMode()` you can pass a value of `ParallelExecutionMode` that can be `Default` or `ForceParallelism`. By default, Parallel LINQ avoids parallelism with high overheads. With the method `WithDegreeOfParallelism()` you can pass an integer value to specify the maximum number of tasks that should run in parallel.

Cancellation

.NET 4 offers a standard way to cancel long-running tasks, and this is also true for Parallel LINQ.

To cancel a long-running query, you can add the method `WithCancellation()` to the query and pass a `CancellationToken` to the parameter. The `CancellationToken` is created from the `CancellationTokenSource`. The query is run in a separate thread where the exception of type `OperationCanceledException` is caught. This exception is fired if the query is cancelled. From the main thread the task can be cancelled by invoking the `Cancel()` method of the `CancellationTokenSource`.

```
var cts = new CancellationTokenSource();

new Thread(() =>
    {
        try
        {
            var sum = (from x in data.AsParallel().
                               WithCancellation(cts.Token)
                           where x < 80
                           select x).Sum();
            Console.WriteLine("query finished, sum: {0}", sum);
        }
        catch (OperationCanceledException ex)
        {
            Console.WriteLine(ex.Message);
        }
    }).Start();

Console.WriteLine("query started");
Console.Write("cancel? ");
int input = Console.Read();
if (input == 'Y' || input == 'y')
{
    // cancel!
    cts.Cancel();
}
```

EXPRESSION TREES

With LINQ to objects, the extension methods require a delegate type as parameter; this way, a Lambda expression can be assigned to the parameter. Lambda expressions can also be assigned to parameters of type `Expression<T>`. The C# compiler defines different behavior for Lambda expressions depending on the type. If the type is `Expression<T>`, the compiler creates an expression tree from the Lambda expression and stores it in the assembly. The expression tree can be analyzed during runtime and optimized for doing the query to the data source.

Let's turn to a query expression that was used previously:

```
var brazilRacers = from r in racers
                   where r.Country == "Brazil"
                   orderby r.Wins
                   select r;
```

code snippet ExpressionTreeSample/Program.cs

This query expression is using the extension methods `Where`, `OrderBy`, and `Select`. The `Enumerable` class defines the `Where()` extension method with the delegate type `Func<T, bool>` as parameter predicate:

```
public static IEnumerable<TSource> Where<TSource>(this IEnumerable<TSource> source,
      Func<TSource, bool> predicate);
```

This way, the Lambda expression is assigned to the predicate. Here, the Lambda expression is similar to an anonymous method, as was explained earlier:

```
Func<Racer, bool> predicate = r => r.Country == "Brazil";
```

The `Enumerable` class is not the only class to define the `Where()` extension method. The `Where()` extension method is also defined by the class `Queryable<T>`. This class has a different definition of the `Where()` extension method:

```
public static IQueryable<TSource> Where<TSource>(this IQueryable<TSource> source,
      Expression<Func<TSource, bool>> predicate);
```

Here, the Lambda expression is assigned to the type `Expression<T>`, which behaves differently:

```
Expression<Func<Racer, bool>> predicate = r => r.Country == "Brazil";
```

Instead of using delegates, the compiler emits an expression tree to the assembly. The expression tree can be read during runtime. Expression trees are built from classes that are derived from the abstract base class `Expression`. The `Expression` class is not the same as `Expression<T>`. Some of the expression classes that inherit from `Expression` are `BinaryExpression`, `ConstantExpression`, `InvocationExpression`, `LambdaExpression`, `NewExpression`, `NewArrayExpression`, `TernaryExpression`, `UnaryExpression`, and so on. The compiler creates an expression tree resulting from the Lambda expression.

For example, the Lambda expression `r.Country == "Brazil"` makes use of `ParameterExpression`, `MemberExpression`, `ConstantExpression`, and `MethodCallExpression` to create a tree and store the tree in the assembly. This tree is then used during runtime to create an optimized query to the underlying data source.

The method `DisplayTree()` is implemented to display an expression tree graphically on the console. Here an `Expression` object can be passed, and depending on the expression type some information about the expression is written to the console. Depending on the type of the expression, `DisplayTree()` is called recursively.

```
private static void DisplayTree(int indent, string message,
                                Expression expression)
{
   string output = String.Format("{0} {1} ! NodeType: {2}; Expr: {3} ",
         "".PadLeft(indent, '>'), message, expression.NodeType, expression);

   indent++;
   switch (expression.NodeType)
   {
      case ExpressionType.Lambda:
         Console.WriteLine(output);
         LambdaExpression lambdaExpr = (LambdaExpression)expression;
         foreach (var parameter in lambdaExpr.Parameters)
         {
            DisplayTree(indent, "Parameter", parameter);
         }
         DisplayTree(indent, "Body", lambdaExpr.Body);
         break;
      case ExpressionType.Constant:
         ConstantExpression constExpr = (ConstantExpression)expression;
         Console.WriteLine("{0} Const Value: {1}", output, constExpr.Value);
         break;
      case ExpressionType.Parameter:
         ParameterExpression paramExpr = (ParameterExpression)expression;
         Console.WriteLine("{0} Param Type: {1}", output,
                           paramExpr.Type.Name);
         break;
      case ExpressionType.Equal:
      case ExpressionType.AndAlso:
      case ExpressionType.GreaterThan:
         BinaryExpression binExpr = (BinaryExpression)expression;
         if (binExpr.Method != null)
         {
            Console.WriteLine("{0} Method: {1}", output,
                              binExpr.Method.Name);
         }
         else
         {
            Console.WriteLine(output);
         }
         DisplayTree(indent, "Left", binExpr.Left);
         DisplayTree(indent, "Right", binExpr.Right);
```

```
                  break;
               case ExpressionType.MemberAccess:
                  MemberExpression memberExpr = (MemberExpression)expression;
                  Console.WriteLine("{0} Member Name: {1}, Type: {2}", output,
                     memberExpr.Member.Name, memberExpr.Type.Name);
                  DisplayTree(indent, "Member Expr", memberExpr.Expression);
                  break;
               default:
                  Console.WriteLine();
                  Console.WriteLine("{0} {1}", expression.NodeType,
                                    expression.Type.Name);
                  break;
            }
         }
```

The expression that is used for showing the tree is already well known. It's a Lambda expression with a `Racer` parameter, and the body of the expression takes racers from Brazil only if they have won more than six races:

```
            Expression<Func<Racer, bool>> expression =
                r => r.Country == "Brazil" && r.Wins > 6;

            DisplayTree(0, "Lambda", expression);
```

Let's look at the tree result. As you can see from the output, the Lambda expression consists of a `Parameter` and an `AndAlso` node type. The `AndAlso` node type has an `Equal` node type to the left and a `GreaterThan` node type to the right. The `Equal` node type to the left of the `AndAlso` node type has a `MemberAccess` node type to the left and a `Constant` node type to the right, and so on:

```
Lambda! NodeType: Lambda; Expr: r => ((r.Country == "Brazil")
    AndAlso (r.Wins > 6))
> Parameter! NodeType: Parameter; Expr: r  Param Type: Racer
> Body! NodeType: AndAlso; Expr: ((r.Country == "Brazil")
    AndAlso (r.Wins > 6))
>> Left! NodeType: Equal; Expr: (r.Country == "Brazil")  Method: op_Equality
>>> Left! NodeType: MemberAccess; Expr: r.Country
    Member Name: Country, Type: String
>>>> Member Expr! NodeType: Parameter; Expr: r  Param Type: Racer
>>> Right! NodeType: Constant; Expr: "Brazil" Const Value: Brazil
>> Right! NodeType: GreaterThan; Expr: (r.Wins > 6)
>>> Left! NodeType: MemberAccess; Expr: r.Wins  Member Name: Wins, Type: Int32
>>>> Member Expr! NodeType: Parameter; Expr: r  Param Type: Racer
>>> Right! NodeType: Constant; Expr: 6  Const Value: 6
```

One example where the `Expression<T>` type is used is with the ADO.NET Entity Framework and LINQ to SQL. These technologies define methods with `Expression<T>` parameters. This way the LINQ provider accessing the database can create a runtime-optimized query by reading the expressions to get the data from the database.

LINQ PROVIDERS

.NET 4 includes several LINQ providers. A LINQ provider implements the standard query operators for a specific data source. LINQ providers might implement more extension methods than are defined by LINQ, but the standard operators must at least be implemented. LINQ to XML implements more methods that are particularly useful with XML, for example, the methods `Elements()`, `Descendants()`, and `Ancestors()` are defined by the class `Extensions` in the `System.Xml.Linq` namespace.

The implementation of the LINQ provider is selected based on the namespace and on the type of the first parameter. The namespace of the class that implements the extension methods must be opened, otherwise the extension class is not in scope. The parameter of the `Where()` method that is defined by LINQ to objects and the `Where()` method that is defined by LINQ to SQL is different.

The `Where()` method of LINQ to objects is defined with the `Enumerable` class:

```
public static IEnumerable<TSource> Where<TSource>(this IEnumerable<TSource> source,
      Func<TSource, bool> predicate);
```

Inside the `System.Linq` namespace there's another class that implements the operator `Where`. This implementation is used by LINQ to SQL. You can find the implementation in the class `Queryable`:

```
public static IQueryable<TSource> Where<TSource>(this IQueryable<TSource> source,
      Expression<Func<TSource, bool>> predicate);
```

Both of these classes are implemented in the `System.Core` assembly in the `System.Linq` namespace. How is it defined and what method is used? The Lambda expression is the same no matter whether it is passed with a `Func<TSource, bool>` parameter or with an `Expression<Func<TSource, bool>>` parameter. Just the compiler behaves differently. The selection is done based on the `source` parameter. The method that matches best based on its parameters is chosen by the compiler. The `CreateQuery<T>()` method of the `ObjectContext` class that is defined by ADO.NET Entity Framework returns an `ObjectQuery<T>` object that implements `IQueryable<TSource>`, and thus the Entity Framework uses the `Where()` method of the `Queryable` class.

SUMMARY

In this chapter, you've seen the LINQ query and the language constructs that the query is based on, such as extension methods and Lambda expressions. You've seen the various LINQ query operators not just for filtering and ordering of data sources, but also for partitioning, grouping, doing conversions, joins, and so on.

With Parallel LINQ you've seen how longer queries can easily be parallelized.

Another important concept is the expression tree. Expression trees allow building the query to the data source at runtime because the tree is stored in the assembly. You can read about the great advantages of it in Chapter 31. LINQ is a very in-depth topic, and you should see Chapters 31 and 33 for more information. Other third-party providers are available for download; for example, LINQ to MySQL, LINQ to Amazon, LINQ to Flickr, LINQ to LDAP, and LINQ to SharePoint. No matter what data source you have, with LINQ you can use the same query syntax.

12

Dynamic Language Extensions

WHAT'S IN THIS CHAPTER?

- Understanding the Dynamic Language Runtime
- The `dynamic` type
- The DLR ScriptRuntime
- `DynamicObject`
- `ExpandoObject`

The growth of languages such as Ruby, Python, and the increased use of JavaScript have intensified interest in dynamic programming. In previous versions of the .NET Framework, the `var` keyword and anonymous methods started C# down the "dynamic" road. In version 4, the `dynamic` type was added. Although C# is still a statically typed language, these additions give it the dynamic capabilities that some developers are looking for.

In this chapter, you'll look at the `dynamic` type and the rules for using it. You'll also see what an implementation of `DynamicObject` looks like and how it can be used.

DYNAMIC LANGUAGE RUNTIME

The dynamic capabilities of C# 4 are part of the Dynamic Language Runtime (DLR). The DLR is a set of services that is added to the CLR to allow the addition of dynamic languages such as Ruby and Python. It also allows C# to take on some of the same dynamic capabilities that these dynamic languages have.

There is a version of the DLR that is open source and resides on the CodePlex web site. This same version is included with the .NET 4 Framework, with some additional support for language implementers.

In the .NET Framework, the DLR is found in the `System.Dynamic` namespace as well as a few additional classes in the `System.Runtime.CompilerServices` namespace.

IronRuby and IronPython, which are open source versions of the Ruby and Python languages, use the DLR. Silverlight also uses the DLR. It's possible to add scripting capabilities to your applications by hosting the DLR. The scripting runtime allows you to pass variables to and from the script.

THE DYNAMIC TYPE

The `dynamic` type allows you to write code that will bypass compile time type checking. The compiler will assume that whatever operation is defined for an object of type `dynamic` is valid. If that operation isn't valid, the error won't be detected until runtime. This is shown in the following example:

```
class Program
{
    static void Main(string[] args)
    {
        var staticPerson = new Person();
        dynamic dynamicPerson = new Person();
        staticPerson.GetFullName("John", "Smith");
        dynamicPerson.GetFullName("John", "Smith");
    }
}

class Person
{
    public string FirstName { get; set; }
    public string LastName { get; set; }
    public string GetFullName()
    {
        return string.Concat(FirstName, " ", LastName);
    }
}
```

This example will not compile because of the call to `staticPerson.GetFullName()`. There isn't a method on the `Person` object that takes two parameters, so the compiler raises the error. If that line of code were to be commented out, the example would compile. If executed, a runtime error would occur. The exception that is raised is `RuntimeBinderException`. The `RuntimeBinder` is the object in the runtime that evaluates the call to see if `Person` really does support the method that was called. This is discussed later in the chapter.

Unlike the `var` keyword, an object that is defined as *dynamic* can change type during runtime. Remember, when the `var` keyword is used, the determination of the object's type is delayed. Once the type is defined, it can't be changed. Not only can you change the type of a dynamic object, you can change it many times. This differs from casting an object from one type to another. When you cast an object you are creating a new object with a different but compatible type. For example, you cannot cast an `int` to a `Person` object. In the following example, you can see that if the object is a dynamic object, you can change it from `int` to `Person`:

```
dynamic dyn;

dyn = 100;
Console.WriteLine(dyn.GetType());
Console.WriteLine(dyn);

dyn = "This is a string";
Console.WriteLine(dyn.GetType());
Console.WriteLine(dyn);

dyn = new Person() { FirstName = "Bugs", LastName = "Bunny" };
Console.WriteLine(dyn.GetType());
Console.WriteLine("{0} {1}", dyn.FirstName, dyn.LastName);
```

code snippet Dynamic\Program.cs

Executing this code would show that the `dyn` object actually changes type from `System.Int32` to `System.String` to `Person`. If `dyn` had been declared as an `int` or `string`, the code would not have compiled.

There are a couple of limitations to the `dynamic` type. A dynamic object does not support extension methods. Anonymous functions (Lambda expressions) also cannot be used as parameters to a dynamic method call, thus LINQ does not work well with dynamic objects. Most LINQ calls are extension methods and Lambda expressions are used as arguments to those extension methods.

Dynamic Behind the Scenes

So what's going on behind the scenes to make this happen? C# is still a statically typed language. That hasn't changed. Take a look at the IL (Intermediate Language) that's generated when the `dynamic` type is used.

First, this is the example C# code that you're looking at:

```
using System;

namespace DeCompile
{
    class Program
    {
        static void Main(string[] args)
        {
            StaticClass staticObject = new StaticClass();
            DynamicClass dynamicObject = new DynamicClass();
            Console.WriteLine(staticObject.IntValue);
            Console.WriteLine(dynamicObject.DynValue);
            Console.ReadLine();
        }
    }

    class StaticClass
    {
        public int IntValue = 100;
    }

    class DynamicClass
    {
        public dynamic DynValue = 100;
    }
}
```

You have two classes, `StaticClass` and `DynamicClass`. `StaticClass` has a single field that returns an `int`. `DynamicClass` has a single field that returns a `dynamic` object. The `Main` method just creates these objects and prints out the value that the methods return. Simple enough.

Now comment out the references to the `DynamicClass` in `Main` like this:

```
static void Main(string[] args)
{
    StaticClass staticObject = new StaticClass();
    //DynamicClass dynamicObject = new DynamicClass();
    Console.WriteLine(staticObject.IntValue);
    //Console.WriteLine(dynamicObject.DynValue);
    Console.ReadLine();
}
```

Using the `ildasm` tool (discussed in Chapter 18, "Assemblies"), you can look at the IL that is generated for the `Main` method:

```
.method private hidebysig static void  Main(string[] args) cil managed
{
  .entrypoint
  // Code size       26 (0x1a)
  .maxstack  1
```

```
    .locals init ([0] class DeCompile.StaticClass staticObject)
    IL_0000:  nop
    IL_0001:  newobj     instance void DeCompile.StaticClass::.ctor()
    IL_0006:  stloc.0
    IL_0007:  ldloc.0
    IL_0008:  ldfld      int32 DeCompile.StaticClass::IntValue
    IL_000d:  call       void [mscorlib]System.Console::WriteLine(int32)
    IL_0012:  nop
    IL_0013:  call       string [mscorlib]System.Console::ReadLine()
    IL_0018:  pop
    IL_0019:  ret
  } // end of method Program::Main
```

Without going into the details of IL but just looking at this section of code, you can still pretty much tell what's going on. Line 0001, the `StaticClass` constructor, is called. Line 0008 calls the `IntValue` field of `StaticClass`. The next line writes out the value.

Now comment out the `StaticClass` references and uncomment the `DynamicClass` references:

```
static void Main(string[] args)
{
    //StaticClass staticObject = new StaticClass();
    DynamicClass dynamicObject = new DynamicClass();
    Console.WriteLine(staticObject.IntValue);
    //Console.WriteLine(dynamicObject.DynValue);
    Console.ReadLine();
}
```

Compile the application again and this is what gets generated:

```
.method private hidebysig static void  Main(string[] args) cil managed
{
  .entrypoint
  // Code size       121 (0x79)
  .maxstack  9
  .locals init ([0] class DeCompile.DynamicClass dynamicObject,
           [1] class [Microsoft.CSharp]Microsoft.CSharp.RuntimeBinder.CSharpArgumentInfo[]
                  CS$0$0000)
  IL_0000:  nop
  IL_0001:  newobj     instance void DeCompile.DynamicClass::.ctor()
  IL_0006:  stloc.0
  IL_0007:  ldsfld     class [System.Core]System.Runtime.CompilerServices.CallSite`1
                       <class [mscorlib]
System.Action`3<class
[System.Core]System.Runtime.CompilerServices.CallSite,class [mscorlib]
System.Type,object>> DeCompile.Program/'<Main>o__SiteContainer0'::'<>p__Site1'
  IL_000c:  brtrue.s   IL_004d
  IL_000e:  ldc.i4.0
  IL_000f:  ldstr "WriteLine"
  IL_0014:  ldtoken    DeCompile.Program
  IL_0019:  call       class [mscorlib]System.Type [mscorlib]System.Type::GetTypeFromHandle
(valuetype [mscorlib]System.RuntimeTypeHandle)
  IL_001e:  ldnull
  IL_001f:  ldc.i4.2
  IL_0020:  newarr     [Microsoft.CSharp]Microsoft.CSharp.RuntimeBinder.CSharpArgumentInfo
  IL_0025:  stloc.1
  IL_0026:  ldloc.1
  IL_0027:  ldc.i4.0
  IL_0028:  ldc.i4.s   33
  IL_002a:  ldnull
  IL_002b:  newobj     instance void [Microsoft.CSharp]Microsoft.CSharp.RuntimeBinder

<class [System.Core]System.Runtime.CompilerServices.CallSite,
class [mscorlib]System.Type,object>>::Target
  IL_0057:  ldsfld     class [System.Core]System.Runtime.CompilerServices.CallSite`1
<class [mscorlib]System.Action`3
<class [System.Core]System.Runtime.CompilerServices.CallSite,
class [mscorlib]System.Type,object>> DeCompile.Program/'<Main>o__SiteContainer0'::'<>p__Site1'
  IL_005c:  ldtoken    [mscorlib]System.Console
  IL_0061:  call       class [mscorlib]System.Type [mscorlib]System.Type::GetTypeFromHandle
(valuetype [mscorlib]System.RuntimeTypeHandle)
  IL_0066:  ldloc.0
  IL_0067:  ldfld      object DeCompile.DynamicClass::DynValue
  IL_006c:  callvirt   instance void class [mscorlib]System.Action`3
             <class [System.Core]System.Runtime.CompilerServices.CallSite, class
             [mscorlib]System.Type,object>::Invoke(!0,!1,!2)
  IL_0071:  nop
  IL_0072:  call       string [mscorlib]System.Console::ReadLine()
  IL_0077:  pop
  IL_0078:  ret
} // end of method Program::Main
```

So it's safe to say that the C# compiler is doing a little extra work to support the dynamic type. Looking at the generated code, you can see references to `System.Runtime.CompilerServices.CallSite` and `System.Runtime.CompilerServices.CallSiteBinder`.

The `CallSite` is a type that handles the lookup at runtime. When a call is made on a dynamic object at runtime, something has to go and look at that object to see if the member really exists. The call site caches this information so the lookup doesn't have to be performed repeatedly. Without this process, performance in looping structures would be questionable.

After the `CallSite` does the member lookup, the `CallSiteBinder` is invoked. It takes the information from the call site and generates an expression tree representing the operation the binder is bound to.

There is obviously a lot going on here. Great care has been taken to optimize what would appear to be a very complex operation. It should be obvious that while using the `dynamic` type can be useful, it does come with a price.

HOSTING THE DLR SCRIPTRUNTIME

Imagine being able to add scripting capabilities to an application. Imagine passing values in and out of the script so the application can take advantage of the work that the script does. These are the kind of capabilities that hosting the DLR's ScriptRuntime in your app gives you. Currently, IronPython, IronRuby, and JavaScript are supported as hosted scripting languages.

With the ScriptRuntime, you have the capability of executing snippets of code or a complete script stored in a file. You can select the proper language engine or allow the DLR to figure out which engine. The script can be created in its own app domain or in the current one. Not only can you pass values in and out of the script, but you can call methods on dynamic objects created in the script.

With this amount of flexibility there are countless uses for hosting the ScriptRuntime. The following example demonstrates one way that the ScriptRuntime can be used. Imagine a shopping cart application. One of the requirements is to calculate a discount based on certain criteria. These discounts change often as new sales campaigns are started and completed. There are many ways of handling such a requirement; this example shows how it could be handled using the ScriptRuntime and a little Python scripting.

For simplicity, the example is a Windows client app. It could be part of a larger web application or any other application. Figure 12-1 shows a sample screen for the application.

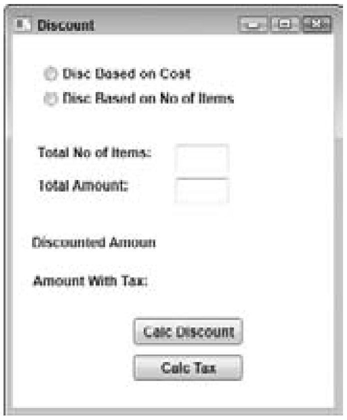

FIGURE 12-1

The application takes the number of items and the total cost of the items and applies a discount based on which radio button is selected. In a real application the system would use a slightly more sophisticated way to determine the discount to apply, but for this example, the radio buttons will work.

Here is the code that performs the discount:

```
private void button1_Click(object sender, RoutedEventArgs e)
{
    string scriptToUse;
    if (CostRadioButton.IsChecked.Value)
    {
        scriptToUse = "AmountDisc.py";
    }
    else
    {
        scriptToUse = "CountDisc.py";
    }
    ScriptRuntime scriptRuntime = ScriptRuntime.CreateFromConfiguration();
    ScriptEngine pythEng = scriptRuntime.GetEngine("Python");
```

```
        ScriptSource source = pythEng.CreateScriptSourceFromFile(scriptToUse);
        ScriptScope scope = pythEng.CreateScope();
        scope.SetVariable("prodCount", Convert.ToInt32(totalItems.Text));
        scope.SetVariable("amt", Convert.ToDecimal(totalAmt.Text));
        source.Execute(scope);
        label5.Content = scope.GetVariable("retAmt").ToString();
    }
```

code snippet Window1.xaml.cs

The first part is just determining which script to apply, `AmountDisc.py` or `CountDisc.py`. `AmountDisc.py` does the discount based on the amount of the purchase:

```
discAmt = .25
retAmt = amt
if amt > 25.00:
  retAmt = amt-(amt*discAmt)
```

The minimum amount needed for a discount to be applied is $25.00. If the amount is less than that, then no discount is applied, otherwise a discount of 25 percent is applied.

`ContDisc.py` applies the discount based on the number of items purchased:

```
discCount = 5
discAmt = .1
retAmt = amt
if prodCount > discCount:
  retAmt = amt-(amt*discAmt)
```

In this Python script, the number of items purchased must be more than 5 for a 10 percent discount to be applied to the total cost.

The next part is getting the ScriptRuntime environment set up. There are four specific steps that are performed, creating the `ScriptRuntime` object, setting the proper `ScriptEngine`, creating the `ScriptSource`, and creating the `ScriptScope`.

The ScriptRuntime object is the starting point or the base for hosting. It has the global state of the hosting environment. The ScriptRuntime is created using the `CreateFromConfiguration` static method. This is what the `app.config` looks like:

```
<configuration>
  <configSections>
    <section
      name="microsoft.scripting"
      type="Microsoft.Scripting.Hosting.Configuration.Section,
          Microsoft.Scripting,
          Version=0.9.6.10,
          Culture=neutral,
          PublicKeyToken=null"
          requirePermission="false" />
  </configSections>

  <microsoft.scripting>
    <languages>
      <language
        names="IronPython;Python;py"
        extensions=".py"
        displayName="IronPython 2.6 Alpha"
        type="IronPython.Runtime.PythonContext,
              IronPython,
              Version=2.6.0.1,
              Culture=neutral,
              PublicKeyToken=null" />
      </languages>
    </microsoft.scripting>
  </configuration>
```

The code defines a section for "microsoft.scripting" and set a couple of properties for the IronPython language engine.

Next, you get a reference to the `ScriptEngine` from the `ScriptRuntime`. In the example, you specify that you want the Python engine, but the `ScriptRuntime` would have been able to determine this on its own because of the `py` extension on the script.

The `ScriptEngine` does the work of executing the script code. There are several methods for executing scripts from files or from snippets of code. The `ScriptEngine` also gives you the `ScriptSource` and `ScriptScope`.

The `ScriptSource` object is what gives you access to the script. It represents the source code of the script. With it you can manipulate the source of the script. Load it from a disk, parse it line by line, and even compile the script into a `CompiledCode` object. This is handy if the same script is executed multiple times.

The `ScriptScope` object is essentially a namespace. To pass a value into or out of a script, you bind a variable to the `ScriptScope`. In the example, you call the `SetVariable` method to pass into the Python script the `prodCount` variable and the `amt` variable. These are the values from the `totalItems` text box and the `totalAmt` text box. The calculated discount is retrieved from the script by using the `GetVariable` method. In this example, the `retAmt` variable has the value you're looking for.

In the `CalcTax` button you look at how to call a method on a Python object. The script `CalcTax.py` is a very simple method that takes an input value, adds 7.5 percent tax, and returns the new value. Here's what the code looks like:

```
def CalcTax(amount):
   return amount*1.075
```

Here is the C# code to call the `CalcTax` method:

```
private void button2_Click(object sender, RoutedEventArgs e)
{
    ScriptRuntime scriptRuntime = ScriptRuntime.CreateFromConfiguration();
    dynamic calcRate = scriptRuntime.UseFile("CalcTax.py");
    label6.Content = calcRate.CalcTax(Convert.ToDecimal(label5.Content)).ToString();
}
```

A very simple process. Again you create the `ScriptRuntime` object using the same configuration settings as before. `calcRate` is a `ScriptScope` object. You defined it as dynamic so you can easily call the `CalcTax` method. This is an example of the how the dynamic type can make life a little easier.

DYNAMICOBJECT AND EXPANDOOBJECT

What if you want to create your own dynamic object? You have a couple of choices for doing that, by deriving from `DynamicObject` or by using `ExpandoObject`. Using `DynamicObject` will be a little more work because you have to override a couple of methods. `ExpandoObject` is a sealed class that is ready to use.

DynamicObject

Consider an object that represents a person. Normally, you would define properties for the first name, middle name, and last name. Now imagine the capability to build that object during runtime, with the system having no prior knowledge of what properties the object may have or what methods the object may support. That's what having a `DynamicObject`-based object can give you. There may be very few times when you need this sort of functionality, but until now, the C# language had no way of accommodating you.

First let's see what the `DynamicObject` looks like:

```
class WroxDynamicObject : DynamicObject
{
    Dictionary<string, object> _dynamicData = new Dictionary<string, object>();

    public override bool TryGetMember(GetMemberBinder binder, out object result)
    {
        bool success = false;
        result = null;
        if (_dynamicData.ContainsKey(binder.Name))
        {
            result = _dynamicData[binder.Name];
            success = true;
        }
        else
        {
            result = "Property Not Found!";
            success = false;
        }
        return success;
    }

    public override bool TrySetMember(SetMemberBinder binder, object value)
    {
        _dynamicData[binder.Name] = value;
        return true;
    }

    public override bool TryInvokeMember(InvokeMemberBinder binder,
                                         object[] args,
                                         out object result)
    {
        dynamic method = _dynamicData[binder.Name];
        result = method((DateTime)args[0]);
        return result != null;
    }

}
```

code snippet Dynamic\Program.cs

In this example, you're overriding three methods: `TrySetMember`, `TryGetMember`, and `TryInvokeMember`.

`TrySetMember` adds the new method, property, or field to the object. In this example, you store the member information in a `Dictionary` object. The `SetMemberBinder` object that is passed into the `TrySetMember` method contains the `Name` property, which is used to identify the element in the `Dictionary`.

The `TryGetMember` retrieves the object stored in the `Dictionary` based on the `GetMemberBinder` `Name` property.

So how are these used? Here is the code that makes use of the new dynamic object just created:

```
dynamic wroxDyn = new WroxDynamicObject();
wroxDyn.FirstName = "Bugs";
wroxDyn.LastName = "Bunny";
Console.WriteLine(wroxDyn.GetType());
Console.WriteLine("{0} {1}", wroxDyn.FirstName, wroxDyn.LastName);
```

Looks simple enough, but where is the call to the methods you overrode? Well, that's where the .NET Framework helps. `DynamicObject` handles the binding for you; all you have to do is reference the properties `FirstName` and `LastName` as if they were there all the time.

What about adding a method? That can be done easily. You can use the same WroxDynamicObject and add a GetTomorrowDate method on it. It takes a DateTime object and returns a date string that is the next day. Here's the code:

```
dynamic wroxDyn = new WroxDynamicObject();
Func<DateTime, string> GetTomorrow = today => today.AddDays(1).ToShortDateString();
wroxDyn.GetTomorrowDate = GetTomorrow;
Console.WriteLine("Tomorrow is {0}", wroxDyn.GetTomorrowDate(DateTime.Now));
```

You create the delegate GetTomorrow using Func<T, TResult>. The method the delegate represents is the call to AddDays. One day is added to the Date that is passed in, and a string of that date is returned. The delegate is then set to GetTomorrowDate on the wroxDyn object. The last line calls the new method, passing in today's date.

Once again the dynamic magic happens and you have an object with a valid method.

ExpandoObject

ExpandoObject works similar to the WroxDynamicObject created in the previous section. The difference is that you don't have to override any methods, as shown in the following code example:

```
static void DoExpando()
{
    dynamic expObj = new ExpandoObject();
    expObj.FirstName = "Daffy";
    expObj.LastName = "Duck";
    Console.WriteLine(expObj.FirstName + " " + expObj.LastName);
    Func<DateTime, string> GetTomorrow = today => today.AddDays(1).ToShortDateString();
    expObj.GetTomorrowDate = GetTomorrow;
    Console.WriteLine("Tomorrow is {0}", expObj.GetTomorrowDate(DateTime.Now));

    expObj.Friends = new List<Person>();
    expObj.Friends.Add(new Person() { FirstName = "Bob", LastName = "Jones" });
    expObj.Friends.Add(new Person() { FirstName = "Robert", LastName = "Jones" });
    expObj.Friends.Add(new Person() { FirstName = "Bobby", LastName = "Jones" });

    foreach (Person friend in expObj.Friends)
    {
        Console.WriteLine(friend.FirstName + " " + friend.LastName);
    }
}
```

Notice that this code is almost identical to what you did earlier. You add a FirstName and LastName property, add a GetTomorrow function, and do one additional thing—add a collection of Person objects as a property of the object.

At first glance, it may seem that this is no different than using the dynamic type. Well, there are a couple of subtle differences that are important. First, you can't just create an empty dynamic typed object. The dynamic type has to have something assigned to it. For example, the following code won't work:

```
dynamic dynObj;
dynObj.FirstName = "Joe";
```

As seen in the previous example, this is possible with ExpandoObject.

Second, because the dynamic type has to be assigned to, it will report back the type of what was assigned to it if you do a GetType call. So if you say assign an int, it will report back that it is an int. This won't happen with ExpandoObject or an object derived from DynamicObject.

If you have to control the addition and access of properties in your dynamic object, then deriving from DynamicObject is your best choice. With DynamicObject, you can use several methods to override and control exactly how the object interacts with the runtime. For other cases, using the dynamic type or the ExpandoObject may be just what you need.

SUMMARY

This chapter showed you how the new dynamic type can be used. You also saw what the compiler does when it sees a dynamic type. The Dynamic Language Runtime was discussed and you were able to host it in a simple app. You used Python as a way to use the DLR, and executed Python scripts, passing in and out values for the scripts to use. And finally, you created your own dynamic type by deriving a class from `DynamicObject`.

Dynamic development is becoming very popular. It allows you to do things that are very difficult in a statically typed language. The `dynamic` type and the DLR allow C# programmers to make use of some dynamic capabilities.

13

Memory Management and Pointers

WHAT'S IN THIS CHAPTER?

- Allocating space on the stack and heap with runtime
- Garbage collection
- Releasing unmanaged resources using destructors and the `System.IDisposable` interface
- The syntax for using pointers in C#
- Using pointers to implement high-performance stack-based arrays

This chapter presents various aspects of memory management and memory access. Although the runtime takes much of the responsibility for memory management away from the programmer, it is useful to understand how memory management works and important to know how to work with unmanaged resources efficiently.

A good understanding of memory management and knowledge of the pointer capabilities provided by C# will better enable you to integrate C# code with legacy code and perform efficient memory manipulation in performance-critical systems.

MEMORY MANAGEMENT UNDER THE HOOD

One of the advantages of C# programming is that the programmer does not need to worry about detailed memory management; the garbage collector deals with the problem of memory cleanup on your behalf. The result is that you get something that approximates the efficiency of languages such as C++ without the complexity of having to handle memory management yourself as you do in C++. However, although you do not have to manage memory manually, it still pays to understand what is going on behind the scenes. Understanding how your program manages memory under the covers will only help you increase the speed and performance of your applications. This section looks at what happens in the computer's memory when you allocate variables.

Value Data Types

Windows uses a system known as *virtual addressing*, in which the mapping from the memory address seen by your program to the actual location in hardware memory is entirely managed by Windows. The result of this is that each process on a 32-bit processor sees 4GB of available memory, regardless of how much hardware memory you actually have in your computer (on 64-bit processors this number will be greater). This 4GB of memory contains everything that is part of the program, including the executable code, any DLLs loaded by the code, and the contents of all variables used when the program runs. This 4GB of memory is known as the *virtual address space* or *virtual memory*. For convenience, in this chapter, we call it simply *memory*.

Each memory location in the available 4GB is numbered starting from zero. To access a value stored at a particular location in memory, you need to supply the number that represents that memory location. In any compiled high-level language, including C#, Visual Basic, C++, and Java, the compiler converts human-readable variable names into memory addresses that the processor understands.

Somewhere inside a processor's virtual memory is an area known as the *stack*. The stack stores value data types that are not members of objects. In addition, when you call a method, the stack is used to hold a copy of any parameters passed to the method. To understand how the stack works, you need to understand the importance of variable scope in C#. If variable `a` goes into scope before variable `b`, then `b` will always go out of scope first. Look at this code:

```
{
   int a;
   // do something
   {
      int b;
      // do something else
   }
}
```

First, `a` gets declared. Then, inside the inner code block, `b` gets declared. Then the inner code block terminates and `b` goes out of scope, then `a` goes out of scope. So, the lifetime of `b` is entirely contained within the lifetime of `a`. The idea that you always deallocate variables in the reverse order to how you allocate them is crucial to the way the stack works.

You will also notice that `b` is in a different block of code (defined by a different nesting of curly braces). For this reason, it is contained within a different scope. This is termed as *block scope* or *structure scope*.

You do not know exactly where in the address space the stack is — you don't need to know for C# development. A *stack pointer* (a variable maintained by the operating system) identifies the next free location on the stack. When your program first starts running, the stack pointer will point to just past the end of the block of memory that is reserved for the stack. The stack actually fills downward, from high memory addresses to low addresses. As data is put on the stack, the stack pointer is adjusted accordingly, so it always points to just past the next free location. This is illustrated in Figure 13-1, which shows a stack pointer with a value of `800000` (`0xC3500` in hex); the next free location is the address `799999`.

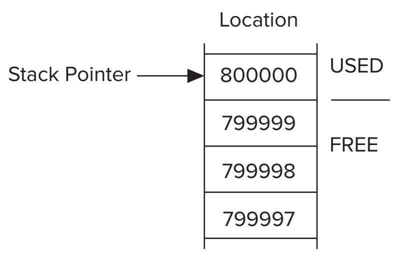

FIGURE 13-1

The following code instructs the compiler that you need space in memory to store an integer and a double, and these memory locations are referred to as nRacingCars and engineSize. The line that declares each variable indicates the point at which you will start requiring access to this variable. The closing curly brace of the block in which the variables are declared identifies the point at which both variables go out of scope:

```
{
   int nRacingCars = 10;
   double engineSize = 3000.0;
   // do calculations;
}
```

Assuming that you use the stack shown in Figure 13-1, when the variable nRacingCars comes into scope and is assigned the value 10, the value 10 is placed in locations 799996 through 799999, the 4 bytes just below the location pointed to by the stack pointer (four bytes because that's how much memory is needed to store an int.) To accommodate this, 4 is subtracted from the value of the stack pointer, so it now points to the location 799996, just after the new first free location (799995).

The next line of code declares the variable engineSize (a double) and initializes it to the value 3000.0. A double occupies 8 bytes, so the value 3000.0 is placed in locations 799988 through 799995 on the stack, and the stack pointer is decremented by 8, so that once again, it points to the location just after the next free location on the stack.

When engineSize goes out of scope, the computer knows that it is no longer needed. Because of the way variable lifetimes are always nested, you can guarantee that, whatever happened while engineSize was in scope, the stack pointer is now pointing to the location where engineSize is stored. To remove engineSize from the stack, the stack pointer is incremented by 8 and it now points to the location immediately after the end of engineSize. At this point in the code, you are at the closing curly brace, so nRacingCars also goes out of scope. The stack pointer is incremented by 4. When another variable comes into scope after engineSize and nRacingCars have been removed from the stack, it overwrites the memory descending from location 799999, where nRacingCars was stored.

If the compiler hits a line such as int i, j, then the order of variables coming into scope looks indeterminate. Both variables are declared at the same time and go out of scope at the same time. In this situation, it does not matter in what order the two variables are removed from memory. The compiler internally always ensures that the one that was put in memory first is removed last, thus preserving the rule about no crossover of variable lifetimes.

Reference Data Types

Although the stack gives very high performance, it is not flexible enough to be used for all variables. The requirement that the lifetimes of variables must be nested is too restrictive for many purposes. Often, you need to use a method to allocate memory for storing data and keeping that data available long after that method has exited. This possibility exists whenever storage space is requested with the new operator — as is the case for all reference types. That is where the *managed heap* comes in.

If you have done any C++ coding that required low-level memory management, you are familiar with the heap. The managed heap is not quite the same as the heap C++ uses; the managed heap works under the control of the garbage collector and provides significant benefits when compared to traditional heaps.

The managed heap (or heap for short) is just another area of memory from the processor's available 4GB. The following code demonstrates how the heap works and how memory is allocated for reference data types:

```
void DoWork()
{
   Customer arabel;
   arabel = new Customer();
   Customer otherCustomer2 = new EnhancedCustomer();
}
```

This code assumes the existence of two classes, `Customer` and `EnhancedCustomer`. The `EnhancedCustomer` class extends the `Customer` class.

First, you declare a `Customer` reference called `arabel`. The space for this is allocated on the stack, but remember that this is only a reference, not an actual `Customer` object. The `arabel` reference takes up 4 bytes, enough space to hold the address at which a `Customer` object will be stored. (You need 4 bytes to represent a memory address as an integer value between 0 and 4GB.)

The next line,

```
arabel = new Customer();
```

does several things. First, it allocates memory on the heap to store a `Customer` object (a real object, not just an address). Then it sets the value of the variable `arabel` to the address of the memory it has allocated to the new `Customer` object. (It also calls the appropriate `Customer()` constructor to initialize the fields in the class instance, but we won't worry about that here.)

The `Customer` instance is not placed on the stack — it is placed on the heap. In this example, you don't know precisely how many bytes a `Customer` object occupies, but assume for the sake of argument that it is 32. These 32 bytes contain the instance fields of `Customer` as well as some information that .NET uses to identify and manage its class instances.

To find a storage location on the heap for the new `Customer` object, the .NET runtime looks through the heap and grabs the first adjacent, unused block of 32 bytes. Again for the sake of argument, assume that this happens to be at address `200000`, and that the `arabel` reference occupied locations `799996` through `799999` on the stack. This means that before instantiating the `arabel` object, the memory content will look similar to Figure 13-2.

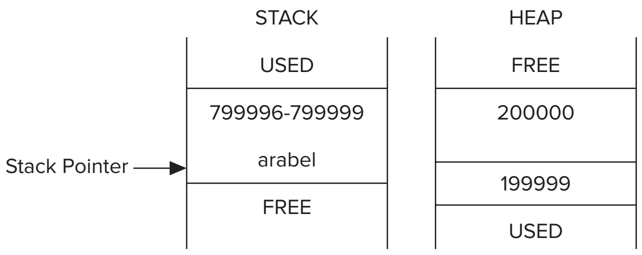

FIGURE 13-2

After allocating the new `Customer` object, the content of memory will look like Figure 13-3. Note that unlike the stack, memory in the heap is allocated upward, so the free space can be found above the used space.

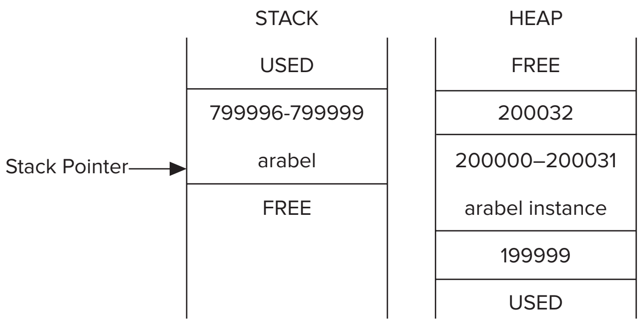

FIGURE 13-3

The next line of code both declares a `Customer` reference and instantiates a `Customer` object. In this instance, space on the stack for the `otherCustomer2` reference is allocated and space for the `mrJones` object is allocated on the heap in a single line of code:

```
Customer otherCustomer2 = new EnhancedCustomer();
```

This line allocates 4 bytes on the stack to hold the `otherCustomer2` reference, stored at locations `799992` through `799995`. The `otherCustomer2` object is allocated space on the heap starting at location `200032`.

It is clear from the example that the process of setting up a reference variable is more complex than that for setting up a value variable, and there is a performance overhead. In fact, the process is somewhat oversimplified here, because the .NET runtime needs to maintain information about the state of the heap, and this information needs to be updated whenever new data is added to the heap. Despite this overhead, you now have a mechanism for allocating variables that is not constrained by the limitations of the stack. By assigning the value of one reference variable to another of the same type, you have two variables that reference the same object in memory. When a reference variable goes out of scope, it is removed from the stack as described in the previous section, but the data for a referenced object is still sitting on the heap. The data will remain on the heap until either the program terminates or the garbage collector removes it, which will happen only when it is no longer referenced by any variables.

That is the power of reference data types, and you will see this feature used extensively in C# code. It means that you have a high degree of control over the lifetime of your data, because it is guaranteed to exist in the heap as long as you are maintaining some reference to it.

Garbage Collection

The previous discussion and diagrams show the managed heap working very much like the stack, to the extent that successive objects are placed next to each other in memory. This means that you can work out where to place the next object by using a heap pointer that indicates the next free memory location, and that is adjusted as you add more objects to the heap. However, things are complicated because the lives of the heap-based objects are not coupled to the scope of the individual stack-based variables that reference them.

When the garbage collector runs, it removes all those objects from the heap that are no longer referenced. Immediately after it has done this, the heap will have objects scattered on it, mixed up with memory that has just been freed (see Figure 13-4).

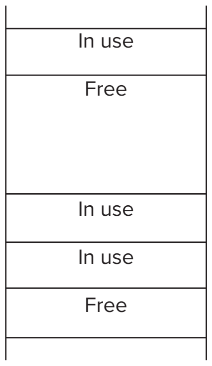

FIGURE 13-4

If the managed heap stayed like this, allocating space for new objects would be an awkward process, with the runtime having to search through the heap for a block of memory big enough to store each new object. However, the garbage collector does not leave the heap in this state. As soon as the garbage collector has freed up all the objects it can, it compacts the heap by moving all remaining objects to form one continuous block of memory. This means that the heap can continue working just like the stack, as far as locating where to store new objects. Of course, when the objects are moved about, all the references to those objects need to be updated with the correct new addresses, but the garbage collector handles that too.

This action of compacting by the garbage collector is where the managed heap really works differently from old, unmanaged heaps. With the managed heap, it is just a question of reading the value of the heap pointer, rather than iterating through a linked list of addresses to find somewhere to put the new data. For this reason, instantiating an object under .NET is much faster. Interestingly, accessing objects tends to be faster too, because the objects are compacted toward the same area of memory on the heap, resulting in less page swapping. Microsoft believes that these performance gains more than compensate for the performance penalty that you get whenever the garbage collector needs to do some work to compact the heap and change all those references to objects it has moved.

Generally, the garbage collector runs when the .NET runtime determines that garbage collection is required. You can force the garbage collector to run at a certain point in your code by calling `System.GC.Collect()`*. The* `System.GC` *class is a .NET class that represents the garbage collector, and the* `Collect()` *method initiates a garbage collection. The* `GC` *class is intended for rare situations in which you know that it's a good time to call the garbage collector; for example, if you have just de-referenced a large number of objects in your code. However, the logic of the garbage collector does not guarantee that all unreferenced objects will be removed from the heap in a single garbage collection pass.*

When the garbage collector runs, it actually hurts the performance of your application as it is impossible for your application to continue running while the garbage collector finishes its tasks. Use the .NET garbage collector to make this less of a problem, as it is a *generational garbage collector.*

When objects are created, they are placed within the managed heap. The first section of the heap is called the generation 0 section or gen 0. As your new objects are created, they are moved into this section of the heap. Therefore, this is where the youngest objects reside.

Your objects are there until the first collection of objects occurs through the garbage collection process. The objects that remain alive after this cleansing are compacted and then moved to the next section or generational part of the heap — the generation 1 or gen 1 section.

At this point, the generation 0 section is empty, and all new objects are again placed in this section. Older objects that survived the GC (garbage collection) process are found further down in the generation 1 section. This movement of aged items actually occurs one more time. The next collection process that occurs is then repeated. This means that the items that survived the GC process from the generation 1 section are moved to the generation 2 section, and the gen 0 items go to gen 1, again leaving gen 0 open for new objects.

It is interesting to note that a garbage collection will occur when you allocate an item that exceeds the capacity of the generation 0 section or when a `GC.Collect()` *is called.*

This process greatly improves the performance of your application. It is generally observed that your youngest objects are usually the ones that can be collected and that there are a large number of younger-related objects that might be reclaimed as well. If these objects reside next to each other in the heap, then the garbage collection process will be faster. In addition, the fact that related objects are residing next to each other will also make program execution faster all around.

Another area in the performance realm of garbage collection in .NET is in how the framework deals with larger objects that go onto the heap. Under the covers of .NET, larger objects have their own managed heap, referred to as the Large Object Heap. When objects greater than 85,000 bytes are utilized, they go to this special heap rather than the main heap. Your .NET application doesn't know the difference, as this is all managed for you. The reason for this is that compressing large items in the heap is expensive and therefore isn't done for the objects residing in the Large Object Heap.

FREEING UNMANAGED RESOURCES

The presence of the garbage collector means that you will usually not worry about objects that you no longer need; you will simply allow all references to those objects to go out of scope and allow the garbage collector to free memory as required. However, the garbage collector does not know how to free unmanaged resources (such as file handles, network connections, and database connections). When managed classes encapsulate direct or indirect references to unmanaged resources, you need to make special provisions to ensure that the unmanaged resources are released when an instance of the class is garbage collected.

When defining a class, you can use two mechanisms to automate the freeing of unmanaged resources. These mechanisms are often implemented together because each provides a slightly different approach to the solution of the problem. The mechanisms are:

- Declaring a *destructor* (or finalizer) as a member of your class
- Implementing the `System.IDisposable` interface in your class

The following sections discuss each of these mechanisms in turn, and then look at how to implement them together for best effect.

Destructors

You have seen that constructors allow you to specify actions that must take place whenever an instance of a class is created. Conversely, destructors are called before an object is destroyed by the garbage collector. Given this behavior, a destructor would initially seem like a great place to put code to free unmanaged resources and perform a general cleanup. Unfortunately, things are not so straightforward.

Although we talk about destructors *in C#, in the underlying .NET architecture these are known as* finalizers. *When you define a destructor in C#, what is emitted into the assembly by the compiler is actually a* `Finalize()` *method. It doesn't affect any of your source code, but you need to be aware of it when examining the content of an assembly.*

The syntax for a destructor will be familiar to C++ developers. It looks like a method, with the same name as the containing class, but prefixed with a tilde (~). It has no return type, and takes no parameters and no access modifiers. Here is an example:

```
class MyClass
{
   ~MyClass()
   {
      // destructor implementation
   }
}
```

When the C# compiler compiles a destructor, it implicitly translates the destructor code to the equivalent of a `Finalize()` method, which ensures that the `Finalize()` method of the parent class is executed. The following example shows the C# code equivalent to the Intermediate Language (IL) that the compiler would generate for the `~MyClass` destructor:

```
protected override void Finalize()
{
   try
   {
      // destructor implementation
   }
   finally
   {
      base.Finalize();
   }
}
```

As shown, the code implemented in the ~MyClass destructor is wrapped in a try block contained in the Finalize() method. A call to the parent's Finalize() method is ensured by placing the call in a finally block. We discuss try and finally blocks in Chapter 15, "Errors and Exceptions."

Experienced C++ developers make extensive use of destructors, sometimes not only to clean up resources but also to provide debugging information or perform other tasks. C# destructors are used far less than their C++ equivalents. The problem with C# destructors as compared to their C++ counterparts is that they are nondeterministic. When a C++ object is destroyed, its destructor runs immediately. However, because of the way the garbage collector works when using C#, there is no way to know when an object's destructor will actually execute. Hence, you cannot place any code in the destructor that relies on being run at a certain time, and you should not rely on the destructor being called for different class instances in any particular order. When your object is holding scarce and critical resources that need to be freed as soon as possible, you do not want to wait for garbage collection.

Another problem with C# destructors is that the implementation of a destructor delays the final removal of an object from memory. Objects that do not have a destructor are removed from memory in one pass of the garbage collector, but objects that have destructors require two passes to be destroyed: The first pass calls the destructor without removing the object, and the second pass actually deletes the object. In addition, the runtime uses a single thread to execute the Finalize() methods of all objects. If you use destructors frequently, and use them to execute lengthy cleanup tasks, the impact on performance can be noticeable.

The IDisposable Interface

In C#, the recommended alternative to using a destructor is using the System.IDisposable interface. The IDisposable interface defines a pattern (with language-level support) that provides a deterministic mechanism for freeing unmanaged resources and avoids the garbage collector–related problems inherent with destructors. The IDisposable interface declares a single method named Dispose(), which takes no parameters and returns void. Here is an implementation for MyClass:

```
class MyClass: IDisposable
{
   public void Dispose()
   {
      // implementation
   }
}
```

The implementation of Dispose() should explicitly free all unmanaged resources used directly by an object and call Dispose() on any encapsulated objects that also implement the IDisposable interface. In this way, the Dispose() method provides precise control over when unmanaged resources are freed.

Suppose that you have a class named ResourceGobbler, which relies on the use of some external resource and implements IDisposable. If you want to instantiate an instance of this class, use it, and then dispose of it, you could do it like this:

```
ResourceGobbler theInstance = new ResourceGobbler();

// do your processing

theInstance.Dispose();
```

Unfortunately, this code fails to free the resources consumed by theInstance if an exception occurs during processing, so you should write the code as follows using a try block (which is discussed fully in Chapter 15):

```
ResourceGobbler theInstance = null;

try
{
   theInstance = new ResourceGobbler();
   // do your processing
}
finally
{
   if (theInstance != null)
   {
      theInstance.Dispose();
   }
}
```

This version ensures that `Dispose()` is always called on `theInstance` and that any resources consumed by it are always freed, even if an exception occurs during processing. However, it would make for confusing code if you always had to repeat such a construct. C# offers a syntax that you can use to guarantee that `Dispose()` will automatically be called against an object that implements `IDisposable` when its reference goes out of scope. The syntax to do this involves the `using` keyword — though now in a very different context, which has nothing to do with namespaces. The following code generates IL code equivalent to the `try` block just shown:

```
using (ResourceGobbler theInstance = new ResourceGobbler())
{
   // do your processing
}
```

The `using` statement, followed in brackets by a reference variable declaration and instantiation, will cause that variable to be scoped to the accompanying statement block. In addition, when that variable goes out of scope, its `Dispose()` method will be called automatically, even if an exception occurs. However, if you are already using `try` blocks to catch other exceptions, it is cleaner and avoids additional code indentation if you avoid the `using` statement and simply call `Dispose()` in the `Finally` clause of the existing `try` block.

Implementing IDisposable and a Destructor

The previous sections discussed two alternatives for freeing unmanaged resources used by the classes you create:

- The execution of a destructor is enforced by the runtime but is nondeterministic and places an unacceptable overhead on the runtime because of the way garbage collection works.
- The `IDisposable` interface provides a mechanism that allows users of a class to control when resources are freed but requires discipline to ensure that `Dispose()` is called.

In general, the best approach is to implement both mechanisms to gain the benefits of both while overcoming their limitations. You implement `IDisposable` on the assumption that most programmers will call `Dispose()` correctly, but implement a destructor as a safety mechanism in case `Dispose()` is not called. Here is an example of a dual implementation:

```
using System;

public class ResourceHolder: IDisposable
{

   private bool isDisposed = false;
```

```
      public void Dispose()
      {
         Dispose(true);
         GC.SuppressFinalize(this);
      }

      protected virtual void Dispose(bool disposing)
      {
         if (!isDisposed)
         {
            if (disposing)
            {
               // Cleanup managed objects by calling their
               // Dispose() methods.
            }
            // Cleanup unmanaged objects
         }
         isDisposed = true;
      }

      ~ResourceHolder()
      {
         Dispose (false);
      }

      public void SomeMethod()
      {
         // Ensure object not already disposed before execution of any method
         if(isDisposed)
         {
            throw new ObjectDisposedException("ResourceHolder");
         }

         // method implementation...
      }
   }
```

code snippet ResourceHolder.cs

You can see from this code that there is a second `protected` overload of `Dispose()`, which takes one `bool` parameter — and this is the method that does all the cleaning up. `Dispose(bool)` is called by both the destructor and by `IDisposable.Dispose()`. The point of this approach is to ensure that all cleanup code is in one place.

The parameter passed to `Dispose(bool)` indicates whether `Dispose(bool)` has been invoked by the destructor or by `IDisposable.Dispose()` — `Dispose(bool)` should not be invoked from anywhere else in your code. The idea is this:

- If a consumer calls `IDisposable.Dispose()`, that consumer is indicating that all managed and unmanaged resources associated with that object should be cleaned up.
- If a destructor has been invoked, all resources still need to be cleaned up. However, in this case, you know that the destructor must have been called by the garbage collector and you should not attempt to access other managed objects because you can no longer be certain of their state. In this situation, the best you can do is clean up the known unmanaged resources and hope that any referenced managed objects also have destructors that will perform their own cleaning up.

The `isDisposed` member variable indicates whether the object has already been disposed of and ensures that you do not try to dispose of member variables more than once. It also allows you to test whether an object has been disposed of before executing any instance methods, as shown in `SomeMethod()`. This simplistic approach is not thread-safe and depends on the caller ensuring that only one thread is calling the method concurrently. Requiring a consumer to enforce synchronization is a reasonable assumption and one that is used repeatedly throughout the .NET class libraries (in the `Collection` classes, for example). Threading and synchronization are discussed in Chapter 20, "Threads, Tasks, and Synchronization."

Finally, `IDisposable.Dispose()` contains a call to the method `System.GC.SuppressFinalize()`. `GC` is the class that represents the garbage collector, and the `SuppressFinalize()` method tells the garbage collector that a class no longer needs to have its destructor called. Because your implementation of `Dispose()` has already done all the cleanup required, there's nothing left for the destructor to do. Calling `SuppressFinalize()` means that the garbage collector will treat that object as if it doesn't have a destructor at all.

UNSAFE CODE

As you have just seen, C# is very good at hiding much of the basic memory management from the developer, thanks to the garbage collector and the use of references. However, sometimes you will want direct access to memory. For example, you might want to access a function in an external (non-.NET) DLL that requires a pointer to be passed as a parameter (as many Windows API functions do), or possibly for performance reasons. This section examines the C# facilities that provide direct access to the content of memory.

Accessing Memory Directly with Pointers

Although we are introducing *pointers* as if they were a new topic, in reality pointers are not new at all. You have been using references freely in your code, and a reference is simply a type-safe pointer. You have already seen how variables that represent objects and arrays actually store the memory address of where the corresponding data (the *referent*) is stored. A pointer is simply a variable that stores the address of something else in the same way as a reference. The difference is that C# does not allow you direct access to the address contained in a reference variable. With a reference, the variable is treated syntactically as if it stores the actual content of the referent.

C# references are designed to make the language simpler to use and to prevent you from inadvertently doing something that corrupts the contents of memory. With a pointer, however, the actual memory address is available to you. This gives you a lot of power to perform new kinds of operations. For example, you can add 4 bytes to the address, so that you can examine or even modify whatever data happens to be stored 4 bytes further on in memory.

The two main reasons for using pointers are:

- **Backward compatibility** — Despite all the facilities provided by the .NET runtime, it is still possible to call native Windows API functions, and for some operations this may be the only way to accomplish your task. These API functions are generally written in C and often require pointers as parameters. However, in many cases it is possible to write the `DllImport` declaration in a way that avoids use of pointers; for example, by using the `System.IntPtr` class.
- **Performance** — On those occasions where speed is of the utmost importance, pointers can provide a route to optimized performance. If you know what you are doing, you can ensure that data is accessed or manipulated in the most efficient way. However, be aware that more often than not, there are other areas of your code where you can make the necessary performance improvements without resorting to using pointers. Try using a code profiler to look for the bottlenecks in your code — one comes with Visual Studio.

Low-level memory access comes at a price. The syntax for using pointers is more complex than that for reference types, and pointers are unquestionably more difficult to use correctly. You need good programming skills and an excellent ability to think carefully and logically about what your code is doing to use pointers successfully. If you are not careful, it is very easy to introduce subtle, difficult-to-find bugs into your program when using pointers. For example, it is easy to overwrite other variables, cause stack overflows, access areas of memory that don't store any variables, or even overwrite information about your code that is needed by the .NET runtime, thereby crashing your program.

In addition, if you use pointers your code must be granted a high level of trust by the runtime's code access security mechanism or it will not be allowed to execute. Under the default code access security policy, this is only possible if your code is running on the local machine. If your code must be run from a remote location, such as the Internet, users must grant your code additional permissions for it to work. Unless the users trust you and your code, they are unlikely to grant these permissions. Code access security is discussed more in Chapter 21, "Security."

Despite these issues, pointers remain a very powerful and flexible tool in the writing of efficient code.

Writing Unsafe Code with the unsafe Keyword

As a result of the risks associated with pointers, C# allows the use of pointers only in blocks of code that you have specifically marked for this purpose. The keyword to do this is `unsafe`. You can mark an individual method as being `unsafe` like this:

```
unsafe int GetSomeNumber()
{
   // code that can use pointers
}
```

Any method can be marked as `unsafe`, regardless of what other modifiers have been applied to it (for example, `static` methods or `virtual` methods). In the case of methods, the `unsafe` modifier applies to the method's parameters, allowing you to use pointers as parameters. You can also mark an entire class or struct as `unsafe`, which means that all of its members are assumed unsafe:

```
unsafe class MyClass
{
   // any method in this class can now use pointers
}
```

Similarly, you can mark a member as `unsafe`:

```
class MyClass
{
   unsafe int* pX;   // declaration of a pointer field in a class
}
```

Or you can mark a block of code within a method as `unsafe`:

```
void MyMethod()
{
   // code that doesn't use pointers
   unsafe
   {
      // unsafe code that uses pointers here
   }
   // more 'safe' code that doesn't use pointers
}
```

Note, however, that you cannot mark a local variable by itself as `unsafe`:

```
int MyMethod()
{
   unsafe int *pX;   // WRONG
}
```

If you want to use an unsafe local variable, you need to declare and use it inside a method or block that is unsafe. There is one more step before you can use pointers. The C# compiler rejects unsafe code unless you tell it that your code includes unsafe blocks. The flag to do this is `unsafe`. Hence, to compile a file named `MySource.cs` that contains unsafe blocks (assuming no other compiler options), the command is this:

```
csc /unsafe MySource.cs
```

or this:

```
csc -unsafe MySource.cs
```

If you are using Visual Studio 2005, 2008, or 2010, you will also find the option to compile unsafe code in the Build tab of the project properties window.

Pointer Syntax

After you have marked a block of code as `unsafe`, you can declare a pointer using this syntax:

```
int* pWidth, pHeight;
double* pResult;
byte*[] pFlags;
```

This code declares four variables: `pWidth` and `pHeight` are pointers to integers, `pResult` is a pointer to a `double`, and `pFlags` is an array of pointers to bytes. It is common practice to use the prefix `p` in front of names of pointer variables to indicate that they are pointers. When used in a variable declaration, the symbol `*` indicates that you are declaring a pointer (that is, something that stores the address of a variable of the specified type).

C++ developers should be aware of the syntax difference between C++ and C#. The C# statement `int* pX, pY;` *corresponds to the C++ statement* `int *pX, *pY;`*. In C#, the * symbol is associated with the type rather than the variable name.*

When you have declared variables of pointer types, you can use them in the same way as normal variables, but first you need to learn two more operators:

- `&` means *take the address of*, and converts a value data type to a pointer, for example `int` to `*int`. This operator is known as the *address operator*.
- `*` means *get the content of this address*, and converts a pointer to a value data type (for example, `*float` to `float`). This operator is known as the *indirection operator* (or sometimes as the *dereference operator*).

You will see from these definitions that `&` and `*` have opposite effects.

The following code shows examples of how to use these operators:

```
int x = 10;
int* pX, pY;
pX = &x;
pY = pX;
*pY = 20;
```

You start by declaring an integer, `x`, with the value 10 followed by two pointers to integers, `pX` and `pY`. You then set `pX` to point to `x` (that is, you set the content of `pX` to the address of `x`). Then you assign the value of `pX` to `pY`, so that `pY` also points to `x`. Finally, in the statement `*pY = 20`, you assign the value 20 as the contents of the location pointed to by `pY` — in effect changing `x` to `20` because `pY` happens to point to `x`. Note that there is no particular connection between the variables `pY` and `x`. It is just that at the present time, `pY` happens to point to the memory location at which `x` is held.

To get a better understanding of what is going on, consider that the integer `x` is stored at memory locations `0x12F8C4` through `0x12F8C7` (`1243332` to `1243335` in decimal) on the stack (there are four locations because an `int` occupies 4 bytes). Because the stack allocates memory downward, this means that the variables `pX` will be stored at locations `0x12F8C0` to `0x12F8C3`, and `pY` will end up at locations `0x12F8BC` to `0x12F8BF`. Note that `pX` and `pY` also occupy 4 bytes each. That is not because an `int` occupies 4 bytes. It is because on a 32-bit processor you need 4 bytes to store an address. With these addresses, after executing the previous code, the stack will look like Figure 13-5.

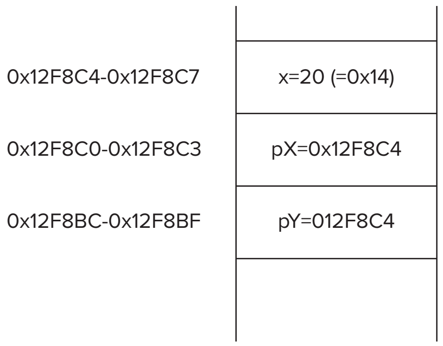

FIGURE 13-5

You can declare a pointer to any value type (that is, any of the predefined types `uint`, `int`, `byte`, and so on, or to a struct). However, it is not possible to declare a pointer to a class or an array; this is because doing so could cause problems for the garbage collector. To work properly, the garbage collector needs to know exactly what class instances have been created on the heap, and where they are, but if your code started manipulating classes using pointers, you could very easily corrupt the information on the heap concerning classes that the .NET runtime maintains for the garbage collector. In this context, any data type that the garbage collector can access is known as a *managed type*. Pointers can only be declared as *unmanaged types* because the garbage collector cannot deal with them.

Casting Pointers to Integer Types

Because a pointer really stores an integer that represents an address, you won't be surprised to know that the address in any pointer can be converted to or from any integer type. Pointer-to-integer-type conversions must be explicit. Implicit conversions are not available for such conversions. For example, it is perfectly legitimate to write the following:

```
int x = 10;
int* pX, pY;
pX = &x;
pY = pX;
*pY = 20;
uint y = (uint)pX;
int* pD = (int*)y;
```

The address held in the pointer `pX` is cast to a `uint` and stored in the variable `y`. You have then cast `y` back to an `int*` and stored it in the new variable `pD`. Hence, now `pD` also points to the value of `x`.

The primary reason for casting a pointer value to an integer type is to display it. The `Console.Write()` and `Console.WriteLine()` methods do not have any overloads that can take pointers, but will accept and display pointer values that have been cast to integer types:

```
Console.WriteLine("Address is " + pX);   // wrong -- will give a
                                         // compilation error
Console.WriteLine("Address is " + (uint)pX);   // OK
```

You can cast a pointer to any of the integer types. However, because an address occupies 4 bytes on 32-bit systems, casting a pointer to anything other than a `uint`, `long`, or `ulong` is almost certain to lead to overflow errors. (An `int` causes problems because its range is from roughly –2 billion to 2 billion, whereas an address runs from zero to about 4 billion.) When C# is released for 64-bit processors, an address will occupy 8 bytes. Hence, on such systems, casting a pointer to anything other than `ulong` is likely to lead to overflow errors. It is also important to be aware that the `checked` keyword does not apply to conversions involving pointers. For such conversions, exceptions will not be raised when overflows occur, even in a `checked` context. The .NET runtime assumes that if you are using pointers you know what you are doing, and are not worried about possible overflows.

Casting Between Pointer Types

You can also explicitly convert between pointers pointing to different types. For example:

```
byte aByte = 8;
byte* pByte= &aByte;
double* pDouble = (double*)pByte;
```

This is perfectly legal code, though again, if you try something like this, be careful. In this example, if you look at the `double` value pointed to by `pDouble`, you will actually be looking up some memory that contains a `byte` (`aByte`), combined with some other memory, and treating it as if this area of memory contained a `double`, which will not give you a meaningful value. However, you might want to convert between types to implement the equivalent of a C `union`, or you might want to cast pointers from other types into pointers to `sbyte` to examine individual bytes of memory.

void Pointers

If you want to maintain a pointer, but do not want to specify what type of data it points to, you can declare it as a pointer to a `void`:

```
int* pointerToInt;
void* pointerToVoid;
pointerToVoid = (void*)pointerToInt;
```

The main use of this is if you need to call an API function that requires `void*` parameters. Within the C# language, there isn't a great deal that you can do using `void` pointers. In particular, the compiler will flag an error if you attempt to dereference a `void` pointer using the `*` operator.

Pointer Arithmetic

It is possible to add or subtract integers to and from pointers. However, the compiler is quite clever about how it arranges this. For example, suppose that you have a pointer to an `int` and you try to add 1 to its value. The compiler will assume that you actually mean you want to look at the memory location following the `int`, and hence it will increase the value by 4 bytes — the size of an `int`. If it is a pointer to a `double`, adding 1 will actually increase the value of the pointer by 8 bytes, the size of a `double`. Only if the pointer points to a `byte` or `sbyte` (1 byte each), will adding 1 to the value of the pointer actually change its value by 1.

You can use the operators `+`, `-`, `+=`, `-=`, `++`, and `--` with pointers, with the variable on the right side of these operators being a `long` or `ulong`.

It is not permitted to carry out arithmetic operations on void pointers.

For example, assume these definitions:

```
uint u = 3;
byte b = 8;
double d = 10.0;
uint* pUint= &u;        // size of a uint is 4
byte* pByte = &b;       // size of a byte is 1
double* pDouble = &d;   // size of a double is 8
```

Next, assume the addresses to which these pointers point are:

- `pUint`: `1243332`
- `pByte`: `1243328`
- `pDouble`: `1243320`

Then execute this code:

```
++pUint;              // adds (1*4) = 4 bytes to pUint
pByte -= 3;           // subtracts (3*1) = 3 bytes from pByte
double* pDouble2 = pDouble + 4; // pDouble2 = pDouble + 32 bytes (4*8 bytes)
```

The pointers now contain this:

- `pUint`: `1243336`
- `pByte`: `1243325`
- `pDouble2`: `1243352`

You need to be aware of the previous rule. If successive values of a given type are stored in successive memory locations, pointer addition works very well, allowing you to move pointers between memory locations. If you are dealing with types such as `byte` *or* `char`*, though, with sizes not in multiples of 4, successive values will not, by default, be stored in successive memory locations.*

You can also subtract one pointer from another pointer, if both pointers point to the same data type. In this case, the result is a `long` whose value is given by the difference between the pointer values divided by the size of the type that they represent:

```
double* pD1 = (double*)1243324;   // note that it is perfectly valid to
                                  // initialize a pointer like this.
double* pD2 = (double*)1243300;
long L = pD1-pD2;                 // gives the result 3 (=24/sizeof(double))
```

The sizeof Operator

This section has been referring to the sizes of various data types. If you need to use the size of a type in your code, you can use the `sizeof` operator, which takes the name of a data type as a parameter and returns the number of bytes occupied by that type. For example:

```
int x = sizeof(double);
```

This will set `x` to the value `8`.

The advantage of using `sizeof` is that you don't have to hard-code data type sizes in your code, making your code more portable. For the predefined data types, `sizeof` returns the following values:

```
sizeof(sbyte) = 1;  sizeof(byte) = 1;
sizeof(short) = 2;  sizeof(ushort) = 2;
sizeof(int) = 4;    sizeof(uint) = 4;
sizeof(long) = 8;   sizeof(ulong) = 8;
sizeof(char) = 2;   sizeof(float) = 4;
sizeof(double) = 8; sizeof(bool) = 1;
```

You can also use `sizeof` for structs that you define yourself, although in that case, the result depends on what fields are in the struct. You cannot use `sizeof` for classes.

Pointers to Structs: The Pointer Member Access Operator

Pointers to structs work in exactly the same way as pointers to the predefined value types. There is, however, one condition — the struct must not contain any reference types. This is due to the restriction mentioned earlier that pointers cannot point to any reference types. To avoid this, the compiler will flag an error if you create a pointer to any struct that contains any reference types.

Suppose that you had a struct defined like this:

```
struct MyStruct
{
   public long X;
   public float F;
}
```

You could define a pointer to it like this:

```
MyStruct* pStruct;
```

Then you could initialize it like this:

```
MyStruct Struct = new MyStruct();
pStruct = &Struct;
```

It is also possible to access member values of a struct through the pointer:

```
(*pStruct).X = 4;
(*pStruct).F = 3.4f;
```

However, this syntax is a bit complex. For this reason, C# defines another operator that allows you to access members of structs through pointers using a simpler syntax. It is known as the *pointer member access operator*, and the symbol is a dash followed by a greater-than sign, so it looks like an arrow: `->`.

C++ developers will recognize the pointer member access operator because C++ uses the same symbol for the same purpose.

Using the pointer member access operator, the previous code can be rewritten:

```
pStruct->X = 4;
pStruct->F = 3.4f;
```

You can also directly set up pointers of the appropriate type to point to fields within a struct:

```
long* pL = &(Struct.X);
float* pF = &(Struct.F);
```

or:

```
long* pL = &(pStruct->X);
float* pF = &(pStruct->F);
```

Pointers to Class Members

As indicated earlier, it is not possible to create pointers to classes. That is because the garbage collector does not maintain any information about pointers, only about references, so creating pointers to classes could cause garbage collection to not work properly.

However, most classes do contain value type members, and you might want to create pointers to them. This is possible but requires a special syntax. For example, suppose that you rewrite the struct from the previous example as a class:

```
class MyClass
{
   public long X;
   public float F;
}
```

Then you might want to create pointers to its fields, `X` and `F`, in the same way as you did earlier. Unfortunately, doing so will produce a compilation error:

```
MyClass myObject = new MyClass();
long* pL = &(myObject.X);   // wrong -- compilation error
float* pF = &(myObject.F);  // wrong -- compilation error
```

Although `X` and `F` are unmanaged types, they are embedded in an object, which sits on the heap. During garbage collection, the garbage collector might move `MyObject` to a new location, which would leave `pL` and `pF` pointing to the wrong memory addresses. Because of this, the compiler will not let you assign addresses of members of managed types to pointers in this manner.

The solution is to use the `fixed` keyword, which tells the garbage collector that there may be pointers referencing members of certain objects, so those objects must not be moved. The syntax for using `fixed` looks like this if you just want to declare one pointer:

```
MyClass myObject = new MyClass();
fixed (long* pObject = &(myObject.X))
{
   // do something
}
```

You define and initialize the pointer variable in the brackets following the keyword `fixed`. This pointer variable (`pObject` in the example) is scoped to the `fixed` block identified by the curly braces. As a result, the garbage collector knows not to move the `myObject` object while the code inside the `fixed` block is executing.

If you want to declare more than one pointer, you can place multiple `fixed` statements before the same code block:

```
MyClass myObject = new MyClass();
fixed (long* pX = &(myObject.X))
fixed (float* pF = &(myObject.F))
{
   // do something
}
```

You can nest entire `fixed` blocks if you want to fix several pointers for different periods:

```
MyClass myObject = new MyClass();
fixed (long* pX = &(myObject.X))
{
   // do something with pX
   fixed (float* pF = &(myObject.F))
   {
      // do something else with pF
   }
}
```

You can also initialize several variables within the same `fixed` block, if they are of the same type:

```
MyClass myObject = new MyClass();
MyClass myObject2 = new MyClass();
fixed (long* pX = &(myObject.X), pX2 = &(myObject2.X))
{
   // etc.
}
```

In all these cases, it is immaterial whether the various pointers you are declaring point to fields in the same or different objects or to static fields not associated with any class instance.

Pointer Example: PointerPlayground

This section presents an example that uses pointers. The following code is an example named `PointerPlayground`. It does some simple pointer manipulation and displays the results, allowing you to see what is happening in memory and where variables are stored:

```
using System;

namespace PointerPlayground
{
   class MainEntryPoint
   {
      static unsafe void Main()
      {
         int x=10;
         short y = -1;
         byte y2 = 4;
         double z = 1.5;
         int* pX = &x;
         short* pY = &y;
         double* pZ = &z;

         Console.WriteLine(
           "Address of x is 0x{0:X}, size is {1}, value is {2}",
           (uint)&x, sizeof(int), x);
         Console.WriteLine(
           "Address of y is 0x{0:X}, size is {1}, value is {2}",
           (uint)&y, sizeof(short), y);
         Console.WriteLine(
           "Address of y2 is 0x{0:X}, size is {1}, value is {2}",
              (uint)&y2, sizeof(byte), y2);
            Console.WriteLine(
              "Address of z is 0x{0:X}, size is {1}, value is {2}",
              (uint)&z, sizeof(double), z);
            Console.WriteLine(
              "Address of pX=&x is 0x{0:X}, size is {1}, value is 0x{2:X}",
              (uint)&pX, sizeof(int*), (uint)pX);
            Console.WriteLine(
              "Address of pY=&y is 0x{0:X}, size is {1}, value is 0x{2:X}",
              (uint)&pY, sizeof(short*), (uint)pY);
            Console.WriteLine(
              "Address of pZ=&z is 0x{0:X}, size is {1}, value is 0x{2:X}",
              (uint)&pZ, sizeof(double*), (uint)pZ);

            *pX = 20;
            Console.WriteLine("After setting *pX, x = {0}", x);
            Console.WriteLine("*pX = {0}", *pX);

            pZ = (double*)pX;
            Console.WriteLine("x treated as a double = {0}", *pZ);

            Console.ReadLine();
         }
      }
   }
```

code snippet PointerPlayground/Program.cs

This code declares four value variables:

- An `int x`
- A `short y`
- A `byte y2`
- A `double z`

It also declares pointers to three of these values: `pX`, `pY`, and `pZ`.

Next, you display the values of these variables as well as their sizes and addresses. Note that in taking the address of `pX`, `pY`, and `pZ`, you are effectively looking at a pointer *to* a pointer — an address of an address of a value. Notice that, in accordance with the usual practice when displaying addresses, you have used the `{0:X}` format specifier in the `Console.WriteLine()` commands to ensure that memory addresses are displayed in hexadecimal format.

Finally, you use the pointer `pX` to change the value of `x` to `20` and do some pointer casting to see what happens if you try to treat the content of `x` as if it were a `double`.

Compiling and running this code results in the following output. This screen output demonstrates the effects of attempting to compile both with and without the `/unsafe` flag:

```
csc PointerPlayground.cs
Microsoft (R) Visual C# 2010 Compiler version 4.0.21006.1
Copyright (C) Microsoft Corporation. All rights reserved.

PointerPlayground.cs(7,26): error CS0227: Unsafe code may only appear if
        compiling with /unsafe

csc /unsafe PointerPlayground.cs
Microsoft (R) Visual C# 2010 Compiler version 4.0.21006.1
Copyright (C) Microsoft Corporation. All rights reserved.

PointerPlayground
```

```
Address of x is 0x12F4B0, size is 4, value is 10
Address of y is 0x12F4AC, size is 2, value is -1
Address of y2 is 0x12F4A8, size is 1, value is 4
Address of z is 0x12F4A0, size is 8, value is 1.5
Address of pX=&x is 0x12F49C, size is 4, value is 0x12F4B0
Address of pY=&y is 0x12F498, size is 4, value is 0x12F4AC
Address of pZ=&z is 0x12F494, size is 4, value is 0x12F4A0
After setting *pX, x = 20
*pX = 20
x treated as a double = 2.86965129997082E-308
```

Checking through these results confirms the description of how the stack operates presented in the "Memory Management Under the Hood" section earlier in this chapter. It allocates successive variables moving downward in memory. Notice how it also confirms that blocks of memory on the stack are always allocated in multiples of 4 bytes. For example, `y` is a `short` (of size 2), and has the (decimal) address `1242284`, indicating that the memory locations reserved for it are locations `1242284` through `1242287`. If the .NET runtime had been strictly packing up variables next to each other, `Y` would have occupied just two locations, `1242284` and `1242285`.

The next example illustrates pointer arithmetic, as well as pointers to structs and class members. This example is named `PointerPlayground2`. To start, you define a struct named `CurrencyStruct`, which represents a currency value as dollars and cents. You also define an equivalent class named `CurrencyClass`:

```
internal struct CurrencyStruct
{
   public long Dollars;
   public byte Cents;

   public override string ToString()
   {
      return "$" + Dollars + "." + Cents;
   }
}

internal class CurrencyClass
{
   public long Dollars;
   public byte Cents;

   public override string ToString()
   {
      return "$" + Dollars + "." + Cents;
   }
}
```

code download PointerPlayground.sln

Now that you have your struct and class defined, you can apply some pointers to them. Following is the code for the new example. Because the code is fairly long, we will go through it in detail. You start by displaying the size of `CurrencyStruct`, creating a couple of `CurrencyStruct` instances and creating some `CurrencyStruct` pointers. You use the `pAmount` pointer to initialize the members of the `amount1` `CurrencyStruct` and then display the addresses of your variables:

```
public static unsafe void Main()
{
   Console.WriteLine(
      "Size of CurrencyStruct struct is " + sizeof(CurrencyStruct));
   CurrencyStruct amount1, amount2;
   CurrencyStruct* pAmount = &amount1;
   long* pDollars = &(pAmount->Dollars);
   byte* pCents = &(pAmount->Cents);
```

```
Console.WriteLine("Address of amount1 is 0x{0:X}", (uint)&amount1);
Console.WriteLine("Address of amount2 is 0x{0:X}", (uint)&amount2);
Console.WriteLine("Address of pAmount is 0x{0:X}", (uint)&pAmount);
Console.WriteLine("Address of pDollars is 0x{0:X}", (uint)&pDollars);
Console.WriteLine("Address of pCents is 0x{0:X}", (uint)&pCents);
pAmount->Dollars = 20;
*pCents = 50;
Console.WriteLine("amount1 contains " + amount1);
```

Now you do some pointer manipulation that relies on your knowledge of how the stack works. Due to the order in which the variables were declared, you know that `amount2` will be stored at an address immediately below `amount1`. The `sizeof(CurrencyStruct)` operator returns 16 (as demonstrated in the screen output coming up), so `CurrencyStruct` occupies a multiple of 4 bytes. Therefore, after you decrement your currency pointer, it will point to `amount2`:

```
--pAmount;   // this should get it to point to amount2
Console.WriteLine("amount2 has address 0x{0:X} and contains {1}",
   (uint)pAmount, *pAmount);
```

Notice that when you call `Console.WriteLine()`, you display the contents of `amount2`, but you haven't yet initialized it. What gets displayed will be random garbage — whatever happened to be stored at that location in memory before execution of the example. There is an important point here: Normally, the C# compiler would prevent you from using an uninitialized variable, but when you start using pointers, it is very easy to circumvent many of the usual compilation checks. In this case, you have done so because the compiler has no way of knowing that you are actually displaying the contents of `amount2`. Only you know that, because your knowledge of the stack means that you can tell what the effect of decrementing `pAmount` will be. Once you start doing pointer arithmetic, you will find that you can access all sorts of variables and memory locations that the compiler would usually stop you from accessing, hence the description of pointer arithmetic as unsafe.

Next, you do some pointer arithmetic on your `pCents` pointer. `pCents` currently points to `amount1.Cents`, but the aim here is to get it to point to `amount2.Cents`, again using pointer operations instead of directly telling the compiler that's what you want to do. To do this, you need to decrement the address `pCents` contains by `sizeof(Currency)`:

```
// do some clever casting to get pCents to point to cents
// inside amount2
CurrencyStruct* pTempCurrency = (CurrencyStruct*)pCents;
pCents = (byte*) ( --pTempCurrency );
Console.WriteLine("Address of pCents is now 0x{0:X}", (uint)&pCents);
```

Finally, you use the `fixed` keyword to create some pointers that point to the fields in a class instance and use these pointers to set the value of this instance. Notice that this is also the first time that you have been able to look at the address of an item stored on the heap rather than the stack:

```
Console.WriteLine("\nNow with classes");
// now try it out with classes
CurrencyClass amount3 = new CurrencyClass();

fixed(long* pDollars2 = &(amount3.Dollars))
fixed(byte* pCents2 = &(amount3.Cents))
{
   Console.WriteLine(
      "amount3.Dollars has address 0x{0:X}", (uint)pDollars2);
   Console.WriteLine(
      "amount3.Cents has address 0x{0:X}", (uint) pCents2);
   *pDollars2 = -100;
   Console.WriteLine("amount3 contains " + amount3);
}
```

Compiling and running this code gives output similar to this:

```
csc /unsafe PointerPlayground2.cs
Microsoft (R) Visual C# 2010 Compiler version 4.0.21006.1
Copyright (C) Microsoft Corporation. All rights reserved.

PointerPlayground2
Size of CurrencyStruct struct is 16
Address of amount1 is 0x12F4A4
Address of amount2 is 0x12F494
Address of pAmount is 0x12F490
Address of pDollars is 0x12F48C
Address of pCents is 0x12F488
amount1 contains $20.50
amount2 has address 0x12F494 and contains $0.0
Address of pCents is now 0x12F488

Now with classes
amount3.Dollars has address 0xA64414
amount3.Cents has address 0xA6441C
amount3 contains $-100.0
```

Notice in this output the uninitialized value of `amount2` that is displayed, and notice that the size of the `CurrencyStruct` struct is `16` — somewhat larger than you would expect given the size of its fields (a `long` and a `byte` should total 9 bytes).

Using Pointers to Optimize Performance

Until now, all the examples have been designed to demonstrate the various things that you can do with pointers. We have played around with memory in a way that is probably interesting only to people who like to know what's happening under the hood, but that doesn't really help you write better code. Now you're going to apply your understanding of pointers and see an example of how judicious use of pointers has a significant performance benefit.

Creating Stack-Based Arrays

This section explores one of the main areas in which pointers can be useful: creating high-performance, low-overhead arrays on the stack. As discussed in Chapter 2, "Core C#," C# includes rich support for handling arrays. Although C# makes it very easy to use both 1-dimensional and rectangular or jagged multidimensional arrays, it suffers from the disadvantage that these arrays are actually objects; they are instances of `System.Array`. This means that the arrays are stored on the heap with all the overhead that this involves. There may be occasions when you need to create a short-lived, high-performance array and don't want the overhead of reference objects. You can do this by using pointers, although as you see in this section, this is easy only for 1-dimensional arrays.

To create a high-performance array, you need to use a new keyword: `stackalloc`. The `stackalloc` command instructs the .NET runtime to allocate an amount of memory on the stack. When you call `stackalloc`, you need to supply it with two pieces of information:

- The type of data you want to store
- The number of these data items you need to store

For example, to allocate enough memory to store 10 `decimal` data items, you can write:

```
decimal* pDecimals = stackalloc decimal[10];
```

This command simply allocates the stack memory; it does not attempt to initialize the memory to any default value. This is fine for the purpose of this example because you are creating a high-performance array, and initializing values unnecessarily would hurt performance.

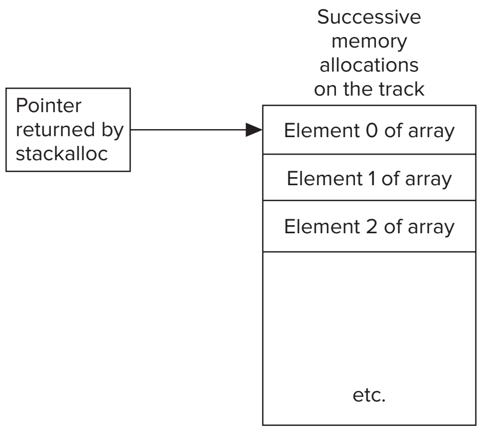
Similarly, to store 20 `double` data items, you write this:

```
double* pDoubles = stackalloc double[20];
```

Although this line of code specifies the number of variables to store as a constant, this can equally be a quantity evaluated at runtime. So, you can write the previous example like this:

```
int size;
size = 20;   // or some other value calculated at run-time
double* pDoubles = stackalloc double[size];
```

You can see from these code snippets that the syntax of `stackalloc` is slightly unusual. It is followed immediately by the name of the data type you want to store (and this must be a value type) and then by the number of items you need space for in square brackets. The number of bytes allocated will be this number multiplied by `sizeof(`data type`)`. The use of square brackets in the preceding code sample suggests an array, which is not too surprising. If you have allocated space for 20 doubles, then what you have is an array of 20 doubles. The simplest type of array that you can have is a block of memory that stores one element after another (see Figure 13-6).



Successive memory allocations on the track
Pointer returned by stackalloc
Element 0 of array
Element 1 of array
Element 2 of array
etc.

FIGURE 13-6

This diagram also shows the pointer returned by `stackalloc`, which is always a pointer to the allocated data type that points to the top of the newly allocated memory block. To use the memory block, you simply dereference the returned pointer. For example, to allocate space for 20 doubles and then set the first element (element 0 of the array) to the value `3.0`, write this:

```
double* pDoubles = stackalloc double [20];
*pDoubles = 3.0;
```

To access the next element of the array, you use pointer arithmetic. As described earlier, if you add 1 to a pointer, its value will be increased by the size of whatever data type it points to. In this case, this will be just enough to take you to the next free memory location in the block that you have allocated. So, you can set the second element of the array (element number `1`) to the value `8.4` like this:

```
double* pDoubles = stackalloc double [20];
*pDoubles = 3.0;
*(pDoubles+1) = 8.4;
```

By the same reasoning, you can access the element with index `X` of the array with the expression `*(pDoubles+X)`.

Effectively, you have a means by which you can access elements of your array, but for general-purpose use, this syntax is too complex. Fortunately, C# defines an alternative syntax using square brackets. C# gives a very precise meaning to square brackets when they are applied to pointers; if the variable `p` is any pointer type and `X` is an integer, then the expression `p[X]` is always interpreted by the compiler as meaning `*(p+X)`. This is true for all pointers, not only those initialized using `stackalloc`. With this shorthand notation, you now have a very convenient syntax for accessing your array. In fact, it means that you have exactly the same syntax for accessing 1-dimensional stack-based arrays as you do for accessing heap-based arrays that are represented by the `System.Array` class:

```
double* pDoubles = stackalloc double [20];
pDoubles[0] = 3.0;   // pDoubles[0] is the same as *pDoubles
pDoubles[1] = 8.4;   // pDoubles[1] is the same as *(pDoubles+1)
```

This idea of applying array syntax to pointers is not new. It has been a fundamental part of both the C and the C++ languages ever since those languages were invented. Indeed, C++ developers will recognize the stack-based arrays they can obtain using `stackalloc` *as being essentially identical to classic stack-based C and C++ arrays. This syntax and the way it links pointers and arrays is one reason why the C language became popular in the 1970s, and the main reason why the use of pointers became such a popular programming technique in C and C++.*

Although your high-performance array can be accessed in the same way as a normal C# array, a word of caution is in order. The following code in C# raises an exception:

```
double[] myDoubleArray = new double [20];
myDoubleArray[50] = 3.0;
```

The exception occurs because you are trying to access an array using an index that is out of bounds; the index is `50`, whereas the maximum allowed value is `19`. However, if you declare the equivalent array using `stackalloc`, there is no object wrapped around the array that can perform bounds checking. Hence, the following code will *not* raise an exception:

```
double* pDoubles = stackalloc double [20];
pDoubles[50] = 3.0;
```

In this code, you allocate enough memory to hold 20 doubles. Then you set `sizeof(double)` memory locations, starting at the location given by the start of this memory + `50*sizeof(double)` to hold the double value `3.0`. Unfortunately, that memory location is way outside the area of memory that you have allocated for the doubles. There is no knowing what data might be stored at that address. At best, you may have used some currently unused memory, but it is equally possible that you may have just overwritten some locations in the stack that were being used to store other variables or even the return address from the method currently being executed. Once again, you see that the high performance to be gained from pointers comes at a cost; you need to be certain you know what you are doing, or you will get some very strange runtime bugs.

QuickArray Example

Our discussion of pointers ends with a `stackalloc` example called `QuickArray`. In this example, the program simply asks users how many elements they want to be allocated for an array. The code then uses `stackalloc` to allocate an array of `long`s that size. The elements of this array are populated with the squares of the integers starting with `0` and the results are displayed on the console:

```
using System;

namespace QuickArray
{
    internal class Program
    {
        private static unsafe void Main()
        {
            Console.Write("How big an array do you want? \n> ");
            string userInput = Console.ReadLine();
            uint size = uint.Parse(userInput);

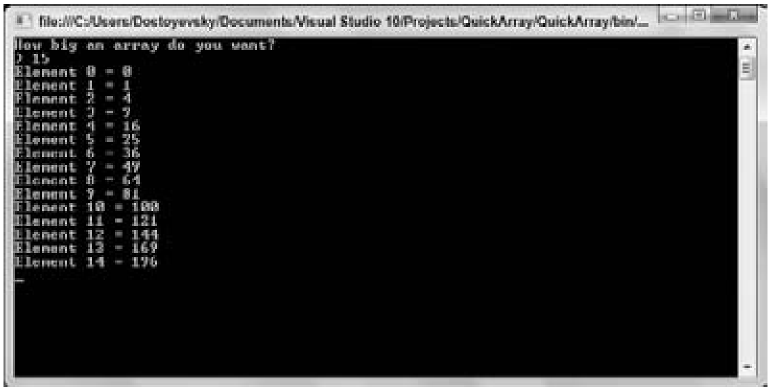
            long* pArray = stackalloc long[(int) size];
            for (int i = 0; i < size; i++)
            {
                pArray[i] = i*i;
            }

            for (int i = 0; i < size; i++)
```

```
                {
                   Console.WriteLine("Element {0} = {1}", i, *(pArray + i));
                }

                Console.ReadLine();
            }
        }
    }
```

The output from the `QuickArray` example is illustrated in Figure 13-7.



```
file:///C:/Users/Dostoyevsky/Documents/Visual Studio 10/Projects/QuickArray/QuickArray/bin/...
How big an array do you want?
> 15
Element 0 = 0
Element 1 = 1
Element 2 = 4
Element 3 = 9
Element 4 = 16
Element 5 = 25
Element 6 = 36
Element 7 = 49
Element 8 = 64
Element 9 = 81
Element 10 = 100
Element 11 = 121
Element 12 = 144
Element 13 = 169
Element 14 = 196
_
```

FIGURE 13-7

SUMMARY

Remember, to become a truly proficient C# programmer, you must have a solid understanding of how memory allocation and garbage collection work. This chapter described how the CLR manages and allocates memory on the heap and the stack. It also illustrated how to write classes that free unmanaged resources correctly, and how to use pointers in C#. These are both advanced topics that are poorly understood and often implemented incorrectly by novice programmers.

This chapter should be treated as a companion to what you learn from Chapter 15 on error handling and in Chapter 20 when dealing with threading. The next chapter of this book looks at reflection in C#.

14

Reflection

WHAT'S IN THIS CHAPTER?

- ➤ Using custom attributes
- ➤ Inspecting the metadata at runtime using reflection
- ➤ Building access points from classes that enable reflection

This chapter focuses on custom attributes and reflection. *Custom attributes* are mechanisms that allow you to associate custom metadata with program elements. This metadata is created at compile time and embedded in an assembly. *Reflection* is a generic term that describes the ability to inspect and manipulate program elements at runtime. For example, reflection allows you to:

- ➤ Enumerate the members of a type
- ➤ Instantiate a new object
- ➤ Execute the members of an object
- ➤ Find out information about a type
- ➤ Find out information about an assembly
- ➤ Inspect the custom attributes applied to a type
- ➤ Create and compile a new assembly

This list represents a great deal of functionality and encompasses some of the most powerful and complex capabilities provided by the .NET Framework class library. Although this chapter does not have the space to cover all the capabilities of reflection, it focuses on those elements that you are likely to use most frequently.

To demonstrate custom attributes and reflection, you develop an example based on a company that regularly ships upgrades of its software and wants to have details of these upgrades documented automatically. In the example, you define custom attributes that indicate the date when program elements were last modified, and what changes were made. You then use reflection to develop an application that looks for these attributes in an assembly, and can automatically display all the details about what upgrades have been made to the software since a given date.

Another example in this chapter considers an application that reads from or writes to a database and uses custom attributes as a way of marking which classes and properties correspond to which database tables and columns. By reading these attributes from the assembly at runtime, the program is able to automatically retrieve or write data to the appropriate location in the database, without requiring specific logic for each table or column.

CUSTOM ATTRIBUTES

From this book, you have seen how you can define attributes on various items within your program. These attributes have been defined by Microsoft as part of the .NET Framework class library, and many of them receive special support from the C# compiler. This means that for those particular attributes, the compiler could customize the compilation process in specific ways; for example, laying out a struct in memory according to the details in the `StructLayout` attributes.

The .NET Framework also allows you to define your own attributes. Clearly, these attributes will not have any effect on the compilation process, because the compiler has no intrinsic awareness of them. However, these attributes will be emitted as metadata in the compiled assembly when they are applied to program elements.

By itself, this metadata might be useful for documentation purposes, but what makes attributes really powerful is that by using reflection, your code can read this metadata and use it to make decisions at runtime. This means that the custom attributes that you define can directly affect how your code runs. For example, custom attributes can be used to enable declarative code access security checks for custom permission classes, to associate information with program elements that can then be used by testing tools, or when developing extensible frameworks that allow the loading of plug-ins or modules.

Writing Custom Attributes

To understand how to write your own custom attributes, it is useful to know what the compiler does when it encounters an element in your code that has a custom attribute applied to it. To take the database example, suppose that you have a C# property declaration that looks like this:

```
[FieldName("SocialSecurityNumber")]
public string SocialSecurityNumber
{
   get {
      // etc.
```

When the C# compiler recognizes that this property has an attribute applied to it (`FieldName`), it will start by appending the string `Attribute` to this name, forming the combined name `FieldNameAttribute`. The compiler will then search all the namespaces in its search path (those namespaces that have been mentioned in a `using` statement) for a class with the specified name. Note that if you mark an item with an attribute whose name already ends in the string `Attribute`, the compiler will not add the string to the name a second time; it will leave the attribute name unchanged. Therefore, the preceding code is equivalent to this:

```
[FieldNameAttribute("SocialSecurityNumber")]
public string SocialSecurityNumber
{
   get {
   // etc.
```

The compiler expects to find a class with this name, and it expects this class to be derived directly or indirectly from `System.Attribute`. The compiler also expects that this class contains information that governs the use of the attribute. In particular, the attribute class needs to specify the following:

➤ The types of program elements to which the attribute can be applied (classes, structs, properties, methods, and so on)

➤ Whether it is legal for the attribute to be applied more than once to the same program element

➤ Whether the attribute, when applied to a class or interface, is inherited by derived classes and interfaces

➤ The mandatory and optional parameters the attribute takes

If the compiler cannot find a corresponding attribute class, or if it finds one but the way that you have used that attribute does not match the information in the attribute class, the compiler will raise a compilation error. For example, if the attribute class indicates that the attribute can be applied only to classes, but you have applied it to a struct definition, a compilation error will occur.

To continue with the example, assume that you have defined the `FieldName` attribute like this:

```
[AttributeUsage(AttributeTargets.Property,
   AllowMultiple=false,
   Inherited=false)]
public class FieldNameAttribute: Attribute
{
   private string name;
   public FieldNameAttribute(string name)
   {
      this.name = name;
   }
}
```

The following sections discuss each element of this definition.

AttributeUsage Attribute

The first thing to note is that the attribute class itself is marked with an attribute — the `System.AttributeUsage` attribute. This is an attribute defined by Microsoft for which the C# compiler provides special support. (You could argue that `AttributeUsage` isn't an attribute at all; it is more like a meta-attribute, because it applies only to other attributes, not simply to any class.) The primary purpose of `AttributeUsage` is to identify the types of program elements to which your custom attribute can be applied. This information is given by the first parameter of the `AttributeUsage` attribute — this parameter is mandatory, and is of an enumerated type, `AttributeTargets`. In the previous example, you have indicated that the `FieldName` attribute can be applied only to properties, which is fine, because that is exactly what you have applied it to in the earlier code fragment. The members of the `AttributeTargets` enumeration are:

- `All`
- `Assembly`
- `Class`
- `Constructor`
- `Delegate`
- `Enum`
- `Event`
- `Field`
- `GenericParameter` (.NET 2.0 and higher only)
- `Interface`
- `Method`
- `Module`
- `Parameter`
- `Property`
- `ReturnValue`
- `Struct`

This list identifies all the program elements to which you can apply attributes. Note that when applying the attribute to a program element, you place the attribute in square brackets immediately before the element. However, two values in the preceding list do not correspond to any program element: `Assembly` and `Module`. An attribute can be applied to an assembly or module as a whole instead of to an element in your code; in this case the attribute can be placed anywhere in your source code, but needs to be prefixed with the `Assembly` or `Module` keyword:

```
[assembly:SomeAssemblyAttribute(Parameters)]
[module:SomeAssemblyAttribute(Parameters)]
```

When indicating the valid target elements of a custom attribute, you can combine these values using the bitwise OR operator. For example, if you want to indicate that your `FieldName` attribute can be applied to both properties and fields, you would write:

```
[AttributeUsage(AttributeTargets.Property | AttributeTargets.Field,
   AllowMultiple=false,
   Inherited=false)]
public class FieldNameAttribute: Attribute
```

You can also use `AttributeTargets.All` to indicate that your attribute can be applied to all types of program elements. The `AttributeUsage` attribute also contains two other parameters, `AllowMultiple` and `Inherited`. These are specified using the syntax of `<ParameterName>=<ParameterValue>`, instead of simply giving the values for these parameters. These parameters are optional — you can omit them if you want.

The `AllowMultiple` parameter indicates whether an attribute can be applied more than once to the same item. The fact that it is set to `false` here indicates that the compiler should raise an error if it sees something like this:

```
[FieldName("SocialSecurityNumber")]
[FieldName("NationalInsuranceNumber")]
public string SocialSecurityNumber
{

   // etc.
```

If the `Inherited` parameter is set to `true`, an attribute applied to a class or interface will also automatically be applied to all derived classes or interfaces. If the attribute is applied to a method or property, it will automatically apply to any overrides of that method or property, and so on.

Specifying Attribute Parameters

This section examines how you can specify the parameters that your custom attribute takes. The way it works is that when the compiler encounters a statement such as the following,

```
[FieldName("SocialSecurityNumber")]
public string SocialSecurityNumber
{

   // etc.
```

the compiler examines the parameters passed into the attribute — which is a string — and looks for a constructor for the attribute that takes exactly those parameters. If the compiler finds an appropriate constructor, the compiler will emit the specified metadata to the assembly. If the compiler does not find an appropriate constructor, a compilation error occurs. As discussed later in this chapter, reflection involves reading metadata (attributes) from assemblies and instantiating the attribute classes they represent. Because of this, the compiler must ensure that an appropriate constructor exists that will allow the runtime instantiation of the specified attribute.

In the example, you have supplied just one constructor for `FieldNameAttribute`, and this constructor takes one string parameter. Therefore, when applying the `FieldName` attribute to a property, you must supply one string as a parameter, as was done in the preceding sample code.

If you want to allow a choice of what types of parameters should be supplied with an attribute, you can provide different constructor overloads, although normal practice is to supply just one constructor and use properties to define any other optional parameters, as explained next.

Specifying Optional Attribute Parameters

As demonstrated with reference to the `AttributeUsage` attribute, an alternative syntax exists by which optional parameters can be added to an attribute. This syntax involves specifying the names and values of the optional parameters. It works through `public` properties or fields in the `attribute` class. For example, suppose that you modified the definition of the `SocialSecurityNumber` property as follows:

```
[FieldName("SocialSecurityNumber", Comment="This is the primary key field")]
public string SocialSecurityNumber
{

   // etc.
```

In this case, the compiler recognizes the `<ParameterName>=<ParameterValue>` syntax of the second parameter and does not attempt to match this parameter to a `FieldNameAttribute` constructor. Instead, it looks for a `public` property or field (although public fields are not considered good programming practice, so normally you will work with properties) of that name that it can use to set the value of this parameter. If you want the previous code to work, you have to add some code to `FieldNameAttribute`:

```
[AttributeUsage(AttributeTargets.Property,
   AllowMultiple=false,
   Inherited=false)]
public class FieldNameAttribute: Attribute
{
   private string comment;
   public string Comment
   {
      get
      {
         return comment;
      }
      set
      {
         comment = value;
      }
   }

      // etc
 }
```

Custom Attribute Example: WhatsNewAttributes

In this section, you start developing the example mentioned at the beginning of the chapter. `WhatsNewAttributes` provides for an attribute that indicates when a program element was last modified. This is a more ambitious code sample than many of the others in that it consists of three separate assemblies:

- The `WhatsNewAttributes` assembly, which contains the definitions of the attributes
- The `VectorClass` assembly, which contains the code to which the attributes have been applied
- The `LookUpWhatsNew` assembly, which contains the project that displays details of items that have changed

Of these, only `LookUpWhatsNew` is a console application of the type that you have used up until now. The remaining two assemblies are libraries — they each contain class definitions but no program entry point. For the `VectorClass` assembly, this means that the entry point and test harness class have been removed from the `VectorAsCollection` sample, leaving only the `Vector` class. These classes are represented later in this chapter.

Managing three related assemblies by compiling at the command line is tricky. Although the commands for compiling all these source files are provided separately, you might prefer to edit the code sample (which you can download from the Wrox web site at www.wrox.com) as a combined Visual Studio solution, as discussed in Chapter 16, "Visual Studio 2010." The download includes the required Visual Studio 2010 solution files.

The WhatsNewAttributes Library Assembly

This section starts with the core WhatsNewAttributes assembly. The source code is contained in the file WhatsNewAttributes.cs, which is located in the WhatsNewAttributes project of the WhatsNewAttributes solution in the example code for this chapter. The syntax for doing this is quite simple. At the command line, you supply the flag target:library to the compiler. To compile WhatsNewAttributes, type the following:

```
csc /target:library WhatsNewAttributes.cs
```

The WhatsNewAttributes.cs file defines two attribute classes, LastModifiedAttribute and SupportsWhatsNewAttribute. The attribute LastModifiedAttribute is the attribute that you can use to mark when an item was last modified. It takes two mandatory parameters (parameters that are passed to the constructor): the date of the modification and a string containing a description of the changes. There is also one optional parameter named issues (for which a public property exists), which can be used to describe any outstanding issues for the item.

In practice, you would probably want this attribute to apply to anything. To keep the code simple, its usage is limited here to classes and methods. You will allow it to be applied more than once to the same item (AllowMultiple=true) because an item might be modified more than once, and each modification will have to be marked with a separate attribute instance.

SupportsWhatsNew is a smaller class representing an attribute that doesn't take any parameters. The idea of this attribute is that it is an assembly attribute that is used to mark an assembly for which you are maintaining documentation via the LastModifiedAttribute. This way, the program that will examine this assembly later on knows that the assembly it is reading is one on which you are actually using your automated documentation process. Here is the complete source code for this part of the example:

```
using System;

namespace WhatsNewAttributes
{
   [AttributeUsage(
      AttributeTargets.Class | AttributeTargets.Method,
      AllowMultiple=true, Inherited=false)]
   public class LastModifiedAttribute: Attribute
   {
        private readonly DateTime _dateModified;
        private readonly string _changes;

        public LastModifiedAttribute(string dateModified, string changes)
        {
            dateModified = DateTime.Parse(dateModified);
            changes = changes;
        }

        public DateTime DateModified
        {
            get { return dateModified; }
        }

        public string Changes
        {
            get { return changes; }
        }

        public string Issues { get; set; }
      }

      [AttributeUsage(AttributeTargets.Assembly)]
      public class SupportsWhatsNewAttribute: Attribute
      {
      }
   }
```

code snippet WhatsNewAttributes.cs

This code should be clear with reference to previous descriptions. Notice, however, that we have not bothered to supply `set` accessors to the `Changes` and `DateModified` properties. There is no need for these accessors because you are requiring these parameters to be set in the constructor as mandatory parameters. You need the `get` accessors so that you can read the values of these attributes.

The VectorClass Assembly

Next, you need to use these attributes. To this end, you use a modified version of the earlier `VectorAsCollection` sample. Note that you need to reference the `WhatsNewAttributes` library that you have just created. You also need to indicate the corresponding namespace with a `using` statement so that the compiler can recognize the attributes:

```
using System;
using System.Collections;
using System.Text;
using WhatsNewAttributes;

[assembly: SupportsWhatsNew]
```

In this code, you have also added the line that will mark the assembly itself with the `SupportsWhatsNew` attribute.

Now for the code for the `Vector` class. You are not making any major changes to this class; you only add a couple of `LastModified` attributes to mark out the work that you have done on this class in this chapter. Then `Vector` is defined as a class instead of a struct to simplify the code (of the next iteration of the sample) that displays the attributes. (In the `VectorAsCollection` sample, `Vector` is a struct, but its enumerator is a class. This means that the next iteration of the sample would have had to pick out both classes and structs when looking at the assembly, which would have made the example less straightforward.)

```
namespace VectorClass
{
   [LastModified("14 Feb 2010", "IEnumerable interface implemented " +
       "So Vector can now be treated as a collection")]
   [LastModified("10 Feb 2010", "IFormattable interface implemented " +
       "So Vector now responds to format specifiers N and VE")]
   class Vector: IFormattable, IEnumerable
   {
      public double x, y, z;

      public Vector(double x, double y, double z)
      {
         this.x = x;
         this.y = y;
         this.z = z;
      }

      [LastModified("10 Feb 2010",
                    "Method added in order to provide formatting support")]
      public string ToString(string format, IFormatProvider formatProvider)
      {
         if (format == null)
         {
            return ToString();
         }
```

You also mark the contained `VectorEnumerator` class as `new`:

```
[LastModified("14 Feb 2010",
              "Class created as part of collection support for Vector")]
private class VectorEnumerator: IEnumerator
{
```

To compile this code from the command line, type the following:

```
csc /target:library /reference:WhatsNewAttributes.dll VectorClass.cs
```

That's as far as you can get with this example for now. You are unable to run anything yet because all you have are two libraries. You will develop the final part of the example, in which you look up and display these attributes, as soon as you have had a look at how reflection works.

USING REFLECTION

In this section, we take a closer look at the `System.Type` class, which lets you access information concerning the definition of any data type. We then discuss the `System.Reflection.Assembly` class, which you can use to access information about an assembly or to load that assembly into your program. Finally, you will combine the code in this section with the code in the previous section to complete the `WhatsNewAttributes` sample.

The System.Type Class

So far you have used the `Type` class only to hold the reference to a type as follows:

```
Type t = typeof(double);
```

Although previously referred to as a class, `Type` is an abstract base class. Whenever you instantiate a `Type` object, you are actually instantiating a class derived from `Type`. `Type` has one derived class corresponding to each actual data type, though in general the derived classes simply provide different overloads of the various `Type` methods and properties that return the correct data for the corresponding data type. They do not generally add new methods or properties. In general, there are three common ways to obtain a `Type` reference that refers to any given type:

1. You can use the C# `typeof` operator as in the preceding code. This operator takes the name of the type (not in quotation marks, however) as a parameter.
2. You can use the `GetType()` method, which all classes inherit from `System.Object`:

   ```
   double d = 10;
   Type t = d.GetType();
   ```

   `GetType()` is called against a variable, rather than taking the name of a type. Note, however, that the `Type` object returned is still associated with only that data type. It does not contain any information that relates to that instance of the type. The `GetType()` method can be useful if you have a reference to an object but are not sure what class that object is actually an instance of.
3. You can call the `static` method of the `Type` class, `GetType()`:

   ```
   Type t = Type.GetType("System.Double");
   ```

`Type` is really the gateway to much of the reflection functionality. It implements a huge number of methods and properties — far too many to provide a comprehensive list here. However, the following subsections should give you some idea of the kinds of things you can do with the `Type` class. Note that the available properties are all read-only; you use `Type` to find out about the data type — you cannot use it to make any modifications to the type!

Type Properties

You can split the properties implemented by `Type` into three categories. First, a number of properties retrieve the strings containing various names associated with the class, as shown in the following table.

PROPERTY	RETURNS
`Name`	The name of the data type
`FullName`	The fully qualified name of the data type (including the namespace name)
`Namespace`	The name of the namespace in which the data type is defined

Second, it is possible to retrieve references to further type objects that represent related classes, as shown in the following table.

PROPERTY	RETURNS TYPE REFERENCE CORRESPONDING TO
`BaseType`	Immediate base type of this type
`UnderlyingSystemType`	The type that this type maps to in the .NET runtime (recall that certain .NET base types actually map to specific predefined types recognized by IL)

A number of Boolean properties indicate whether this type is, for example, a `class`, an `enum`, and so on. These properties include `IsAbstract`, `IsArray`, `IsClass`, `IsEnum`, `IsInterface`, `IsPointer`, `IsPrimitive` (one of the predefined primitive data types), `IsPublic`, `IsSealed`, and `IsValueType`. For example, using a primitive data type:

```
Type intType = typeof(int);
Console.WriteLine(intType.IsAbstract);     // writes false
Console.WriteLine(intType.IsClass);        // writes false
Console.WriteLine(intType.IsEnum);         // writes false
Console.WriteLine(intType.IsPrimitive);    // writes true
Console.WriteLine(intType.IsValueType);    // writes true
```

Or using the `Vector` class:

```
Type vecType = typeof(Vector);
Console.WriteLine(vecType.IsAbstract);     // writes false
Console.WriteLine(vecType.IsClass);        // writes true
Console.WriteLine(vecType.IsEnum);         // writes false
Console.WriteLine(vecType.IsPrimitive);    // writes false
Console.WriteLine(vecType.IsValueType);    // writes false
```

Finally, you can also retrieve a reference to the assembly that the type is defined in. This is returned as a reference to an instance of the `System.Reflection.Assembly` class, which is examined shortly:

```
Type t = typeof (Vector);
Assembly containingAssembly = new Assembly(t);
```

Methods

Most of the methods of `System.Type` are used to obtain details of the members of the corresponding data type — the constructors, properties, methods, events, and so on. Quite a large number of methods exist, but they all follow the same pattern. For example, two methods retrieve details of the methods of the data type: `GetMethod()` and `GetMethods()`. `GetMethod()` returns a reference to a `System.Reflection.MethodInfo` object, which contains details of a method. `GetMethods()` returns an array of such references. The difference is that `GetMethods()` returns details of all the methods, whereas `GetMethod()` returns details of just one method with a specified parameter list. Both methods have overloads that take an extra parameter, a `BindingFlags` enumerated value that indicates which members should be returned — for example, whether to return public members, instance members, static members, and so on.

For example, the simplest overload of `GetMethods()` takes no parameters and returns details of all the public methods of the data type:

```
Type t = typeof(double);
MethodInfo[] methods = t.GetMethods();
foreach (MethodInfo nextMethod in methods)
{
   // etc.
       }
```

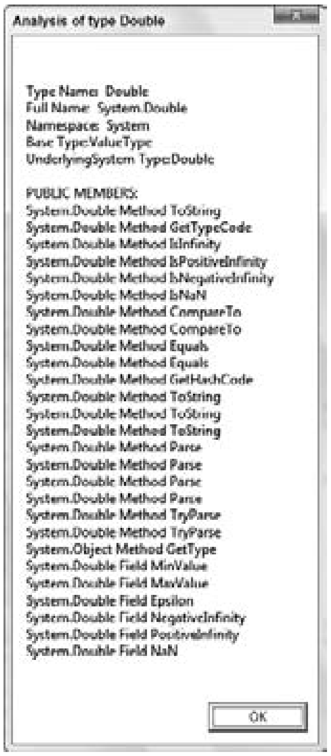
The member methods of `Type` that follow the same pattern are shown in the following table.

TYPE OF OBJECT RETURNED	METHODS (THE METHOD WITH THE PLURAL NAME RETURNS AN ARRAY)
`ConstructorInfo`	`GetConstructor(), GetConstructors()`
`EventInfo`	`GetEvent(), GetEvents()`
`FieldInfo`	`GetField(), GetFields()`
`MemberInfo`	`GetMember(), GetMembers(), GetDefaultMembers()`
`MethodInfo`	`GetMethod(), GetMethods()`
`PropertyInfo`	`GetProperty(), GetProperties()`

The `GetMember()` and `GetMembers()` methods return details of any or all members of the data type, regardless of whether these members are constructors, properties, methods, and so on.

The TypeView Example

This section demonstrates some of the features of the `Type` class with a short example, `TypeView`, which you can use to list the members of a data type. The example demonstrates how to use `TypeView` for a `double`; however, you can swap this type with any other data type just by changing one line of the code in the sample. `TypeView` displays far more information than can be displayed in a console window, so we're going to take a break from our normal practice and display the output in a message box. Running `TypeView` for a `double` produces the results shown in Figure 14-1.



```
Analysis of type Double

Type Name: Double
Full Name: System.Double
Namespace: System
Base Type:ValueType
UnderlyingSystem Type:Double

PUBLIC MEMBERS:
System.Double Method ToString
System.Double Method GetTypeCode
System.Double Method IsInfinity
System.Double Method IsPositiveInfinity
System.Double Method IsNegativeInfinity
System.Double Method IsNaN
System.Double Method CompareTo
System.Double Method CompareTo
System.Double Method Equals
System.Double Method Equals
System.Double Method GetHashCode
System.Double Method ToString
System.Double Method ToString
System.Double Method ToString
System.Double Method Parse
System.Double Method Parse
System.Double Method Parse
System.Double Method Parse
System.Double Method TryParse
System.Double Method TryParse
System.Object Method GetType
System.Double Field MinValue
System.Double Field MaxValue
System.Double Field Epsilon
System.Double Field NegativeInfinity
System.Double Field PositiveInfinity
System.Double Field NaN
```

FIGURE 14-1

The message box displays the name, full name, and namespace of the data type as well as the name of the underlying type and the base type. Next, it simply iterates through all the public instance members of the data type, displaying for each member the declaring type, the type of member (method, field, and so on), and the name of the member. The *declaring type* is the name of the class that actually declares the type member (for example, `System.Double` if it is defined or overridden in `System.Double`, or the name of the relevant base type if the member is simply inherited from some base class).

`TypeView` does not display signatures of methods because you are retrieving details of all public instance members through `MemberInfo` objects, and information about parameters is not available through a `MemberInfo` object. To retrieve that information, you would need references to `MethodInfo` and other more specific objects, which means that you would need to obtain details of each type of member separately.

`TypeView` does display details of all public instance members, but for doubles, the only ones defined are fields and methods. For this example, you will compile `TypeView` as a console application — there is no problem with displaying a message box from a console application. However, the fact that you are using a message box means that you need to reference the base class assembly `System.Windows.Forms.dll`, which contains the classes in the `System.Windows.Forms` namespace in which the `MessageBox` class that you will need is defined. The code for `TypeView` is as follows. To begin, you need to add a few `using` statements:

```
using System;
using System.Reflection;
using System.Text;
using System.Windows.Forms;
```

You need `System.Text` because you will be using a `StringBuilder` object to build up the text to be displayed in the message box, and `System.Windows.Forms` for the message box itself. The entire code is in one class, `MainClass`, which has a couple of `static` methods and one `static` field, a `StringBuilder` instance called `OutputText`, which will be used to build up the text to be displayed in the message box. The main method and class declaration look like this:

```
class MainClass
{
   static StringBuilder OutputText = new StringBuilder();

   static void Main()
   {
      // modify this line to retrieve details of any
      // other data type
      Type t = typeof(double);

      AnalyzeType(t);
      MessageBox.Show(OutputText.ToString(), "Analysis of type "
                                             + t.Name);
      Console.ReadLine();
   }
```

The `Main()` method implementation starts by declaring a `Type` object to represent your chosen data type. You then call a method, `AnalyzeType()`, which extracts the information from the `Type` object and uses it to build up the output text. Finally, you show the output in a message box. Using the `MessageBox` class is fairly intuitive. You just call its `static Show()` method, passing it two strings, which will, respectively, be the text in the box and the caption. `AnalyzeType()` is where the bulk of the work is done:

```
static void AnalyzeType(Type t)
{
   AddToOutput("Type Name: " + t.Name);
   AddToOutput("Full Name: " + t.FullName);
   AddToOutput("Namespace: " + t.Namespace);

   Type tBase = t.BaseType;

   if (tBase != null)
   {
      AddToOutput("Base Type:" + tBase.Name);
   }

   Type tUnderlyingSystem = t.UnderlyingSystemType;

   if (tUnderlyingSystem != null)
   {
      AddToOutput("UnderlyingSystem Type:" + tUnderlyingSystem.Name);
   }

   AddToOutput("\nPUBLIC MEMBERS:");
```

```
            MemberInfo [] Members = t.GetMembers();

            foreach (MemberInfo NextMember in Members)
            {
               AddToOutput(NextMember.DeclaringType + " " +
               NextMember.MemberType + " " + NextMember.Name);
            }
         }
```

You implement the `AnalyzeType()` method by calling various properties of the `Type` object to get the information you need concerning the type names, then call the `GetMembers()` method to get an array of `MemberInfo` objects that you can use to display the details of each member. Note that you use a helper method, `AddToOutput()`, to build up the text to be displayed in the message box:

```
         static void AddToOutput(string Text)
         {
            OutputText.Append("\n" + Text);
         }
```

Compile the `TypeView` assembly using this command:

```
    csc /reference:System.Windows.Forms.dll Program.cs
```

The Assembly Class

The `Assembly` class is defined in the `System.Reflection` namespace and provides access to the metadata for a given assembly. It also contains methods to allow you to load and even execute an assembly — assuming that the assembly is an executable. As with the `Type` class, `Assembly` contains a large number of methods and properties — too many to cover here. Instead, this section is confined to covering those methods and properties that you need to get started and that you will use to complete the `WhatsNewAttributes` example.

Before you can do anything with an `Assembly` instance, you need to load the corresponding assembly into the running process. You can do this with either the `static` members `Assembly.Load()` or `Assembly.LoadFrom()`. The difference between these methods is that `Load()` takes the name of the assembly, and the runtime searches in a variety of locations in an attempt to locate the assembly. These locations include the local directory and the global assembly cache. `LoadFrom()` takes the full path name of an assembly and does not attempt to find the assembly in any other location:

```
       Assembly assembly1 = Assembly.Load("SomeAssembly");
       Assembly assembly2 = Assembly.LoadFrom
          (@"C:\My Projects\Software\SomeOtherAssembly");
```

A number of other overloads of both methods exist, which supply additional security information. After you have loaded an assembly, you can use various properties on it to find out, for example, its full name:

```
       string name = assembly1.FullName;
```

Finding Out About Types Defined in an Assembly

One nice feature of the `Assembly` class is that it allows you to obtain details of all the types that are defined in the corresponding assembly. You simply call the `Assembly.GetTypes()` method, which returns an array of `System.Type` references containing details of all the types. You can then manipulate these `Type` references as explained in the previous section:

```
    Type[] types = theAssembly.GetTypes();

    foreach(Type definedType in types)
    {
       DoSomethingWith(definedType);
    }
```

Finding Out About Custom Attributes

The methods you use to find out which custom attributes are defined on an assembly or type depend on what type of object the attribute is attached to. If you want to find out what custom attributes are attached to an assembly as a whole, you need to call a `static` method of the `Attribute` class, `GetCustomAttributes()`, passing in a reference to the assembly:

```
Attribute[] definedAttributes =
            Attribute.GetCustomAttributes(assembly1);
            // assembly1 is an Assembly object
```

This is actually quite significant. You may have wondered why, when you defined custom attributes, you had to go to all the trouble of actually writing classes for them, and why Microsoft hadn't come up with some simpler syntax. Well, the answer is here. The custom attributes do genuinely exist as objects, and when an assembly is loaded you can read in these attribute objects, examine their properties, and call their methods.

`GetCustomAttributes()`, which is used to get assembly attributes, has a few overloads. If you call it without specifying any parameters other than an assembly reference, it will simply return all the custom attributes defined for that assembly. You can also call `GetCustomAttributes()` specifying a second parameter, which is a `Type` object that indicates the attribute class in which you are interested. In this case, `GetCustomAttributes()` returns an array consisting of all the attributes present that are of the specified type.

Note that all attributes are retrieved as plain `Attribute` references. If you want to call any of the methods or properties you defined for your custom attributes, you will need to cast these references explicitly to the relevant custom attribute classes. You can obtain details of custom attributes that are attached to a given data type by calling another overload of `Assembly.GetCustomAttributes()`, this time passing a `Type` reference that describes the type for which you want to retrieve any attached attributes. If you want to obtain attributes that are attached to methods, constructors, fields, and so on, however, you will need to call a `GetCustomAttributes()` method that is a member of one of the classes `MethodInfo`, `ConstructorInfo`, `FieldInfo`, and so on.

If you expect only a single attribute of a given type, you can call the `GetCustomAttribute()` method instead, which returns a single `Attribute` object. You will use `GetCustomAttribute()` in the `WhatsNewAttributes` example to find out whether the `SupportsWhatsNew` attribute is present in the assembly. To do this, you call `GetCustomAttribute()`, passing in a reference to the `WhatsNewAttributes` assembly, and the type of the `SupportsWhatsNewAttribute` attribute. If this attribute is present, you get an `Attribute` instance. If no instances of it are defined in the assembly, you get `null`. And if two or more instances are found, `GetCustomAttribute()` throws a `System.Reflection.AmbiguousMatchException`.

```
Attribute supportsAttribute =
          Attribute.GetCustomAttributes(assembly1,
          typeof(SupportsWhatsNewAttribute));
```

Completing the WhatsNewAttributes Example

You now have enough information to complete the `WhatsNewAttributes` example by writing the source code for the final assembly in the sample, the `LookUpWhatsNew` assembly. This part of the application is a console application. However, it needs to reference the other assemblies of `WhatsNewAttributes` and

VectorClass. Although this is going to be a command-line application, you will follow the previous TypeView sample in actually displaying your results in a message box because there is a lot of text output — too much to show in a console window screenshot.

The file is called LookUpWhatsNew.cs, and the command to compile it is:

```
csc /reference:WhatsNewAttributes.dll /reference:VectorClass.dll LookUpWhatsNew.cs
```

In the source code of this file, you first indicate the namespaces you want to infer. System.Text is there because you need to use a StringBuilder object again:

```
using System;
using System.Reflection;
using System.Windows.Forms;
using System.Text;
using WhatsNewAttributes;

namespace LookUpWhatsNew
{
```

The class that contains the main program entry point as well as the other methods is WhatsNewChecker. All the methods you define are in this class, which also has two static fields: outputText, which contains the text as you build it up in preparation for writing it to the message box, and backDateTo, which stores the date you have selected. All modifications made since this date will be displayed. Normally, you would display a dialog box inviting the user to pick this date, but we don't want to get sidetracked into that kind of code. For this reason, backDateTo is hard-coded to a value of 1 Feb 2010. You can easily change this date if you want when you download the code:

```
   internal class WhatsNewChecker
   {
      private static readonly StringBuilder outputText = new StringBuilder(1000);
      private static DateTime backDateTo = new DateTime(2010, 2, 1);

      static void Main()
      {
         Assembly theAssembly = Assembly.Load("VectorClass");
         Attribute supportsAttribute =
            Attribute.GetCustomAttribute(
               theAssembly, typeof(SupportsWhatsNewAttribute));
         string name = theAssembly.FullName;

         AddToMessage("Assembly: " + name);

         if (supportsAttribute == null)
         {
            AddToMessage(
                "This assembly does not support WhatsNew attributes");
            return;
         }
         else
         {
            AddToMessage("Defined Types:");
         }

         Type[] types = theAssembly.GetTypes();

         foreach(Type definedType in types)
            DisplayTypeInfo(definedType);

         MessageBox.Show(outputText.ToString(),
            "What\'s New since " + backDateTo.ToLongDateString());
         Console.ReadLine();
      }
```

The `Main()` method first loads the `VectorClass` assembly, and then verifies that it is marked with the `SupportsWhatsNew` attribute. You know `VectorClass` has the `SupportsWhatsNew` attribute applied to it because you have only recently compiled it, but this is a check that would be worth making if users were given a choice of what assembly they wanted to check.

Assuming that all is well, you use the `Assembly.GetTypes()` method to get an array of all the types defined in this assembly, and then loop through them. For each one, you call a method, `DisplayTypeInfo()`, which will add the relevant text, including details of any instances of `LastModifiedAttribute` to the `outputText` field. Finally, you show the message box with the complete text. The `DisplayTypeInfo()` method looks like this:

```
      private static void DisplayTypeInfo(Type type)
      {
         // make sure we only pick out classes
         if (!(type.IsClass))
         {
            return;
         }

         AddToMessage("\nclass " + type.Name);

         Attribute [] attribs = Attribute.GetCustomAttributes(type);

         if (attribs.Length == 0)
         {
            AddToMessage("No changes to this class\n");
         }
         else
         {
            foreach (Attribute attrib in attribs)
            {
               WriteAttributeInfo(attrib);
            }
         }

         MethodInfo [] methods = type.GetMethods();
         AddToMessage("CHANGES TO METHODS OF THIS CLASS:");

         foreach (MethodInfo nextMethod in methods)
         {
            object [] attribs2 =
               nextMethod.GetCustomAttributes(
                  typeof(LastModifiedAttribute), false);

            if (attribs2 != null)
            {
               AddToMessage(
                  nextMethod.ReturnType + " " + nextMethod.Name + "()");
               foreach (Attribute nextAttrib in attribs2)
               {
                  WriteAttributeInfo(nextAttrib);
               }
            }
         }
      }
```

Notice that the first thing you do in this method is check whether the `Type` reference you have been passed actually represents a class. Because, to keep things simple, you have specified that the `LastModified` attribute can be applied only to classes or member methods — you would be wasting your time by doing any processing if the item is not a class (it could be a class, delegate, or enum).

Next, you use the `Attribute.GetCustomAttributes()` method to find out if this class has any `LastModifiedAttribute` instances attached to it. If it does, you add their details to the output text, using a helper method, `WriteAttributeInfo()`.

Finally, you use the `Type.GetMethods()` method to iterate through all the member methods of this data type, and then do the same with each method as you did for the class — check if it has any `LastModifiedAttribute` instances attached to it and, if so, display them using `WriteAttributeInfo()`.

The next bit of code shows the `WriteAttributeInfo()` method, which is responsible for working out what text to display for a given `LastModifiedAttribute` instance. Note that this method is passed an `Attribute` reference, so it needs to cast this to a `LastModifiedAttribute` reference first. After it has done that, it uses the properties that you originally defined for this attribute to retrieve its parameters. It checks that the date of the attribute is sufficiently recent before actually adding it to the text for display:

```
        private static void WriteAttributeInfo(Attribute attrib)
        {

          LastModifiedAttribute lastModifiedAttrib =
            attrib as LastModifiedAttribute;

          if (lastModifiedAttrib == null)
          {
            return;
          }

          // check that date is in range
          DateTime modifiedDate = lastModifiedAttrib.DateModified;

          if (modifiedDate < backDateTo)
          {
            return;
          }

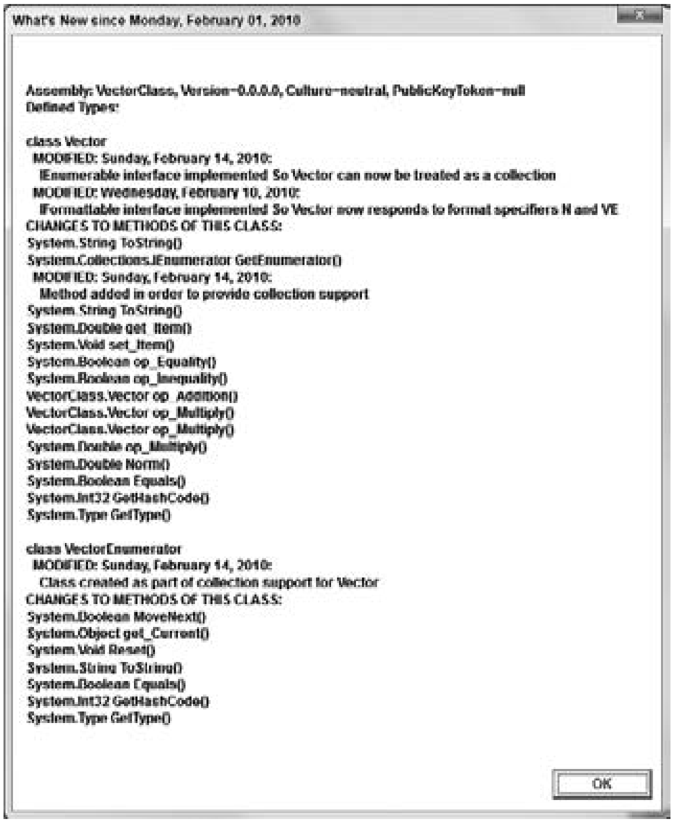
          AddToMessage(" MODIFIED: " +
            modifiedDate.ToLongDateString() + ":");
          AddToMessage(" " + lastModifiedAttrib.Changes);

          if (lastModifiedAttrib.Issues != null)
          {
            AddToMessage(" Outstanding issues:" +
              lastModifiedAttrib.Issues);
          }
        }
```

Finally, here is the helper `AddToMessage()` method:

```
        static void AddToMessage(string message)
        {
          outputText.Append("\n" + message);
        }
      }
    }
```

Running this code produces the results shown in Figure 14-2.



```
Assembly: VectorClass, Version=0.0.0.0, Culture=neutral, PublicKeyToken=null
Defined Types:

class Vector
  MODIFIED: Sunday, February 14, 2010:
    IEnumerable interface implemented So Vector can now be treated as a collection
  MODIFIED: Wednesday, February 10, 2010:
    IFormattable interface implemented So Vector now responds to format specifiers N and VE
CHANGES TO METHODS OF THIS CLASS:
System.String ToString()
System.Collections.IEnumerator GetEnumerator()
  MODIFIED: Sunday, February 14, 2010:
    Method added in order to provide collection support
System.String ToString()
System.Double get_Item()
System.Void set_Item()
System.Boolean op_Equality()
System.Boolean op_Inequality()
VectorClass.Vector op_Addition()
VectorClass.Vector op_Multiply()
VectorClass.Vector op_Multiply()
System.Double op_Multiply()
System.Double Norm()
System.Boolean Equals()
System.Int32 GetHashCode()
System.Type GetType()

class VectorEnumerator
  MODIFIED: Sunday, February 14, 2010:
    Class created as part of collection support for Vector
CHANGES TO METHODS OF THIS CLASS:
System.Boolean MoveNext()
System.Object get_Current()
System.Void Reset()
System.String ToString()
System.Boolean Equals()
System.Int32 GetHashCode()
System.Type GetType()
```

FIGURE 14-2

Notice that when you list the types defined in the `VectorClass` assembly, you actually pick up two classes: `Vector` and the embedded `VectorEnumerator` class. Also notice that because the `backDateTo` date of 1 Feb is hard-coded in this example, you actually pick up the attributes that are dated 14 Feb (when you added the collection support) but not those dated 10 Feb (when you added the `IFormattable` interface).

SUMMARY

This chapter did not attempt to cover the entire topic of reflection. Reflection is an extensive subject worthy of a book of its own. Instead, it illustrated the `Type` and `Assembly` classes, which are the primary entry points through which you can access the extensive capabilities provided by reflection.

In addition, this chapter demonstrated a specific aspect of reflection that you are likely to use more often than any other — the inspection of custom attributes. You learned how to define and apply your own custom attributes, and how to retrieve information about custom attributes at runtime.

Chapter 15, "Errors and Exceptions," explores exceptions and structured exception handling.

15 Errors and Exceptions

WHAT'S IN THIS CHAPTER?

- ➤ Looking at the exception classes
- ➤ Using `try...catch...finally` to capture exceptions
- ➤ Creating user-defined exceptions

Errors happen, and they are not always caused by the person who coded the application. Sometimes your application will generate an error because of an action that was initiated by the end user of your application or it might be simply due to the environmental context in which your code is running. In any case, you should anticipate errors occurring in your applications and code accordingly.

The .NET Framework has enhanced the ways in which you deal with errors. C#'s mechanism for handling error conditions allows you to provide custom handling for each type of error condition as well as to separate the code that identifies errors from the code that handles them.

By the end of this chapter, you will have a good grasp on advanced exception handling in your C# applications.

No matter how good your coding is, your programs should have the ability to handle any possible errors that may occur. For example, in the middle of some complex processing of your code, you may discover that it doesn't have permission to read a file, or, while it is sending network requests, the network may go down. In such exceptional situations, it is not enough for a method to simply return an appropriate error code — there might be 15 or 20 nested method calls, so what you really want the program to do is jump back up through all those 15 or 20 calls to exit the task completely and take the appropriate counteractions. The C# language has very good facilities to handle this kind of situation, through the mechanism known as *exception handling*.

EXCEPTION CLASSES

In C#, an exception is an object created (or *thrown*) when a particular exceptional error condition occurs. This object contains information that should help track down the problem. Although you can create your own exception classes (and you will be doing so later), .NET provides you with many predefined exception classes.

This section provides a quick survey of some of the exceptions available in the .NET base class library. Microsoft has provided a large number of exception classes in .NET — too many to provide a comprehensive list here. The class hierarchy diagram in Figure 15-1 shows a few of these classes, which give you a sense of the general pattern.

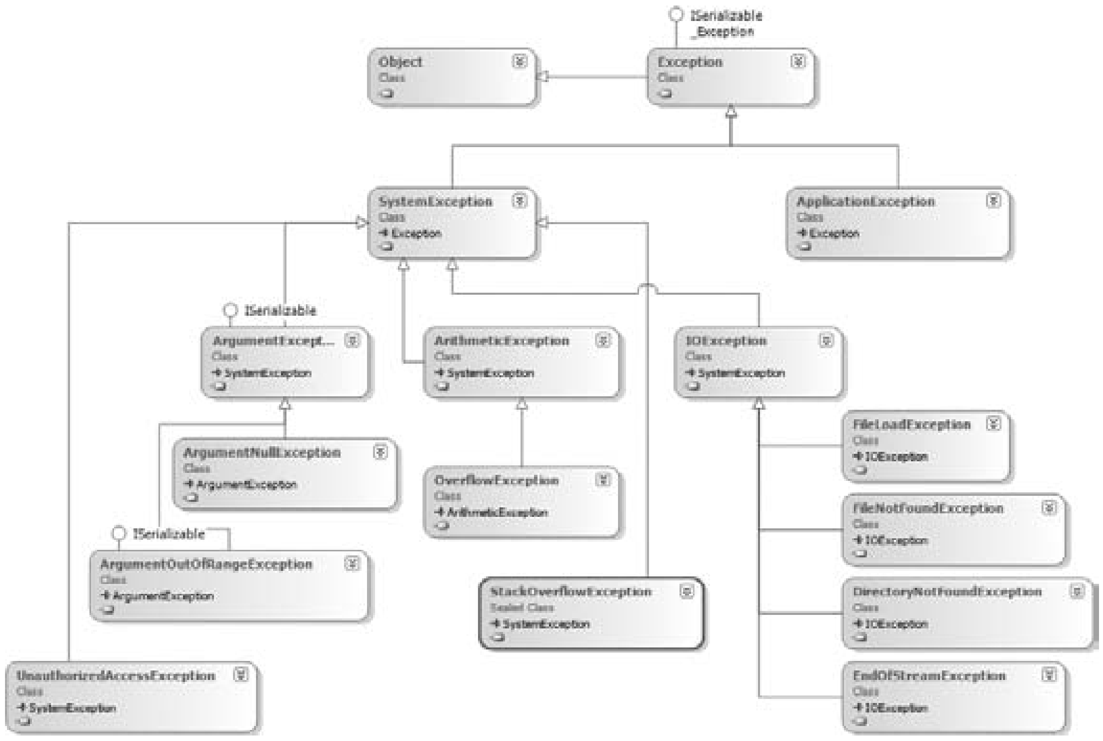


FIGURE 15-1

All the classes in Figure 15-1 are part of the `System` namespace, except for `IOException` and the classes derived from `IOException`, which are part of the namespace `System.IO`. The `System.IO` namespace deals with reading and writing data to files. In general, there is no specific namespace for exceptions. Exception classes should be placed in whatever namespace is appropriate to the classes that can generate them — hence IO-related exceptions are in the `System.IO` namespace. You will find exception classes in quite a few of the base class namespaces.

The generic exception class, `System.Exception`, is derived from `System.Object`, as you would expect for a .NET class. In general, you should not throw generic `System.Exception` objects in your code, because they provide no specifics about the error condition.

Two important classes in the hierarchy are derived from `System.Exception`:

➤ `System.SystemException` — This class is for exceptions that are usually thrown by the .NET runtime or that are considered to be of a generic nature and might be thrown by almost any application. For example, `StackOverflowException` will be thrown by the .NET runtime if it detects the stack is full. However, you might choose to throw `ArgumentException` or its subclasses in your own code if you detect that a method has been called with inappropriate arguments. Subclasses of `System.SystemException` include classes that represent both fatal and nonfatal errors.

- `System.ApplicationException` — This class is important, because it is the intended base for any class of exception defined by third parties. If you define any exceptions covering error conditions unique to your application, you should derive these directly or indirectly from `System.ApplicationException`.

Other exception classes that might come in handy include:

- `StackOverflowException` — This exception is thrown when the area of memory allocated to the stack is full. A stack overflow can occur if a method continuously calls itself recursively. This is generally a fatal error, because it prevents your application from doing anything apart from terminating (in which case it is unlikely that even the `finally` block will execute). Trying to handle errors like this yourself is usually pointless; instead, you should get the application to gracefully exit.
- `EndOfStreamException` — The usual cause of an `EndOfStreamException` is an attempt to read past the end of a file. A *stream* represents a flow of data between data sources. Streams are covered in detail in Chapter 24, "Networking."
- `OverflowException` — An `OverflowException` is what happens if you attempt to cast an `int` containing a value of `-40` to a `uint` in a `checked` context.

The other exception classes shown in Figure 15-1 are not discussed here.

The class hierarchy for exceptions is somewhat unusual in that most of these classes do not add any functionality to their respective base classes. However, in the case of exception handling, the common reason for adding inherited classes is to indicate more specific error conditions. There is often no need to override methods or add any new ones (although it is not uncommon to add extra properties that carry extra information about the error condition). For example, you might have a base `ArgumentException` class intended for method calls where inappropriate values are passed in, and an `ArgumentNullException` class derived from it, which is intended to handle a `null` argument if passed.

CATCHING EXCEPTIONS

Given that the .NET Framework includes a selection of predefined base class exception objects, how do you use them in your code to trap error conditions? To deal with possible error conditions in C# code, you will normally divide the relevant part of your program into blocks of three different types:

- `try` blocks encapsulate the code that forms part of the normal operation of your program and that might encounter some serious error conditions.
- `catch` blocks encapsulate the code that deals with the various error conditions that your code might have encountered by working through any of the code in the accompanying `try` block. This place could also be used for logging errors.
- `finally` blocks encapsulate the code that cleans up any resources or takes any other action that you will normally want done at the end of a `try` or `catch` block. It is important to understand that the `finally` block is executed whether or not an exception is thrown. Because the aim is that the `finally` block contains cleanup code that should always be executed, the compiler will flag an error if you place a `return` statement inside a `finally` block. For an example of using the `finally` block, you might close any connections that were opened in the `try` block. It is also important to understand that the `finally` block is completely optional. If you do not have a requirement for any cleanup code (such as disposing or closing any open objects), then there is no need for this block.

So how do these blocks fit together to trap error conditions? Here is how:

1. The execution flow first enters the `try` block.
2. If no errors occur in the `try` block, execution proceeds normally through the block, and when the end of the `try` block is reached, the flow of execution jumps to the `finally` block if one is present

(Step 5). However, if an error does occur within the `try` block, execution jumps to a `catch` block (Step 3).

3. The error condition is handled in the `catch` block.
4. At the end of the `catch` block, execution automatically transfers to the `finally` block if one is present.
5. The `finally` block is executed (if present).

The C# syntax used to bring all this about looks roughly like this:

```
try
{
   // code for normal execution
}
catch
{
   // error handling
}
finally
{
   // clean up
}
```

Actually, a few variations on this theme exist:

- You can omit the `finally` block because it is optional.
- You can also supply as many `catch` blocks as you want to handle specific types of errors. However, the idea is not to get too carried away and have a huge number of `catch` blocks, because this can hurt the performance of your application.
- You can omit the `catch` blocks altogether, in which case the syntax serves not to identify exceptions, but as a way of guaranteeing that code in the `finally` block will be executed when execution leaves the `try` block. This is useful if the `try` block contains several exit points.

So far so good, but the question that has yet to be answered is this: If the code is running in the `try` block, how does it know when to switch to the `catch` block if an error has occurred? If an error is detected, the code does something known as *throwing an exception*. In other words, it instantiates an exception object class and throws it:

```
throw new OverflowException();
```

Here, you have instantiated an exception object of the `OverflowException` class. As soon as the computer encounters a `throw` statement inside a `try` block, it immediately looks for the `catch` block associated with that `try` block. If there is more than one `catch` block associated with the `try` block, it identifies the correct `catch` block by checking which exception class the `catch` block is associated with. For example, when the `OverflowException` object is thrown, execution jumps to the following `catch` block:

```
catch (OverflowException ex)
{
   // exception handling here
}
```

In other words, the computer looks for the `catch` block that indicates a matching exception class instance of the same class (or of a base class).

With this extra information, you can expand the `try` block just demonstrated. Assume, for the sake of argument, that there are two possible serious errors that can occur in the `try` block: an overflow and an array out of bounds. Assume that your code contains two Boolean variables, `Overflow` and `OutOfBounds`, which indicate whether these conditions exist. You have already seen that a predefined exception class exists to indicate overflow (`OverflowException`); similarly, an `IndexOutOfRangeException` class exists to handle an array that is out of bounds.

Now your `try` block looks like this:

```
try
{
   // code for normal execution

   if (Overflow == true)
  {
     throw new OverflowException();
   }

   // more processing

   if (OutOfBounds == true)
   {
      throw new IndexOutOfRangeException();
   }

   // otherwise continue normal execution
}
catch (OverflowException ex)
{
   // error handling for the overflow error condition
}
catch (IndexOutOfRangeException ex)
{
   // error handling for the index out of range error condition
}
finally
{
   // clean up
}
```

So far, this might not look that much different from what you could have done a long time ago if you ever used the Visual Basic 6 `On Error GoTo` statement (with the exception perhaps that the different parts in the code are separated). C#, however, provides a far more powerful and flexible mechanism for error handling.

This is because you can have `throw` statements that are nested in several method calls inside the `try` block, but the same `try` block continues to apply even as execution flow enters these other methods. If the computer encounters a `throw` statement, it immediately goes back up through all the method calls on the stack, looking for the end of the containing `try` block and the start of the appropriate `catch` block. During this process, all the local variables in the intermediate method calls will correctly go out of scope. This makes the `try...catch` architecture well suited to the situation described at the beginning of this section, where the error occurs inside a method call that is nested inside 15 or 20 method calls, and processing has to stop immediately.

As you can probably gather from this discussion, `try` blocks can play a very significant part in controlling the flow of execution of your code. However, it is important to understand that exceptions are intended for exceptional conditions, hence their name. You wouldn't want to use them as a way of controlling when to exit a `do...while` loop.

Implementing Multiple Catch Blocks

The easiest way to see how `try...catch...finally` blocks work in practice is with a couple of examples. The first example is called `SimpleExceptions`. It repeatedly asks the user to type in a number and then displays it. However, for the sake of this example, imagine that the number has to be between 0 and 5; otherwise, the program won't be able to process the number properly. Therefore, you will throw an exception if the user types in anything outside of this range.

The program then continues to ask for more numbers for processing until the user simply presses the Enter key without entering anything.

The code for `SimpleExceptions` looks like this:

```
using System;

namespace Wrox.ProCSharp.AdvancedCSharp
{
   public class MainEntryPoint
   {
      public static void Main()
      {
         while (true)
         {
            try
            {
               string userInput;

               Console.Write("Input a number between 0 and 5 " +
                  "(or just hit return to exit)> ");
               userInput = Console.ReadLine();

               if (userInput == "")
               {
                  break;
               }

               int index = Convert.ToInt32(userInput);

               if (index < 0 || index > 5)
               {
                  throw new IndexOutOfRangeException(
                     "You typed in " + userInput);
               }

               Console.WriteLine("Your number was " + index);
            }
            catch (IndexOutOfRangeException ex)
            {
               Console.WriteLine("Exception: " +
                  "Number should be between 0 and 5. {0}", ex.Message);
            }
            catch (Exception ex)
            {
               Console.WriteLine(
                    "An exception was thrown. Message was: {0}", ex.Message);
                }
                finally
                {
                    Console.WriteLine("Thank you");
                }
            }
        }
    }
}
```

code snippet SimpleExceptions.cs

The core of this code is a `while` loop, which continually uses `Console.ReadLine()` to ask for user input. `ReadLine()` returns a string, so your first task is to convert it to an `int` using the `System.Convert.ToInt32()` method. The `System.Convert` class contains various useful methods to perform data conversions and provides an alternative to the `int.Parse()` method. In general, `System.Convert` contains methods to perform various type conversions. Recall that the C# compiler resolves `int` to instances of the `System.Int32` base class.

> *It is also worth pointing out that the parameter passed to the* `catch` *block is scoped to that* `catch` *block — which is why you are able to use the same parameter name,* `ex`*, in successive* `catch` *blocks in the preceding code.*

In the preceding example, you also check for an empty string, because this is your condition for exiting the `while` loop. Notice how the `break` statement actually breaks right out of the enclosing `try` block as well as the `while` loop because this is valid behavior. Of course, when execution breaks out of the `try` block, the `Console.WriteLine()` statement in the `finally` block is executed. Although you just display a greeting here, more commonly you will be doing tasks like closing file handles and calling the `Dispose()` method of various objects to perform any cleaning up. After the computer leaves the `finally` block, it simply carries on executing into the next statement that it would have executed had the `finally` block not been present. In the case of this example, though, you iterate back to the start of the `while` loop, and enter the `try` block again (unless the `finally` block was entered as a result of executing the `break` statement in the `while` loop, in which case you simply exit the `while` loop).

Next, you check for your exception condition:

```
if (index < 0 || index > 5)
{
   throw new IndexOutOfRangeException("You typed in " + userInput);
}
```

When throwing an exception, you need to choose what type of exception to throw. Although the class `System.Exception` is available, it is intended only as a base class. It is considered bad programming practice to throw an instance of this class as an exception, because it conveys no information about the nature of the error condition. Instead, the .NET Framework contains many other exception classes that are derived from `System.Exception`. Each of these matches a particular type of exception condition, and you are free to define your own ones as well. The idea is that you give as much information as possible about the particular exception condition by throwing an instance of a class that matches the particular error condition. In the preceding example, `System.IndexOutOfRangeException` is the best choice for the circumstances. `IndexOutOfRangeException` has several constructor overloads. The one chosen in the example takes a string, which describes the error. Alternatively, you might choose to derive your own custom `Exception` object that describes the error condition in the context of your application.

Suppose that the user then types a number that is not between 0 and 5. This will be picked up by the if statement and an IndexOutOfRangeException object will be instantiated and thrown. At this point, the computer will immediately exit the try block and hunt for a catch block that handles IndexOutOfRangeException. The first catch block it encounters is this:

```
catch (IndexOutOfRangeException ex)
{
   Console.WriteLine(
      "Exception: Number should be between 0 and 5. {0}", ex.Message);
}
```

Because this catch block takes a parameter of the appropriate class, the catch block will be passed the exception instance and executed. In this case, you display an error message and the Exception.Message property (which corresponds to the string you passed to the IndexOutOfRangeException's constructor). After executing this catch block, control then switches to the finally block, just as if no exception had occurred.

Notice that in the example, you have also provided another catch block:

```
catch (Exception ex)
{
   Console.WriteLine("An exception was thrown. Message was: {0}", ex.Message);
}
```

This catch block would also be capable of handling an IndexOutOfRangeException if it weren't for the fact that such exceptions will already have been caught by the previous catch block. A reference to a base class can also refer to any instances of classes derived from it, and all exceptions are derived from System.Exception. So why isn't this catch block executed? The answer is that the computer executes only the first suitable catch block it finds from the list of available catch blocks. So why is this second catch block even here? Well, it is not only your code that is covered by the try block. Inside the block, you actually make three separate calls to methods in the System namespace (Console.ReadLine(), Console.Write(), and Convert.ToInt32()), and any of these methods might throw an exception.

If you type in something that is not a number — say a or hello — the Convert.ToInt32() method will throw an exception of the class System.FormatException to indicate that the string passed into ToInt32() is not in a format that can be converted to an int. When this happens, the computer will trace back through the method calls, looking for a handler that can handle this exception. Your first catch block (the one that takes an IndexOutOfRangeException) will not do. The computer then looks at the second catch block. This one will do because FormatException is derived from Exception, so a FormatException instance can be passed in as a parameter here.

The structure of the example is actually fairly typical of a situation with multiple catch blocks. You start with catch blocks that are designed to trap very specific error conditions. Then, you finish with more general blocks that will cover any errors for which you have not written specific error handlers. Indeed, the order of the catch blocks is important. If you had written the previous two blocks in the opposite order, the code would not have compiled, because the second catch block is unreachable (the Exception catch block would catch all exceptions). Therefore, the uppermost catch blocks should be the most granular options available and ending with the most general options.

Now that you have analyzed the code for the example, you can run it. The following output illustrates what happens with different inputs and demonstrates both the IndexOutOfRangeException and the FormatException being thrown:

```
SimpleExceptions
Input a number between 0 and 5 (or just hit return to exit)>4
Your number was 4
Thank you
Input a number between 0 and 5 (or just hit return to exit)>0
Your number was 0
Thank you
Input a number between 0 and 5 (or just hit return to exit)>10
```

```
Exception: Number should be between 0 and 5. You typed in 10
Thank you
Input a number between 0 and 5 (or just hit return to exit)>hello
An exception was thrown. Message was: Input string was not in a correct format.
Thank you
Input a number between 0 and 5 (or just hit return to exit)>
Thank you
```

Catching Exceptions from Other Code

The previous example demonstrates the handling of two exceptions. One of them, `IndexOutOfRangeException`, was thrown by your own code. The other, `FormatException`, was thrown from inside one of the base classes. It is very common for code in a library to throw an exception if it detects that some problem has occurred, or if one of the methods has been called inappropriately by being passed the wrong parameters. However, library code rarely attempts to catch exceptions; this is regarded as the responsibility of the client code.

Often, you will find that exceptions are thrown from the base class libraries while you are debugging. The process of debugging to some extent involves determining why exceptions have been thrown and removing the causes. Your aim should be to ensure that by the time the code is actually shipped, exceptions do occur only in very exceptional circumstances, and if possible, are handled in some appropriate way in your code.

System.Exception Properties

The example has illustrated the use of only the `Message` property of the exception object. However, a number of other properties are available in `System.Exception`, as shown in the following table.

PROPERTY	DESCRIPTION
`Data`	This provides you with the ability to add key/value statements to the exception that can be used to supply extra information about the exception.
`HelpLink`	This is a link to a help file that provides more information about the exception.
`InnerException`	If this exception was thrown inside a `catch` block, then `InnerException` contains the exception object that sent the code into that `catch` block.
`Message`	This is text that describes the error condition.
`Source`	This is the name of the application or object that caused the exception.
`StackTrace`	This provides details of the method calls on the stack (to help track down the method that threw the exception).
`TargetSite`	This is a .NET reflection object that describes the method that threw the exception.

Of these properties, `StackTrace` and `TargetSite` are supplied automatically by the .NET runtime if a stack trace is available. `Source` will always be filled in by the .NET runtime as the name of the assembly in which the exception was raised (though you might want to modify the property in your code to give more specific information), whereas `Data`, `Message`, `HelpLink`, and `InnerException` must be filled in by the code that threw the exception, by setting these properties immediately before throwing the exception. For example, the code to throw an exception might look something like this:

```
if (ErrorCondition == true)
{
   Exception myException = new ClassMyException("Help!!!!");
   myException.Source = "My Application Name";
   myException.HelpLink = "MyHelpFile.txt";
   myException.Data["ErrorDate"] = DateTime.Now;
```

```
        myException.Data.Add("AdditionalInfo", "Contact Bill from the Blue Team");
        throw myException;
    }
```

Here, `ClassMyException` is the name of the particular exception class you are throwing. Note that it is common practice for the names of all exception classes to end with `Exception`. Also, note that the `Data` property is assigned in two possible ways.

What Happens If an Exception Isn't Handled?

Sometimes an exception might be thrown, but there might not be a `catch` block in your code that is able to handle that kind of exception. The `SimpleExceptions` example can serve to illustrate this. Suppose, for example, that you omitted the `FormatException` and catch-all `catch` blocks, and supplied only the block that traps an `IndexOutOfRangeException`. In that circumstance, what would happen if a `FormatException` were thrown?

The answer is that the .NET runtime would catch it. Later in this section, you learn how you can nest `try` blocks, and in fact, there is already a nested `try` block behind the scenes in the example. The .NET runtime has effectively placed the entire program inside another huge `try` block — it does this for every .NET program. This `try` block has a `catch` handler that can catch any type of exception. If an exception occurs that your code does not handle, the execution flow will simply pass right out of your program and be trapped by this `catch` block in the .NET runtime. However, the results of this probably will not be what you want. What happens is that the execution of your code will be terminated promptly; the user will see a dialog box that complains that your code has not handled the exception, and that provides any details about the exception the .NET runtime was able to retrieve. At least the exception will have been caught! This is what happened earlier in Chapter 2, "Core C#," in the `Vector` example when the program threw an exception.

In general, if you are writing an executable, try to catch as many exceptions as you reasonably can and handle them in a sensible way. If you are writing a library, it is normally best not to handle exceptions (unless a particular exception represents something wrong in your code that you can handle), but instead, assume that the calling code will handle any errors it encounters. However, you may nevertheless want to catch any Microsoft-defined exceptions, so that you can throw your own exception objects that give more specific information to the client code.

Nested try Blocks

One nice feature of exceptions is that you can nest `try` blocks inside each other, like this:

```
try
{
   // Point A
   try
   {
      // Point B
   }
   catch
   {
      // Point C
   }
   finally
   {
      // clean up
   }
   // Point D
}
catch
```

```
{
   // error handling
}
finally
{
   // clean up
}
```

Although each `try` block is accompanied by only one `catch` block in this example, you could string several `catch` blocks together, too. This section takes a closer look at how nested `try` blocks work.

If an exception is thrown inside the outer `try` block but outside the inner `try` block (points A and D), the situation is no different from any of the scenarios you have seen before: either the exception is caught by the outer `catch` block and the outer `finally` block is executed, or the `finally` block is executed and the .NET runtime handles the exception.

If an exception is thrown in the inner `try` block (point B), and there is a suitable inner `catch` block to handle the exception, then, again, you are in familiar territory: the exception is handled there, and the inner `finally` block is executed before execution resumes inside the outer `try` block (at point D).

Now suppose that an exception occurs in the inner `try` block, but there *isn't* a suitable inner `catch` block to handle it. This time, the inner `finally` block is executed as usual, but then the .NET runtime will have no choice but to leave the entire inner `try` block to search for a suitable exception handler. The next obvious place to look is in the outer `catch` block. If the system finds one here, then that handler will be executed and then the outer `finally` block will be executed. If there is no suitable handler here, the search for one will go on. In this case, it means the outer `finally` block will be executed, and then, because there are no more `catch` blocks, control will be transferred to the .NET runtime. Note that the code beyond point D in the outer `try` block is not executed at any point.

An even more interesting thing happens if an exception is thrown at point C. If the program is at point C, it must be already processing an exception that was thrown at point B. It is quite legitimate to throw another exception from inside a `catch` block. In this case, the exception is treated as if it had been thrown by the outer `try` block, so flow of execution will immediately leave the inner `catch` block, and execute the inner `finally` block, before the system searches the outer `catch` block for a handler. Similarly, if an exception is thrown in the inner `finally` block, control will immediately be transferred to the best appropriate handler, with the search starting at the outer `catch` block.

It is perfectly legitimate to throw exceptions from `catch` *and* `finally` *blocks.*

Although the situation has been shown with just two `try` blocks, the same principles hold no matter how many `try` blocks you nest inside each other. At each stage, the .NET runtime will smoothly transfer control up through the `try` blocks, looking for an appropriate handler. At each stage, as control leaves a `catch` block, any cleanup code in the corresponding `finally` block (if present) will be executed, but no code outside any `finally` block will be run until the correct `catch` handler has been found and run.

The nesting of `try` blocks can also occur between methods themselves. For example, if method A calls method B from within a `try` block, then method B itself has a `try` block within it as well.

You have now seen how having nested `try` blocks can work. The obvious next question is why would you want to do that? There are two reasons:

- To modify the type of exception thrown
- To enable different types of exception to be handled in different places in your code

Modifying the Type of Exception

Modifying the type of the exception can be useful when the original exception thrown does not adequately describe the problem. What typically happens is that something — possibly the .NET runtime — throws a fairly low-level exception that says something like an overflow occurred (`OverflowException`) or an argument passed to a method was incorrect (a class derived from `ArgumentException`). However, because of the context in which the exception occurred, you will know that this reveals some other underlying problem (for example, an overflow can only happen at that point in your code because a file you have just read contained incorrect data). In that case, the most appropriate thing that your handler for the first exception can do is throw another exception that more accurately describes the problem, so that another `catch` block further along can deal with it more appropriately. In this case, it can also forward the original exception through a property implemented by `System.Exception` called `InnerException`. `InnerException` simply contains a reference to any other related exception that was thrown — in case the ultimate handler routine will need this extra information.

Of course, the situation also exists where an exception occurs inside a `catch` block. For example, you might normally read in some configuration file that contains detailed instructions for handling the error, and it might turn out that this file is not there.

Handling Different Exceptions in Different Places

The second reason for having nested `try` blocks is so that different types of exceptions can be handled at different locations in your code. A good example of this is if you have a loop where various exception conditions can occur. Some of these might be serious enough that you need to abandon the entire loop, whereas others might be less serious and simply require that you abandon that iteration and move on to the next iteration around the loop. You could achieve this by having one `try` block inside the loop, which handles the less serious error conditions, and an outer `try` block outside the loop, which handles the more serious error conditions. You will see how this works in the next exceptions example.

USER-DEFINED EXCEPTION CLASSES

You are now ready to look at a second example that illustrates exceptions. This example, called `SolicitColdCall`, contains two nested `try` blocks and illustrates the practice of defining your own custom exception classes and throwing another exception from inside a `try` block.

This example assumes that a sales company wants to have additional customers on its sales list. The company's sales team is going to phone a list of people to invite them to become customers, a practice known in sales jargon as *cold calling*. To this end, you have a text file available that contains the names of the people to be cold called. The file should be in a well-defined format in which the first line contains the number of people in the file and each subsequent line contains the name of the next person. In other words, a correctly formatted file of names might look like this:

```
4
George Washington
Benedict Arnold
John Adams
Thomas Jefferson
```

This version of cold calling is designed to display the name of the person on the screen (perhaps for the salesperson to read). That is why only names and not phone numbers of the individuals are contained in the file.

For this example, your program will ask the user for the name of the file and will then simply read it in and display the names of people. That sounds like a simple task, but even so, a couple of things can go wrong and require you to abandon the entire procedure:

➤ The user might type the name of a file that does not exist. This will be caught as a `FileNotFound` exception.

- The file might not be in the correct format. There are two possible problems here. First, the first line of the file might not be an integer. Second, there might not be as many names in the file as the first line of the file indicates. In both cases, you want to trap this oddity as a custom exception that has been written specially for this purpose, `ColdCallFileFormatException`.

There is something else that can go wrong that, while not causing you to abandon the entire process, will mean that you need to abandon that person and move on to the next person in the file (and therefore will need to be trapped by an inner `try` block). Some people are spies working for rival sales companies, and obviously, you would not want to let these people know what you are up to by accidentally phoning one of them. Your research has indicated that you can identify who the spies are because their names begin with B. Such people should have been screened out when the data file was first prepared, but just in case any have slipped through, you will need to check each name in the file and throw a `SalesSpyFoundException` if you detect a sales spy. This, of course, is another custom exception object.

Finally, you will implement this example by coding a class, `ColdCallFileReader`, which maintains the connection to the cold-call file and retrieves data from it. You will code this class in a very safe way, which means that its methods will all throw exceptions if they are called inappropriately; for example, if a method that will read a file is called before the file has even been opened. For this purpose, you will write another exception class, `UnexpectedException`.

Catching the User-Defined Exceptions

Let's start with the `Main()` method of the `SolicitColdCall` sample, which catches your user-defined exceptions. Note that you will need to call up file-handling classes in the `System.IO` namespace as well as the `System` namespace.

```
using System;
using System.IO;

namespace Wrox.ProCSharp.AdvancedCSharp
{
   class MainEntryPoint
   {
      static void Main()
      {
         Console.Write("Please type in the name of the file " +
            "containing the names of the people to be cold called > ");
         string fileName = Console.ReadLine();
         ColdCallFileReader peopleToRing = new ColdCallFileReader();

         try
         {
            peopleToRing.Open(fileName);
            for (int i=0; i<peopleToRing.NPeopleToRing; i++)
            {
               peopleToRing.ProcessNextPerson();
            }
            Console.WriteLine("All callers processed correctly");
         }
         catch(FileNotFoundException)
         {
            Console.WriteLine("The file {0} does not exist", fileName);
         }
         catch(ColdCallFileFormatException ex)
         {
            Console.WriteLine(
          "The file {0} appears to have been corrupted", fileName);
            Console.WriteLine("Details of problem are: {0}", ex.Message);
            if (ex.InnerException != null)
            {
                Console.WriteLine(
                   "Inner exception was: {0}", ex.InnerException.Message);
              }
            }
            catch(Exception ex)
            {
              Console.WriteLine("Exception occurred:\n" + ex.Message);
            }
            finally
            {
              peopleToRing.Dispose();
            }
            Console.ReadLine();
          }
        }
```

This code is a little more than just a loop to process people from the file. You start by asking the user for the name of the file. Then you instantiate an object of a class called `ColdCallFileReader`, which is defined shortly. The `ColdCallFileReader` class is the class that handles the file reading. Notice that you do this outside the initial `try` block — that's because the variables that you instantiate here need to be available in the subsequent `catch` and `finally` blocks, and if you declared them inside the `try` block they would go out of scope at the closing curly brace of the `try` block, which would not be a good thing.

In the `try` block, you open the file (using the `ColdCallFileReader.Open()` method) and loop over all the people in it. The `ColdCallFileReader.ProcessNextPerson()` method reads in and displays the name of the next person in the file, and the `ColdCallFileReader.NPeopleToRing` property tells you how many people should be in the file (obtained by reading the first line of the file). There are three `catch` blocks: one for `FileNotFoundException`, one for `ColdCallFileFormatException`, and one to trap any other .NET exceptions.

In the case of a `FileNotFoundException`, you display a message to that effect. Notice that in this `catch` block, the exception instance is not actually used at all. This `catch` block is used to illustrate the user-friendliness of the application. Exception objects generally contain technical information that is useful for developers, but not the sort of stuff you want to show to your end users. So in this case, you create a simpler message of your own.

For the `ColdCallFileFormatException` handler, you have done the opposite, and illustrated how to give fuller technical information, including details of the inner exception, if one is present.

Finally, if you catch any other generic exceptions, you display a user-friendly message, instead of letting any such exceptions fall through to the .NET runtime. Note that you have chosen not to handle any other exceptions not derived from `System.Exception`, because you are not calling directly into non-.NET code.

The `finally` block is there to clean up resources. In this case, this means closing any open file — performed by the `ColdCallFileReader.Dispose()` method.

Throwing the User-Defined Exceptions

Now take a look at the definition of the class that handles the file reading and (potentially) throws your user-defined exceptions: `ColdCallFileReader`. Because this class maintains an external file connection, you need to make sure that it is disposed of correctly in accordance with the principles laid down for the disposing of objects in Chapter 4, "Inheritance." Therefore, you derive this class from `IDisposable`.

First, you declare some variables:

```
class ColdCallFileReader: IDisposable
{
  FileStream fs;
  StreamReader sr;
```

```
uint nPeopleToRing;
bool isDisposed = false;
bool isOpen = false;
```

FileStream and StreamReader, both in the System.IO namespace, are the base classes that you will use to read the file. FileStream allows you to connect to the file in the first place, whereas StreamReader is specially geared up to reading text files and implements a method, ReadLine(), which reads a line of text from a file. You look at StreamReader more closely in Chapter 29, "Manipulating Files and the Registry," which discusses file handling in depth.

The isDisposed field indicates whether the Dispose() method has been called. ColdCallFileReader is implemented so that after Dispose() has been called, it is not permitted to reopen connections and reuse the object. isOpen is also used for error checking — in this case, checking whether the StreamReader actually connects to an open file.

The process of opening the file and reading in that first line — the one that tells you how many people are in the file — is handled by the Open() method:

```
public void Open(string fileName)
{
   if (isDisposed)
      throw new ObjectDisposedException("peopleToRing");

   fs = new FileStream(fileName, FileMode.Open);
   sr = new StreamReader(fs);

   try
   {
      string firstLine = sr.ReadLine();
      nPeopleToRing = uint.Parse(firstLine);
      isOpen = true;
   }
   catch (FormatException ex)
   {
      throw new ColdCallFileFormatException(
         "First line isn\'t an integer", ex);
   }
}
```

code snippet SolicitColdCall.cs

The first thing you do in this method (as with all other ColdCallFileReader methods) is check whether the client code has inappropriately called it after the object has been disposed of, and if so, throw a predefined ObjectDisposedException object. The Open() method checks the isDisposed field to see whether Dispose() has already been called. Because calling Dispose() implies that the caller has now finished with this object, you regard it as an error to attempt to open a new file connection if Dispose() has been called.

Next, the method contains the first of two inner try blocks. The purpose of this one is to catch any errors resulting from the first line of the file not containing an integer. If that problem arises, the .NET runtime will throw a FormatException, which you trap and convert to a more meaningful exception that indicates there is actually a problem with the format of the cold-call file. Note that System.FormatException is there to indicate format problems with basic data types, not with files, and so is not a particularly useful exception to pass back to the calling routine in this case. The new exception thrown will be trapped by the outermost try block. Because no cleanup is needed here, there is no need for a finally block.

If everything is fine, you set the isOpen field to true to indicate that there is now a valid file connection from which data can be read.

The `ProcessNextPerson()` method also contains an inner `try` block:

```
public void ProcessNextPerson()
{
   if (isDisposed)
   {
      throw new ObjectDisposedException("peopleToRing");
   }

   if (!isOpen)
   {
      throw new UnexpectedException(
         "Attempted to access coldcall file that is not open");
   }

   try
   {
      string name;
      name = sr.ReadLine();
      if (name == null)
         throw new ColdCallFileFormatException("Not enough names");
      if (name[0] == 'B')
      {
         throw new SalesSpyFoundException(name);
      }
      Console.WriteLine(name);
   }
   catch(SalesSpyFoundException ex)
   {
      Console.WriteLine(ex.Message);
   }

   finally
   {
   }
}
```

Two possible problems exist with the file here (assuming that there actually is an open file connection; the `ProcessNextPerson()` method checks this first). First, you might read in the next name and discover that it is a sales spy. If that condition occurs, the exception is trapped by the first of the `catch` blocks in this method. Because that exception has been caught here, inside the loop, it means that execution can subsequently continue in the `Main()` method of the program and the subsequent names in the file will continue to be processed.

A problem might also occur if you try to read the next name and discover that you have already reached the end of the file. The way that the `StreamReader` object's `ReadLine()` method works is if it has gone past the end of the file, it doesn't throw an exception, but simply returns `null`. Therefore, if you find a null string, you know that the format of the file was incorrect because the number in the first line of the file indicated a larger number of names than were actually present in the file. If that happens, you throw a `ColdCallFileFormatException`, which will be caught by the outer exception handler (which will cause the execution to terminate).

Once again, you don't need a `finally` block here because there is no cleanup to do; however, this time an empty `finally` block is included, just to show that you can do so, if you want.

The example is nearly finished. You have just two more members of `ColdCallFileReader` to look at: the `NPeopleToRing` property, which returns the number of people supposed to be in the file, and the `Dispose()` method, which closes an open file. Notice that the `Dispose()` method returns only if it has already been called — this is the recommended way of implementing it. It also checks that there actually is a file stream to close before closing it. This example is shown here to illustrate defensive coding techniques, so that's what you are doing!

```
      public uint NPeopleToRing
      {
         get
         {
            if (isDisposed)
            {
               throw new ObjectDisposedException("peopleToRing");
            }

            if (!isOpen)
            {
               throw new UnexpectedException(
                  "Attempted to access cold-call file that is not open");
            }

            return nPeopleToRing;
         }
      }

      public void Dispose()
      {
         if (isDisposed)
         {
            return;
         }

         isDisposed = true;
         isOpen = false;

         if (fs != null)
         {
            fs.Close();
            fs = null;
         }
      }
```

Defining the User-Defined Exception Classes

Finally, you need to define your own three exception classes. Defining your own exception is quite easy because there are rarely any extra methods to add. It is just a case of implementing a constructor to ensure that the base class constructor is called correctly. Here is the full implementation of `SalesSpyFoundException`:

```
   class SalesSpyFoundException: ApplicationException
   {
      public SalesSpyFoundException(string spyName)
      :   base("Sales spy found, with name " + spyName)
      {
      }

      public SalesSpyFoundException(
         string spyName, Exception innerException)
      :   base(
            "Sales spy found with name " + spyName, innerException)
      {
      }
   }
```

code snippet SolicitColdCall.cs

Notice that it is derived from `ApplicationException`, as you would expect for a custom exception. In fact, in practice, you would probably have put in an intermediate class, something like `ColdCallFileException`, derived from `ApplicationException`, and derived both of your exception classes from this class. This ensures that the handling code has that extra-fine degree of control over which exception handler handles each exception. However, to keep the example simple, you will not do that.

You have done one bit of processing in `SalesSpyFoundException`. You have assumed that the message passed into its constructor is just the name of the spy found, so you turn this string into a more meaningful error message. You have also provided two constructors, one that simply takes a message, and one that also takes an inner exception as a parameter. When defining your own exception classes, it is best to include, at a minimum, at least these two constructors (although you will not actually be using the second `SalesSpyFoundException` constructor in this example).

Now for the `ColdCallFileFormatException`. This follows the same principles as the previous exception, except that you don't do any processing on the message:

```
class ColdCallFileFormatException: ApplicationException
{
   public ColdCallFileFormatException(string message)
   :   base(message)
   {
   }

   public ColdCallFileFormatException(
      string message, Exception innerException)
   :   base(message, innerException)
   {
   }
}
```

And finally, `UnexpectedException`, which looks much the same as `ColdCallFileFormatException`:

```
class UnexpectedException: ApplicationException
{
   public UnexpectedException(string message)
   :   base(message)
   {
   }

   public UnexpectedException(string message, Exception innerException)
   :   base(message, innerException)
   {
   }
}
```

Now you are ready to test the program. First, try the `people.txt` file; the contents are defined here:

```
4
George Washington
Benedict Arnold
John Adams
Thomas Jefferson
```

This has four names (which match the number given in the first line of the file), including one spy. Then try the following `people2.txt` file, which has an obvious formatting error:

```
49
George Washington
Benedict Arnold
John Adams
Thomas Jefferson
```

Finally, try the example but specify the name of a file that does not exist, say, `people3.txt`. Running the program three times for the three filenames gives these results:

```
SolicitColdCall
Please type in the name of the file containing the names of the people to be cold
  called > people.txt
George Washington
Sales spy found, with name Benedict Arnold
John Adams
Thomas Jefferson
All callers processed correctly

SolicitColdCall
Please type in the name of the file containing the names of the people to be cold
  called > people2.txt
George Washington
Sales spy found, with name Benedict Arnold
John Adams
Thomas Jefferson
The file people2.txt appears to have been corrupted.
Details of the problem are: Not enough names

SolicitColdCall
Please type in the name of the file containing the names of the people to be cold
  called > people3.txt
The file people3.txt does not exist.
```

In the end, this application shows you a number of different ways in which you can handle the errors and exceptions that you might find in your own applications.

SUMMARY

This chapter examined the rich mechanism C# has for dealing with error conditions through exceptions. You are not limited to the generic error codes that could be output from your code; instead, you have the ability to go in and uniquely handle the most granular of error conditions. Sometimes these error conditions are provided to you through the .NET Framework itself, but at other times, you might want to go in and code your own error conditions as illustrated in this chapter. In either case, you have many ways of protecting the workflow of your applications from unnecessary and dangerous faults.

The next chapter allows you to take a lot of what you learned so far in this book and works at implementing these lessons within the .NET developers IDE — Visual Studio 2010.

PART II
Visual Studio

16 Visual Studio 2010

WHAT'S IN THIS CHAPTER?

- Using Visual Studio 2010
- Refactoring with Visual Studio
- Visual Studio 2010's multi-targeting capabilities
- Working with the technologies WPF, WCF, WF, and more.

At this point, you should be familiar with the C# language and almost ready to move on to the applied sections of the book, which cover how to use C# to program a variety of applications. Before doing that, however, you need to examine how you can use Visual Studio and some of the features provided by the .NET environment to get the best from your programs.

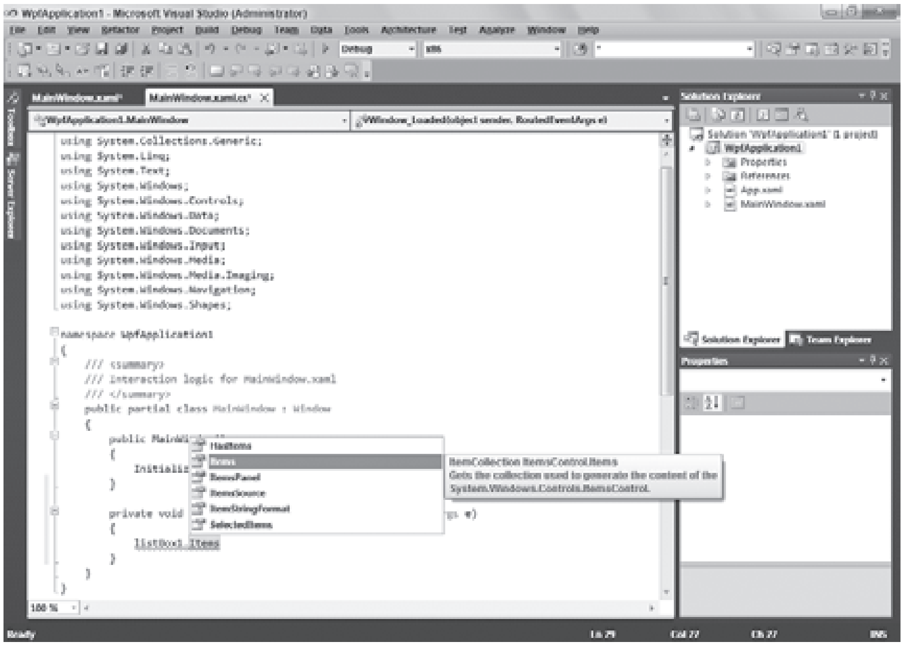
This chapter explains what programming in the .NET environment means in practice. It covers Visual Studio, the main development environment in which you will write, compile, debug, and optimize your C# programs, and provides guidelines for writing good applications. Visual Studio is the main IDE used for everything from writing Web Forms, Windows Forms, Windows Presentation Foundation (WPF) applications, and even Silverlight applications to XML Web services, and more. For more details on Windows Forms and how to write user interface code, see Chapter 39, "Windows Forms."

This chapter also explores what it takes to build applications that are targeted at the .NET Framework 4. Working with Visual Studio 2010 will provide you the ability to work with the latest application types, such as WPF, the Windows Communication Foundation (WCF), and the Windows Workflow Foundation (WF), directly.

WORKING WITH VISUAL STUDIO 2010

Visual Studio 2010 is a fully integrated development environment. It is designed to make the process of writing your code, debugging it, and compiling it to an assembly to be shipped as easy as possible. What this means is that Visual Studio gives you a very sophisticated multiple-document-interface application in which you can do just about everything related to developing your code. It offers these features:

- **Text editor** — Using this editor, you can write your C# (as well as Visual Basic 2010 and Visual C++) code. This text editor is quite sophisticated. For example, as you type, it automatically lays out your code by indenting lines, matching start and end brackets of code blocks, and color-coding keywords. It also performs some syntax checks as you type, and it underlines code that causes compilation errors, also known as design-time debugging. In addition, it features IntelliSense, which automatically displays the names of classes, fields, or methods as you begin to type them. As you start typing parameters to methods, it will also show you the parameter lists for the available overloads. Figure 16-1 shows the IntelliSense feature in action with one of the .NET base classes, `ListBox`.



```

FIGURE 16-1

By pressing Ctrl+Space, you can bring back the IntelliSense list box if you need it or if for any reason it is not visible.

- **Design view editor** — This editor enables you to place user-interface and data-access controls in your project; Visual Studio automatically adds the necessary C# code to your source files to instantiate these controls in your project. (This is possible because all .NET controls are instances of particular base classes.)
- **Supporting windows** — These windows allow you to view and modify aspects of your project, such as the classes in your source code, as well as the available properties (and their startup values) for Windows Forms and Web Forms classes. You can also use these windows to specify compilation options, such as which assemblies your code needs to reference.
- **The ability to compile from within the environment** — Instead of needing to run the C# compiler from the command line, you can simply select a menu option to compile the project, and Visual Studio will call the compiler for you and pass all the relevant command-line parameters to the compiler, detailing such things as which assemblies to reference and what type of assembly you want to be emitted (executable or library `.dll`, for example). If you want, it can also run the compiled executable

for you so that you can see whether it runs satisfactorily. You can even choose between different build configurations (for example, a release or debug build).

- **Integrated debugger** — It is in the nature of programming that your code will not run correctly the first time you try it. Or the second time. Or the third time. Visual Studio seamlessly links up to a debugger for you, allowing you to set breakpoints and watches on variables from within the environment.
- **Integrated MSDN help** — Visual Studio enables you to access the MSDN documentation from within the IDE. For example, if you are not sure of the meaning of a keyword while using the text editor, simply select the keyword and press the F1 key, and Visual Studio will access MSDN to show you related topics. Similarly, if you are not sure what a certain compilation error means, you can bring up the documentation for that error by selecting the error message and pressing F1.
- **Access to other programs** — Visual Studio can also access a number of other utilities that allow you to examine and modify aspects of your computer or network, without your having to leave the developer environment. With the tools available, you can check running services and database connections, look directly into your SQL Server tables, and even browse the Web using an Internet Explorer window.

If you have developed previously using C++ or Visual Basic, you will already be familiar with the relevant Visual Studio 6 version of the IDE, and many of the features in the preceding list will not be new to you. What is new in Visual Studio is that it combines all the features that were previously available across all Visual Studio 6 development environments. This means that regardless of what language you used in Visual Studio 6, you will find some new features in Visual Studio. For example, in the older Visual Basic environment, you could not compile separate debug and release builds. If you are coming to C# from a background of C++, though, then much of the support for data access and the ability to drop controls into your application with a click of the mouse, which has long been part of the Visual Basic developer's experience, will be new to you.

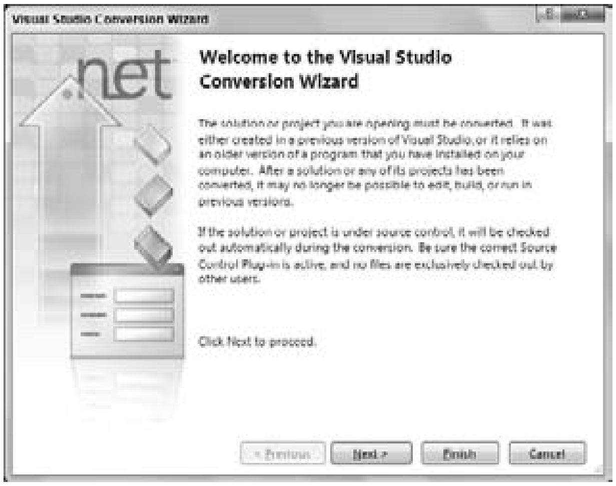
C++ developers will miss two Visual Studio 6 features in Visual Studio 2010: edit-and-continue debugging and an integrated profiler. Visual Studio 2010 also does not include a full profiler application. Instead, you will find a number of .NET classes that assist with profiling in the `System.Diagnostics` *namespace. The perfmon profiling tool is available from the command line (just type perfmon) and has a number of new .NET-related performance monitors.*

Whatever your background, you will find that the overall look of the Visual Studio 2010 developer environment has changed since the days of Visual Studio 6 to accommodate the new features, the single cross-language IDE, and the integration with .NET. There are new menu and toolbar options, and many of the existing ones from Visual Studio 6 have been renamed. Therefore, you will need to spend some time familiarizing yourself with the layout and commands available in Visual Studio 2010.

The differences between Visual Studio 2008 and Visual Studio 2010 are a few nice additions that facilitate working in Visual Studio 2010. Probably the biggest change to Visual Studio this time around is that the entire editor was rebuilt on the .NET Framework 4 and makes use of the Microsoft Extensibility Framework (MEF) as well as WPF. Visual Studio 2010 includes the ability to target specific versions of the .NET Framework (including the .NET Framework versions 2.0, 3.0, 3.5, or 4), JavaScript IntelliSense support, and outstanding abilities to work with CSS. You will also find built-in features that allow you to build ASP.NET AJAX applications as well as applications using some of the newest technical capabilities coming out of Microsoft, including the WCF, WF, and WPF.

One of the biggest items to notice with your installation of Visual Studio 2010 is that this rebuilt IDE works with the .NET Framework 4. In fact, when you install Visual Studio 2010, you will also be installing the .NET Framework 4 if it isn't already installed. Like Visual Studio 2005/2008, this new IDE, Visual Studio 2010, is not built to work with version 1.0 or 1.1 of the .NET Framework, which means that if you still want to develop 1.0 or 1.1 applications, you will want to keep Visual Studio 2002 or 2003, respectively, installed on your machine. Installing Visual Studio 2010 installs a complete and new copy of Visual Studio and does not upgrade the previous Visual Studio 2002, 2003, 2005, or 2008 IDEs. The four copies of Visual Studio will then run side by side on your machine if required.

Note that if you attempt to open your Visual Studio 2002 to 2008 projects using Visual Studio 2010, the IDE will warn you that your solution will be upgraded to Visual Studio 2010 if you continue by popping up the Visual Studio Conversion Wizard (see Figure 16-2).



Welcome to the Visual Studio Conversion Wizard

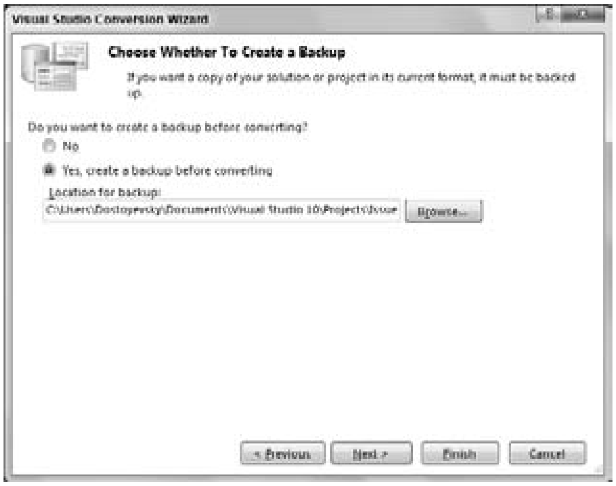
The solution or project you are opening must be converted. It was either created in a previous version of Visual Studio, or it relies on an older version of a program that you have installed on your computer. After a solution or any of its projects has been converted, it may no longer be possible to edit, build, or run in previous versions.

If the solution or project is under source control, it will be checked out automatically during the conversion. Be sure the correct Source Control Plug-in is active, and no files are exclusively checked out by other users.

Click Next to proceed.

FIGURE 16-2

The Upgrade Wizard has been dramatically improved since Visual Studio 2003 to this one provided by Visual Studio 2010. This wizard can make backup copies of the solutions prior to backing it up (see Figure 16-3), and it can also back up solutions that are contained within source control.



Choose Whether To Create a Backup

If you want a copy of your solution or project in its current format, it must be backed up.

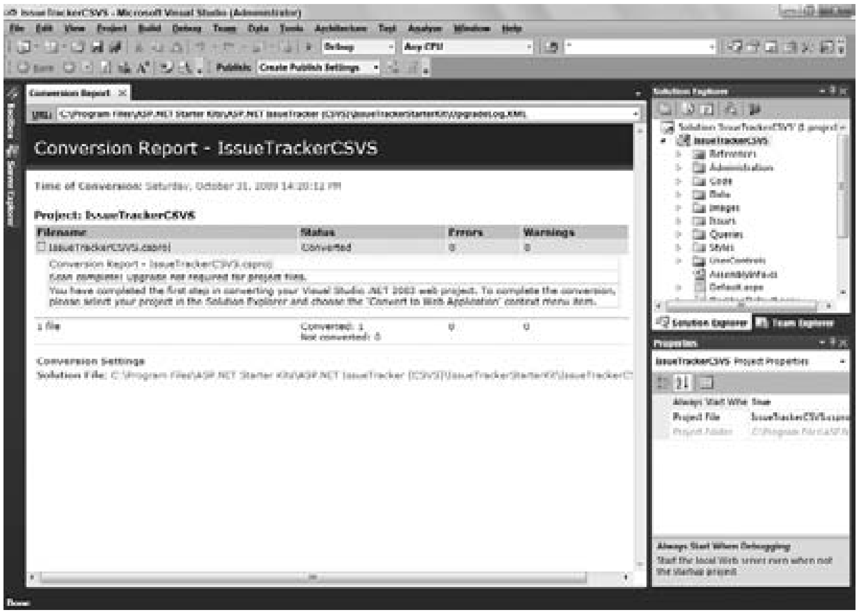
Do you want to create a backup before converting?

No [✓ Yes, create a backup before converting]

Location for backup:
C:\Users\Dostoyevsky\Documents\Visual Studio 10\Projects\Issue

FIGURE 16-3

It is also possible to have Visual Studio generate a conversion report for you in the conversion process's final step. The report will then be viewable directly in the document window of Visual Studio. This report is illustrated (done with a simple conversion) in Figure 16-4.



Conversion Report - IssueTrackerCSVS

Time of Conversion: Saturday, October 31, 2009 14:20:12 PM

Project: IssueTrackerCSVS

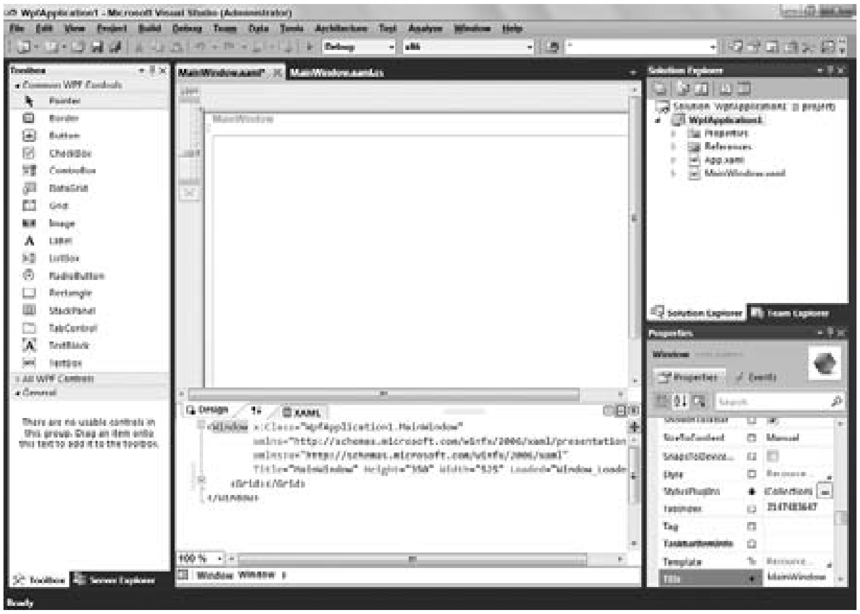
FIGURE 16-4

Because this is a professional-level book, it does not look in detail at every feature or menu option available in Visual Studio 2010. Surely, you will be able to find your way around the IDE. The real aim of this Visual Studio coverage is to ensure that you are sufficiently familiar with the concepts involved when building and debugging a C# application that you can make the most of working with Visual Studio 2010.

Figure 16-5 shows what your screen might look like when working in Visual Studio 2010. (Note that because the appearance of Visual Studio is highly customizable, the windows might not be in the same locations, or different windows might be visible when you launch this development environment.)



```
<Window x:Class="WpfApplication1.MainWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        Title="MainWindow" Height="350" Width="525" Loaded="Window_Loade
    <Grid></Grid>
</Window>
```

FIGURE 16-5

The following sections walk you through the process of creating, coding, and debugging a project, showing what Visual Studio can do to help you at each stage.

Creating a Project

Once you have installed Visual Studio 2010, you will want to start your first project. With Visual Studio, you rarely start with a blank file and then add C# code, in the way that you have been doing in the previous chapters in this book. (Of course, the option of asking for an empty application project is there if you really do want to start writing your code from scratch or if you are going to create a solution that will contain a number of projects.)

Instead, the idea is that you tell Visual Studio roughly what type of project you want to create, and it will generate the files and C# code that provide a framework for that type of project. You then work by adding your code to this outline. For example, if you want to build a Windows GUI-interface-based application (or, in .NET terminology, a Windows Form), Visual Studio will start you off with a file containing C# source code that creates a basic form. This form is capable of talking to Windows and receiving events. It can be maximized, minimized, or resized; all you need to do is add the controls and functionality you want. If your application is intended to be a command-line utility (a console application), Visual Studio will give you a basic namespace, class, and a `Main()` method to start you off.

Last, but hardly least, when you create your project, Visual Studio also sets up the compilation options that you are likely to supply to the C# compiler — whether it is to compile to a command-line application, a library, or a WPF application. It will also tell the compiler which base class libraries you will need to reference (a WPF GUI application will need to reference many of the WPF-related libraries; a console application probably will not). Of course, you can modify all these settings as you are editing, if you need to.

The first time you start Visual Studio, you will be presented with a blank IDE (see Figure 16-6). The Start Page contains various links to useful web sites and enables you to open existing projects or start a new project altogether.

Figure 16-6 shows the type of Start Page you get after you have used Visual Studio 2010; it includes a list of the most recently edited projects. You can just click one of these projects to open it again.

Selecting a Project Type

You can create a new project by selecting File ➪ New Project from the Visual Studio menu. From there you will get the New Project dialog box (see Figure 16-7) — and your first inkling of the variety of different projects you can create.

Using this dialog box, you effectively select the initial framework files and code you want Visual Studio to generate for you, the type of compilation options you want, and the compiler you want to compile your code with — either the C# 2010, Visual Basic 2010, or C++ 2010 compiler. You can immediately see the language integration that Microsoft has promised for .NET at work here! This particular example uses a C# console application.

Add to source control

FIGURE 16-7

We do not have space to cover all the various options for different types of projects here. On the C++ side, all the old C++ project types are there — MFC application, ATL project, and so on. On the Visual Basic side, the options have changed somewhat. For example, you can create a Visual Basic command-line application (Console Application), a .NET component (Class Library), a Windows Forms control (Windows Forms Control Library), and more. However, you cannot create an old-style COM-based control (the .NET control is intended to replace such ActiveX controls).

The following table lists all the options that are available to you under the Visual C# Projects. Note that some other, more specialized C# template projects are available under the Other Projects option.

IF YOU CHOOSE . . .	YOU GET THE C# CODE AND COMPILATION OPTIONS TO GENERATE . . .
Windows Forms Application	A basic empty form that responds to events.
Class Library	A .NET class that can be called up by other code.
WPF Application	A basic empty form that responds to events. Although the project type is similar to the Windows Forms Application project type (Windows Forms), this Windows Application project type allows you to build an XAML-based smart client solution.
WPF Browser Application	Quite similar to the Windows Application for WPF, this variant allows you to build an XAML-based application that is targeted at the browser.
ASP.NET Web Application	An ASP.NET-based web site: ASP.NET pages and C# classes that generate the HTML response sent to browsers from those pages. This option includes a base demo application.
Empty ASP.NET Web Application	An ASP.NET-based web site: ASP.NET pages and C# classes that generate the HTML response set to browsers from those pages. This option doesn't include the base demo application.
ASP.NET MVC 2 Web Application	A project type that allows you to create an ASP.NET MVC application.
ASP.NET MVC2 Empty Web Application	A project type that allows you to create an ASP.NET MVC application. This option doesn't include the base demo application.
ASP.NET Server Control	A control that can be called up by ASP.NET pages, to generate the HTML code that gives the appearance of a control when displayed on a browser.
ASP.NET AJAX Server Control	Allows you to build a custom server control for use within ASP.NET applications.
ASP.NET AJAX Server Control Extender	A project type that allows you to create extenders for ASP.NET server controls.
ASP.NET Dynamic Data Linq to SQL Web Application	A project type that allows you to build an ASP.NET that will take advantage of ASP.NET Dynamic Data using Linq to SQL.
ASP.NET Dynamic Data Entities Web Application	A project type that allows you to build an ASP.NET that will take advantage of ASP.NET Dynamic Data using Linq to Entities.
Silverlight Application	A project type that allows you to create a Silverlight application.
Silverlight Navigation Application	A project type that allows you to create a Silverlight application. This application starts with a core Silverlight application that can be extended for your personal needs.
Silverlight Class Library	A project type that allows you to create a Silverlight class library.
WPF Custom Control Library	A custom control that can be used in a Windows Presentation Foundation application.
WPF User Control Library	A user control library built using the Windows Presentation Foundation.
Windows Forms Control Library	A project for creating controls to use in Windows Forms applications.

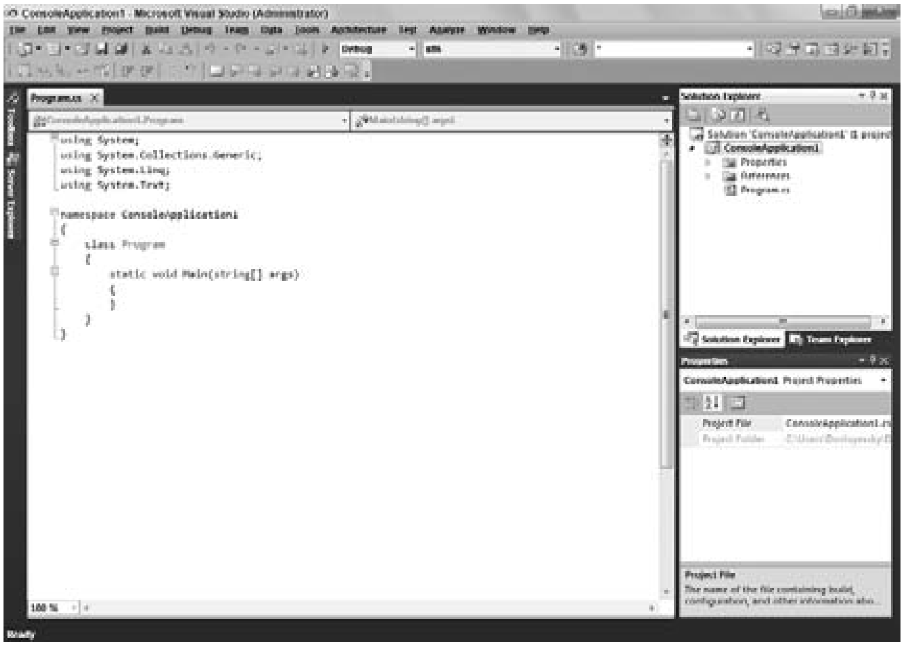
IF YOU CHOOSE . . .	YOU GET THE C# CODE AND COMPILATION OPTIONS TO GENERATE . . .
Syndication Service Library	A WCF project that allows you to build and expose a syndication service.
Console Application	An application that runs at the command-line prompt, or in a console window.
WCF Service Application	A project type for Windows Communication Foundation services.
Windows Service	A service that runs in the background on a Windows operating system.
Enable Windows Azure Tools	Allows you to load Azure-based tools for cloud computing solutions.
Reports Application	A project for creating an application with a Windows user interface and a report.
Crystal Reports Application	A project for creating a C# application with a Windows user interface and a sample Crystal Report.
Activity Designer Library	A project that provides an Activity Designer template for working with Windows Workflow.
Activity Library	A project that provides a blank Workflow Activity Library. This project provides for creating a library of activities that can later be reused as building blocks in workflows.
Workflow Console Application	A project that provides a basic console application to use with Windows Workflow.
WCF Service Library	A project that provides for creating a WCF service class library (`.dll`) that has endpoints controlled via XML configuration files.
WCF Workflow Service Application	A project type that allows you to create a WCF-based distributed communication applications that make use of Windows Workflow.
Office	A series of projects that are aimed at building applications or add-ins targeted at the Microsoft Office applications (Word, Excel, PowerPoint, InfoPath, Outlook, Visio, and SharePoint).

As mentioned, this is not a full list of the .NET Framework 4 projects, but it is a good start. The big additions to this project table are the latest projects that are aimed at the WPF, the WCF, and the WF. You will find chapters covering these new capabilities later in this book. Be sure to look at Chapter 35, "Core WPF," Chapter 43, "Windows Communication Foundation," and Chapter 44, "Windows Workflow Foundation 4."

You will also notice that new project templates are available because of the ability to search online for templates through the New Project dialog.

Reviewing the Newly Created Console Project

When you click OK after selecting the Console Application option, Visual Studio gives you a couple of files, including a source code file, `Program.cs`, which contains the initial framework code. Figure 16-8 shows what code Visual Studio has written for you.



```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Text;

namespace ConsoleApplication1
{
    class Program
    {
        static void Main(string[] args)
        {
        }
    }
}
```

FIGURE 16-8

As you can see, you have a C# program that does not do anything yet but contains the basic items required in any C# executable program: a namespace and a class that contains the `Main()` method, which is the program's entry point. (Strictly speaking, the namespace is not necessary, but it would be very bad programming practice not to declare one.) This code is all ready to compile and run, which you can do immediately by pressing the F5 key or by selecting the Debug menu and choosing Start. However, before you do that, add the following line of code — to make your application actually do something!

```
static void Main(string[] args)
   {
      Console.WriteLine("Hello from all the authors of Professional C#");
   }
```

If you compile and run the project, you will see a console window that stays onscreen barely long enough to read the message. The reason this happens is that Visual Studio, remembering the settings you specified when you created the project, arranged for it to be compiled and run as a console application. Windows then realizes that it has to run a console application but does not have a console window to run it from. Therefore, Windows creates a console window and runs the program. As soon as the program exits, Windows recognizes that it does not need the console window anymore and promptly removes it. That is all very logical but does not help you very much if you actually want to look at the output from your project!

A good way to prevent this problem is to insert the following line just before the `Main()` method returns in your code:

```
static void Main(string[] args)
{
   Console.WriteLine("Hello from all the folks at Wrox Press");
   Console.ReadLine();
}
```

That way, your code will run, display its output, and come across the `Console.ReadLine()` statement, at which point it will wait for you to press the Return (or Enter) key before the program exits. This means that the console window will hang around until you press Return.

Note that all this is only an issue for console applications that you test run from Visual Studio — if you are writing a Windows Presentation Foundation or Windows Forms application, the window displayed by the application will automatically remain onscreen until you exit it. Similarly, if you run a console application from the command-line prompt, you will not have any problems with the window disappearing.

Viewing Other Project Files

The `Program.cs` source code file is not the only file that Visual Studio has created for you. Looking in the folder in which you asked Visual Studio to create your project, you will see not just the C# file but also a complete directory structure that looks like the one shown in Figure 16-9.

The two folders, `bin` and `obj`, store compiled and intermediate files. Subfolders of `obj` hold various temporary or intermediate files; subfolders of `bin` hold the compiled assemblies.

You will also find a `Properties` folder that holds the `AssemblyInfo.cs` file. The remaining files in the project's main folder, `ConsoleApplication1`, are there for Visual Studio's benefit. They contain information about the project (for example, the files it contains) so that Visual Studio knows how to have the project compiled and how to read it in the next time you open the project.

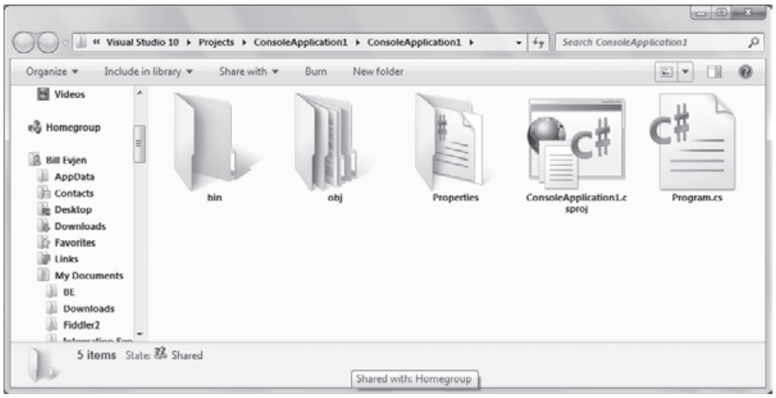


FIGURE 16-9

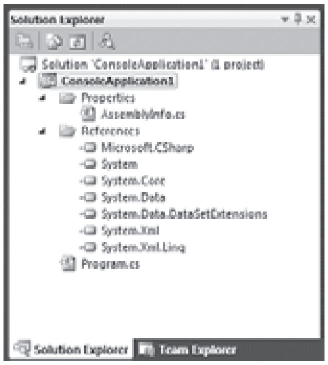
Distinguishing Projects from Solutions

One important distinction you must understand is that between a project and a solution:

- A *project* is a set of all the source code files and resources that will compile into a single assembly (or in some cases, a single module). For example, a project might be a class library or a Windows GUI application.
- A *solution* is the set of all the projects that make up a particular software package (application).

To understand this distinction, look at what happens when you ship a project — the project consists of more than one assembly. For example, you might have a user interface, custom controls, and other components that ship as libraries of the parts of the application. You might even have a different user interface for administrators. Each of these parts of the application might be contained in a separate assembly, and hence, they are regarded by Visual Studio as separate projects. However, it is quite likely that you will be coding these projects in parallel and in conjunction with each other. Thus, it is quite useful to be able to edit them all as one single unit in Visual Studio. Visual Studio allows this by regarding all the projects as forming one solution and by treating the solution as the unit that it reads in and allows you to work on.

Up until now, we have been loosely talking about creating a console project. In fact, in the example you are working on, Visual Studio has actually created a solution for you — although this particular solution contains just one project. You can see the situation in a window in Visual Studio known as the Solution Explorer (see Figure 16-10), which contains a tree structure that defines your solution.



```
Solution Explorer
Solution 'ConsoleApplication1' (1 project)
  ConsoleApplication1
    Properties
      AssemblyInfo.cs
    References
      Microsoft.CSharp
      System
      System.Core
      System.Data
      System.Data.DataSetExtensions
      System.Xml
      System.Xml.Linq
    Program.cs
Solution Explorer | Team Explorer
```

FIGURE 16-10

Figure 16-10 shows that the project contains your source file, `Program.cs`, as well as another C# source file, `AssemblyInfo.cs` (found in the `Properties` folder), which allows you to provide information that describes the assembly as well as the ability to specify versioning information. (You look at this file in detail in Chapter 18, "Assemblies.") The Solution Explorer also indicates the assemblies that your project references according to namespace. You can see this by expanding the `References` folder in the Solution Explorer.

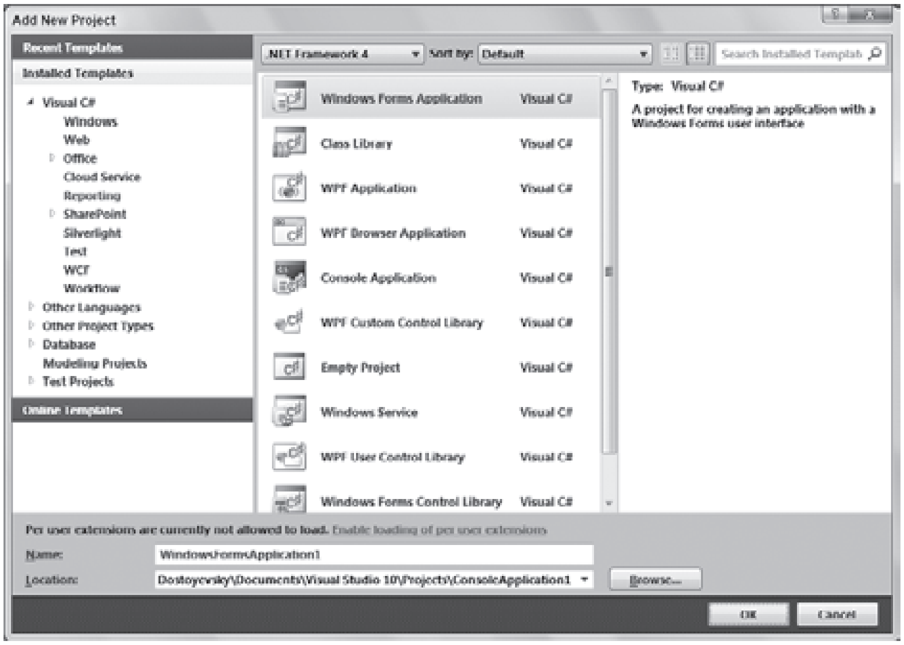
If you have not changed any of the default settings in Visual Studio, you will probably find the Solution Explorer in the top-right corner of your screen. If you cannot see it, just go to the View menu and select Solution Explorer.

The solution is described by a file with the extension `.sln` — in this example, it is `ConsoleApplication1.sln`. The project is described by various other files in the project's main folder. If you attempt to edit these files using Notepad, you will find that they are mostly plain-text files, and, in accordance with the principle that .NET and .NET tools rely on open standards wherever possible, they are mostly in XML format.

Adding Another Project to the Solution

As you work through the following sections, you will see how Visual Studio works with Windows applications as well as with console applications. To that end, you create a Windows project called `BasicForm` that you will add to your current solution, `ConsoleApplication1`.

You can create the new project in two ways. You can select New Project from the File menu (as you have done already) or you can select Add ➪ New Project from the File menu. If you select New Project from the File menu, this will bring up the familiar Add New Project dialog box; this time, however, you will notice that Visual Studio wants to create the new project in the preexisting `ConsoleApplication1` project location (see Figure 16-11).



Type: Visual C#

A project for creating an application with a Windows Forms user interface

Per user extensions are currently not allowed to load. Enable loading of per user extensions

Name: WindowsFormsApplication1

Location: Dostoyevsky\Documents\Visual Studio 10\Projects\ConsoleApplication1

FIGURE 16-11

If you select this option, a new project is added so that the `ConsoleApplication1` solution now contains a console application and a Windows application.

In accordance with the language independence of Visual Studio, the new project does not need to be a C# project. It is perfectly acceptable to put a C# project, a Visual Basic project, and a C++ project in the same solution. However, we will stick with C# here because this is a C# book!

Of course, this means that `ConsoleApplication1` is not really an appropriate name for the solution anymore! To change the name, you can right-click the name of the solution and select Rename from the context menu. Call the new solution `DemoSolution`. The Solution Explorer window now looks like Figure 16-12.

You can see from this that Visual Studio has made your newly added Windows project automatically reference some of the extra base classes that are important for Windows Forms functionality.

You will notice if you look in Windows Explorer that the name of the solution file has changed to `DemoSolution.sln`. In general, if you want to rename any files, the Solution Explorer window is the best place to do so, because Visual Studio will then automatically update any references to that file in the other project files. If you rename files using just Windows Explorer, you might break the solution because Visual Studio will not be able to locate all the files it needs to read into the IDE. You will then need to manually edit the project and solution files to update the file references.

Setting the Startup Project

Bear in mind that if you have multiple projects in a solution, only one of them can be run at a time! When you compile the solution, all the projects in it will be compiled. However, you must specify which one you want Visual Studio to start running when you press F5 or select Start. If you have one executable and several libraries that it calls, this will clearly be the executable. In this case, where you have two independent executables in the project, you would simply need to debug each in turn.

You can tell Visual Studio which project to run by right-clicking that project in the Solution Explorer window and selecting Set as Startup Project from the context menu. You can tell which one is the current startup project — it is the one that appears in bold in the Solution Explorer window (`ConsoleApplication1` in Figure 16-12).

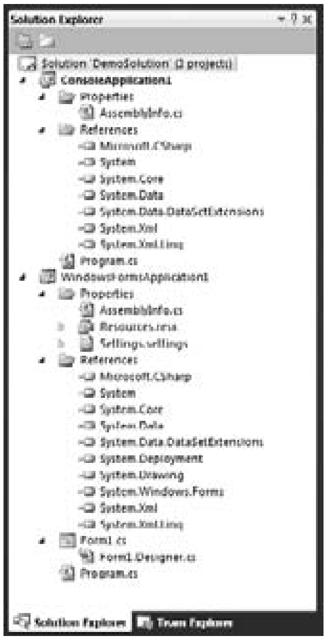


FIGURE 16-12

Windows Application Code

A Windows application contains a lot more code right from the start than a console application when Visual Studio first creates it. That is because creating a window is an intrinsically more complex process. Chapter 39, "Windows Forms," discusses the code for a Windows application in detail. For now, look at the code in the `Form1` class in the `WindowsApplication1` project to see for yourself how much is auto-generated.

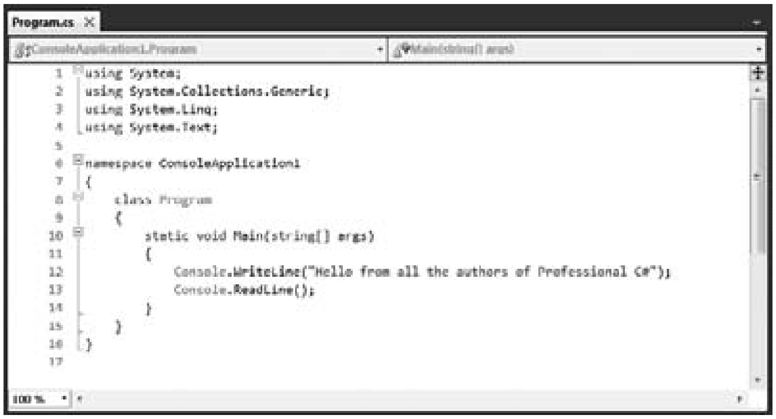
Exploring and Coding a Project

This section looks at the features that Visual Studio provides to help you add code to your project.

The Folding Editor

One really exciting feature of Visual Studio is its use of a folding editor as its default code editor.

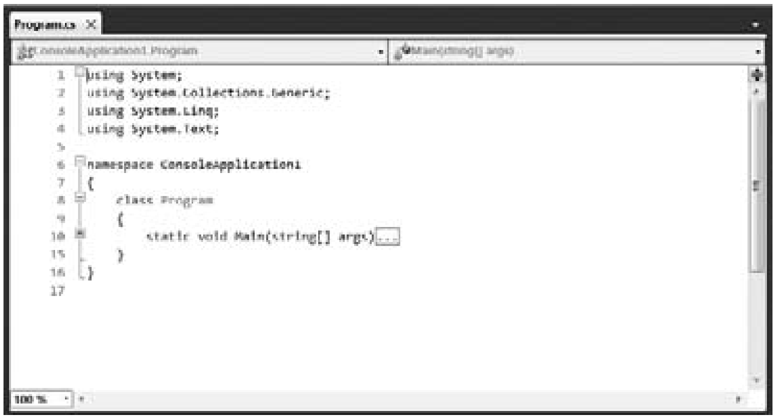
Figure 16-13 shows the code for the console application that you generated earlier. Notice those little minus signs on the left-hand side of the window. These signs mark the points where the editor assumes that a new block of code (or documentation comment) begins. You can click these icons to close up the view of the corresponding block of code just as you would close a node in a tree control (see Figure 16-14).



```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Text;

namespace ConsoleApplication1
{
    class Program
    {
        static void Main(string[] args)
        {
            Console.WriteLine("Hello from all the authors of Professional C#");
            Console.ReadLine();
        }
    }
}
```

FIGURE 16-13

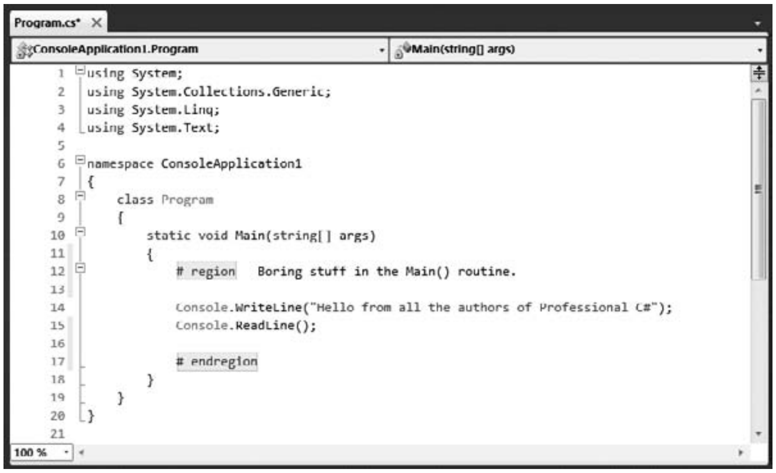


```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Text;

namespace ConsoleApplication1
{
    class Program
    {
        static void Main(string[] args)...
    }
}
```

FIGURE 16-14

This means that while you are editing you can focus on just the areas of code you want to look at, and you can hide the bits of code you are not interested in working with at that moment. If you do not like the way the editor has chosen to block off your code, you can indicate your own blocks of collapsing code with the C# preprocessor directives, `#region` and `#endregion`, which were examined earlier in the book. For example, to collapse the code inside the `Main()` method, you would add the code shown in Figure 16-15.



```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Text;

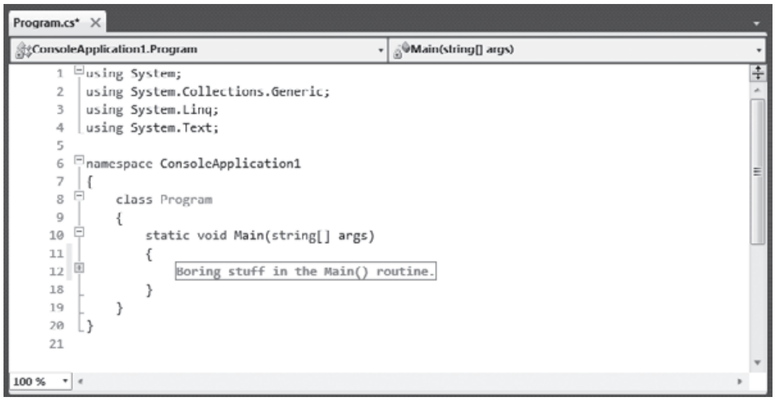
namespace ConsoleApplication1
{
    class Program
    {
        static void Main(string[] args)
        {
            # region   Boring stuff in the Main() routine.

            Console.WriteLine("Hello from all the authors of Professional C#");
            Console.ReadLine();

            # endregion
        }
    }
}
```

FIGURE 16-15

The code editor will automatically detect the `#region` block and place a new minus sign by the `#region` directive, as shown in Figure 16-15, allowing you to close the region. Enclosing this code in a region means that you can get the editor to close the block of code (see Figure 16-16), marking the area with the comment you specified in the `#region` directive. The compiler, however, ignores the directives and compiles the `Main()` method as normal.



```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Text;

namespace ConsoleApplication1
{
    class Program
    {
        static void Main(string[] args)
        {
            Boring stuff in the Main() routine.
        }
    }
}
```

FIGURE 16-16

In addition to the folding editor feature, Visual Studio's code editor brings across all the familiar functionality from Visual Studio 6. In particular, it features IntelliSense, which not only saves you typing but also ensures that you use the correct parameters. C++ developers will notice that the Visual Studio IntelliSense feature is a bit more robust than the Visual Studio 6 version and works more quickly. You will also notice that IntelliSense has been improved since Visual Studio 2005. It is now smarter in that it remembers your preferred choices and starts with one of these choices instead of starting directly at the beginning of the sometimes rather lengthy lists that IntelliSense can now provide.

The code editor also performs some syntax checking on your code and underlines most syntax errors with a short wavy line, even before you compile the code. Hovering the mouse pointer over the underlined text brings up a small box telling you what the error is. Visual Basic developers have been familiar with this feature, known as *design-time debugging*, for years; now C# and C++ developers can benefit from it as well.

Other Windows

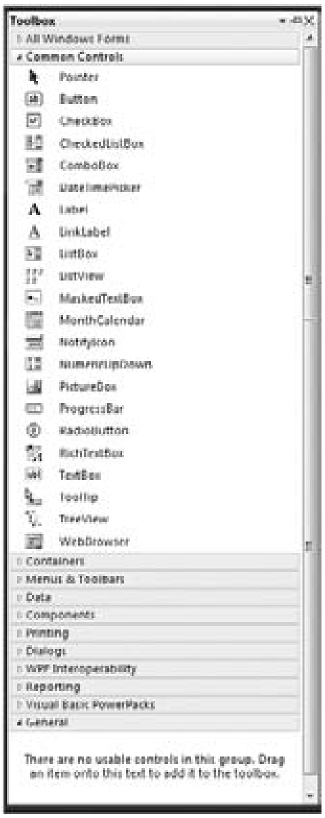
In addition to the code editor, Visual Studio provides a number of other windows that allow you to view your project from different points of view.

The Design View Window

If you are designing a user interface application, such as a Windows application, Windows control library, or an ASP.NET application, you will use the Design View window. This window presents a visual overview of what your form will look like. You normally use the Design View window in conjunction with a window known as the toolbox. The toolbox contains a large number of .NET components that you can drag onto your program (see Figure 16-17).

Visual Studio 2010 provides a toolbox with a large number of components that are available for your development purposes. The categories of components available through the toolbox depend, to some extent, on the type of project you are editing — for example, you will get a far wider range when you are editing the `WindowsFormsApplication1` project in the `DemoSolution` solution than you will when you are editing the `ConsoleApplication1` project. The most important ranges of items available include the following:

- **Data** — Classes that allow you to connect to data sources and manage the data they contain. Here, you will find components for working with Microsoft SQL Server, Oracle, and any OleDb data source.
- **Windows Forms Controls (labeled as Common Controls)** — Classes that represent visual controls such as text boxes, list boxes, or tree views for working with thick-client applications.
- **Web Forms Controls (labeled as Standard)** — Classes that basically do the same thing as Windows controls but work in the context of web browsers, and that work by sending HTML output to simulate the controls to the browser. (You will see this only when working with ASP.NET applications.)
- **Components** — Miscellaneous .NET classes that perform various useful tasks on your machine, such as connecting to directory services or to the event log.



There are no usable controls in this group. Drag an item onto this text to add it to the toolbox.

FIGURE 16-17

You can also add your own custom categories to the toolbox by right-clicking any category and selecting Add Tab from the context menu. You can also place other tools in the toolbox by selecting Choose Items from the same context menu — this is particularly useful for adding your favorite COM components and ActiveX controls, which are not present in the toolbox by default. If you add a COM control, you can still click to place it in your project just as you would with a .NET control. Visual Studio automatically adds all the required COM interoperability code to allow your project to call up the control. In this case, what is actually added to your project is a .NET control that Visual Studio creates behind the scenes and that acts as a wrapper for your COM control.

To see how the toolbox works, place a text box in your basic form project. You simply click the `TextBox` control contained within the toolbox and then click again to place it in the form in the design view (or if you prefer, you can simply drag and drop the control directly onto the design surface). Now the design view looks like Figure 16-18, showing roughly what `WindowsFormsApplication1` will look like if you compile and run it.

If you look at the code view of your form, you can see that Visual Studio 2010 does not add the code that instantiates a `TextBox` object to go on the form directly as it did in the early versions of the IDE. Instead, you will need to expand the plus sign next to `Form1.cs` in the Visual Studio Solution Explorer. Here, you will find a file that is dedicated to the design of the form and the controls that are placed on the form — `Form1.Designer.cs`. In this class file, you will find a new member variable in the `Form1` class:

```
partial class Form1
{
    private System.Windows.Forms.TextBox textBox1;
```

There is also some code to initialize it in the method, `InitializeComponent()`, which is called from the `Form1` constructor:

```
/// <summary>
/// Required method for Designer support — do not modify
/// the contents of this method with the code editor.
/// </summary>
private void InitializeComponent()
{
            this.textBox1 = new System.Windows.Forms.TextBox();
            this.SuspendLayout();
            //
            // textBox1
            //
            this.textBox1.Location = new System.Drawing.Point(0, 0);
            this.textBox1.Name = "textBox1";
            this.textBox1.Size = new System.Drawing.Size(100, 20);
            this.textBox1.TabIndex = 0;
            //
            // Form1
            //
            this.AutoScaleDimensions = new System.Drawing.SizeF(6F, 13F);
            this.AutoScaleMode = System.Windows.Forms.AutoScaleMode.Font;
            this.ClientSize = new System.Drawing.Size(284, 265);
            this.Controls.Add(this.textBox1);
            this.Name = "Form1";
            this.Text = "Form1";
            this.ResumeLayout(false);
            this.PerformLayout();

}
```

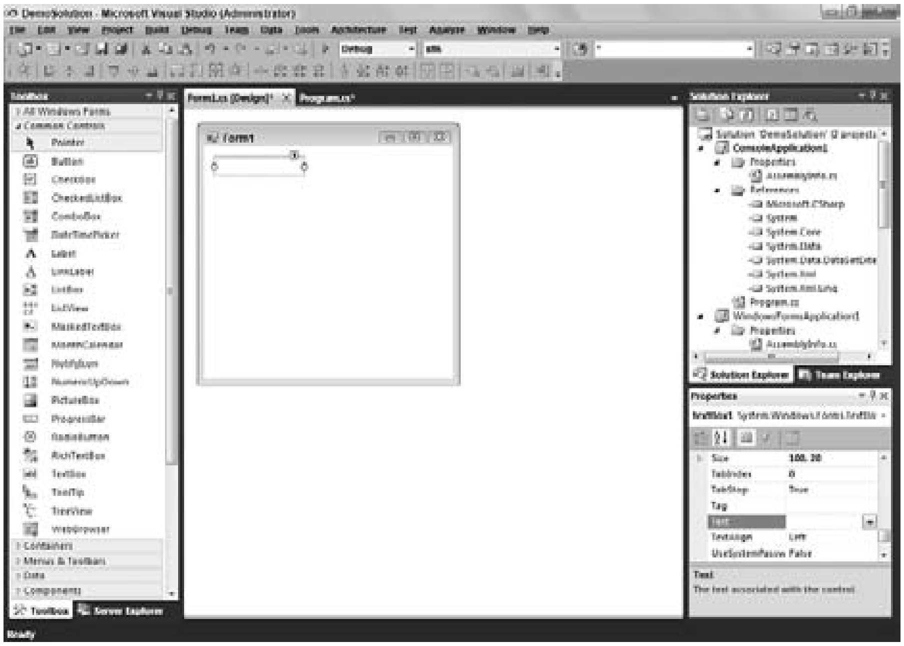


FIGURE 16-18

In one sense, there is no difference between the code editor and the design view; they simply present different views of the same code. What actually happened when you clicked to add the `TextBox` to the design view is that the editor placed the preceding extra code in your C# source file for you. The design view simply reflects this change because Visual Studio is able to read your source code and determine from it what controls should be around when the application starts up. This is a fundamental shift from the old Visual Basic way of looking at things, in which everything was based around the visual design. Now, your C# source code is what fundamentally controls your application, and the design view is just a different way of viewing the source code. Incidentally, if you do write any Visual Basic 2010 code with Visual Studio, you will find the same principles at work.

If you had wanted to, you could have worked the other way around. If you had manually added the same code to your C# source files, Visual Studio would have automatically detected from the code that your application contained a `TextBox` control and would have shown it in the design view at the designated position. It is best to add these controls visually, and let Visual Studio handle the initial code generation — it is a lot quicker and less error-prone to click the mouse button a couple of times than to type a few lines of code!

Another reason for adding these controls visually is that, to recognize that they are there, Visual Studio does need the relevant code to conform to certain criteria — and code that you write by hand might not do so. In particular, you will notice that the `InitializeComponent()` method that contains the code to initialize the `TextBox` is commented to warn you against modifying it. That is because this is the method that Visual Studio looks at to determine what controls are around when your application starts up. If you create and define a control somewhere else in your code, Visual Studio will not be aware of it, and you will not be able to edit it in the design view or in certain other useful windows.

In fact, despite the warnings, you can modify the code in `InitializeComponent()`, provided that you are careful. There is generally no harm in changing the values of some of the properties, for example, so that a control displays different text or so that it is a different size. In practice, the developer studio is pretty robust when it comes to working around any other code you place in this method. Just be aware that if you make too many changes to `InitializeComponent()`, you do run the risk that Visual Studio will not recognize some of your controls. We should stress that this will not affect your application in any way whatsoever when it is compiled, but it might disable some of the editing features of Visual Studio for those controls. Hence, if you want to add any other substantial initialization, it is probably better to do so in the `Form1` constructor or in some other method.

The Properties Window

This is another window that has its origins in the old Visual Basic IDE. You know from the first part of the book that .NET classes can implement properties. In fact, as you will discover when building Windows Forms (see Chapter 39), the .NET base classes that represent forms and controls have a lot of properties that define their action or appearance — properties such as `Width`, `Height`, `Enabled` (whether the user can type input to the control), and `Text` (the text displayed by the control) — and Visual Studio knows about many of these properties. The Properties window, shown in Figure 16-19, appears and allows you to edit the initial values of most of these properties for the controls that Visual Studio has been able to detect by reading your source code.

At the top of the Properties window is a list box that allows you to select which control you want to view. In the example in this chapter, you have selected `Form1`, the main form class for your `WindowsFormsApplication1` project, and have edited the text to "Basic Form — Hello!" If you now check the source code, you can see that what you have actually done is edit the source code — using a friendlier user interface:

```
this.AutoScaleDimensions = new System.Drawing.SizeF(6F, 13F);
this.AutoScaleMode = System.Windows.Forms.AutoScaleMode.Font;
this.ClientSize = new System.Drawing.Size(284, 265);
this.Controls.Add(this.textBox1);
this.Name = "Form1";
this.Text = "Basic Form – Hello";
this.ResumeLayout(false);
this.PerformLayout();
```

Not all the properties shown in the Properties window are explicitly mentioned in your source code. For those that are not, Visual Studio will display the default values that were set when the form was created and that are set when the form is actually initialized. Obviously, if you change a value for one of these properties in the Properties window, a statement explicitly setting that property will magically appear in your source code — and vice versa. It is interesting to note that if a property is changed from its original value, this property will then appear in bold type within the list box of the Properties window. Sometimes double-clicking the property in the Properties window returns the value to its original value.

The Properties window provides a convenient way to get a broad overview of the appearance and properties of a particular control or window.

FIGURE 16-19

The Class View Window

Unlike the Properties window, the Class View window, shown in Figure 16-20, owes its origins to the C++ (and J++) developer environments. The class view is not actually treated by Visual Studio as a window in its own right — rather it is an additional tab in the Solution Explorer window. By default, the class view will not even appear in the Visual Studio Solution Explorer. To invoke the class view, select View ➪ Class View. The class view (see Figure 16-20) shows the hierarchy of the namespaces and classes in your code. It gives you a tree view that you can expand to see which namespaces contain what classes and what classes contain what members.

A nice feature of the class view is that if you right-click the name of any item for which you have access to the source code, then the context menu features the Go To Definition option, which takes you to the definition of the item in the code editor. Alternatively, you can do this by double-clicking the item in class view (or, indeed, by right-clicking the item you want in the source code editor and choosing the same option from the resulting context menu). The context menu also gives you the option to add a field, method, property, or indexer to a class. This means that you specify the details of the relevant member in a dialog box, and the code is added for you. This might not be that useful for fields or methods, which can be quickly added to your code; however, you might find this feature helpful for properties and indexers, where it can save you quite a bit of typing.

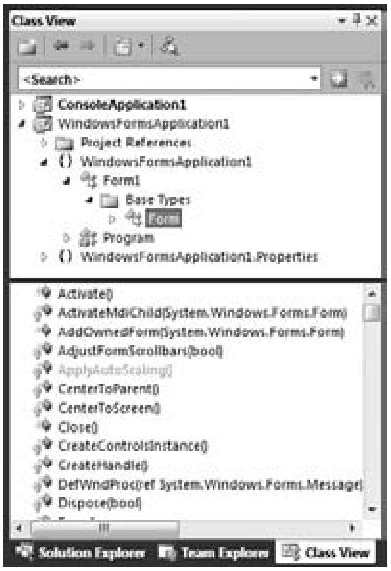

FIGURE 16-20

The Object Browser Window

One important aspect of programming in the .NET environment is being able to find out what methods and other code items are available in the base classes and any other libraries that you are referencing from your assembly. This feature is available through a window called the Object Browser. You can access this window by selecting Object Browser from the View menu in Visual Studio 2010.

The Object Browser window is quite similar to the Class View window in that it displays a tree view that gives the class structure of your application, allowing you to inspect the members of each class. The user interface is slightly different in that it displays class members in a separate pane rather than in the tree view itself. The real difference is that it lets you look at not just the namespaces and classes in your project but also the ones in all the assemblies referenced by the project. Figure 16-21 shows the Object Browser viewing the `SystemException` class from the .NET base classes.

One note of caution with the Object Browser is that it groups classes by the assembly in which they are located first and by namespace second. Unfortunately, because namespaces for the base classes are often spread across several assemblies, this means you might have trouble locating a particular class unless you know what assembly it is in.

The Object Browser is there to view .NET objects. If for any reason you want to investigate installed COM objects, you will find that the OLEView tool previously used in the C++ IDE is still available — it is located in the folder `C:\Program Files\Microsoft SDKs\Windows\v6.0A\bin` along with several other similar utilities.

The Server Explorer Window

You can use the Server Explorer window, shown in Figure 16-22, to find out about aspects of the computers in your network while coding.

As you can see from the screenshot, among the things you can access through the Server Explorer are database connections, information about services, event logs, and more.

The Server Explorer is linked to the Properties window so that if you open the Services node, for example, and click a particular service, the properties of that service will be displayed in the Properties window.

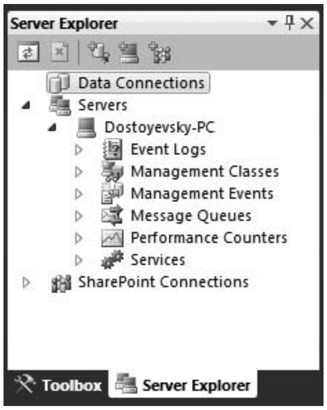

FIGURE 16-22

Pin Buttons

While exploring Visual Studio, you might have noticed that many of the windows have some interesting functionality more reminiscent of toolbars. In particular, apart from the code editor, they can all be docked. Another feature of them is that when they are docked, they have an extra icon that looks like a pin next to the minimize button in the top-right corner of each window. This icon really does act like a pin — it can be used to pin the windows open. When they are pinned (the pin is displayed vertically), they behave just like the regular windows that you are used to. When they are unpinned, however (the pin is displayed horizontally), they remain open only as long as they have the focus. As soon as they lose the focus (because you clicked or moved your mouse somewhere else), they smoothly retreat into the main border around the entire Visual Studio application. (You can also feel the speed of your computer by how quickly or slowly they open and close.)

Pinning and unpinning windows provides another way of making the best use of the limited space on your screen. It has not really been seen a great deal in Windows before, though a few third-party applications, such as PaintShop Pro, have used similar concepts. Pinned windows have, however, been around on many UNIX-based systems for quite a while.

Building a Project

Visual Studio is not only about coding your projects. It is actually an IDE that manages the full lifecycle of your project including the building or compiling of your solutions. This section examines the options that Visual Studio gives you for building your project.

Building, Compiling, and Making

Before examining the various build options, it is important to clarify some terminology. You will often see three different terms used in connection with the process of getting from your source code to some sort of executable code: compiling, building, and making. The origin of these various terms comes from the fact that until recently, the process of getting from source code to executable code involved more than one step (and this is still the case in C++). This was due in large part to the number of source files in a program.

In C++, for example, each source file needs to be compiled individually. This leads to what are known as object files, each containing something like executable code, but where each object file relates to only one source file. To generate an executable, these object files need to be linked together, a process that is officially known as linking. The combined process was usually referred to — at least on the Windows platform — as building your code. However, in C# terms the compiler is more sophisticated and is able to read in and treat all your source files as one block. Hence, there is not really a separate linking stage, so in the context of C#, the terms *compile* and *build* are used interchangeably.

In addition to this, the term *make* basically means the same thing as *build,* although it is not really used in the context of C#. The term originated on old mainframe systems on which, when a project was composed of many source files, a separate file would be written that contained instructions to the compiler on how to build a project — which files to include and what libraries to link to and so on. This file was generally known as a make file and is still quite standard on UNIX systems. Make files are not normally needed on Windows, although you can still write them (or get Visual Studio to generate them) if you need to.

Debugging and Release Builds

The idea of having separate builds is very familiar to C++ developers, and to a lesser degree, to those with a Visual Basic background. The point here is that when you are debugging, you typically want your executable to behave differently from when you are ready to ship the software. When you are ready to ship your software, you want the size of the executable to be as small as possible and the executable itself to be as fast as possible. Unfortunately, these requirements are not compatible with your needs when you are debugging code, as explained in the following sections.

Optimization

High performance is achieved partly by the compiler doing many optimizations on the code. This means that the compiler actively looks at your source code as it is compiling to identify places where it can modify the precise details of what you are doing in a way that does not change the overall effect, but that makes things more efficient. For example, if the compiler encountered the following source code:

```
double InchesToCm(double Ins)
{
   return Ins*2.54;
}

// later on in the code

Y = InchesToCm(X);
```

it might replace it with this:

```
Y = X * 2.54;
```

Or it might replace this code:

```
{
   string Message = "Hi";
   Console.WriteLine(Message);
}
```

with this:

```
Console.WriteLine("Hi");
```

By doing so, it bypasses having to declare an unnecessary object reference in the process.

It is not possible to exactly pin down what optimizations the C# compiler does — nor whether the two previous examples actually would occur with any particular example — because those kinds of details are not documented. (Chances are that for managed languages such as C#, the previous optimizations would occur at JIT compilation time, not when the C# compiler compiles source code to assembly.) For obvious commercial reasons, companies that write compilers are usually quite reluctant to give too many details about the tricks that their compilers use. We should stress that optimizations do not affect your source code — they affect only the contents of the executable code. However, the previous examples should give you a good idea of what to expect from optimizations.

The problem is that although optimizations like the previous ones help a great deal in making your code run faster, they are not that helpful for debugging. Suppose that, in the first example, you want to set a breakpoint inside the `InchesToCm()` method to see what is going on in there. How can you possibly do that if the executable code does not actually have an `InchesToCm()` method because the compiler has removed it? Moreover, how can you set a watch on the `Message` variable when that does not exist in the compiled code either?

Debugger Symbols

When you are debugging, you often have to look at values of variables, and you will specify them by their source code names. The trouble is that executable code generally does not contain those names — the compiler replaces the names with memory addresses. .NET has modified this situation somewhat to the extent that certain items in assemblies are stored with their names, but this is only true of a small minority of items — such as public classes and methods — and those names will still be removed when the assembly is JIT-compiled. Asking the debugger to tell you what the value is in the variable called `HeightInInches` is not going to get you very far if, when the debugger examines the executable code, it sees only addresses and no reference to the name `HeightInInches` anywhere. Therefore, to debug properly, you need to have extra debugging information made available in the executable. This information includes, among other things, names of variables and line information that allows the debugger to match up which executable machine assembly language instructions correspond to your original source code instructions. You will not, however, want that information in a release build, both for commercial reasons (debugging information makes it a lot easier for other people to disassemble your code) and because it increases the size of the executable.

Extra Source Code Debugging Commands

A related issue is that quite often while you are debugging there will be extra lines in your code to display crucial debugging-related information. Obviously, you want the relevant commands removed entirely from the executable before you ship the software. You could do this manually, but wouldn't it be so much easier if you could simply mark those statements in some way so that the compiler ignores them when it is compiling your code to be shipped? You've already seen in the first part of the book how this can be done in C# by defining a suitable processor symbol, and possibly using this in conjunction with the `Conditional` attribute, giving you what is known as *conditional compilation*.

What all these factors add up to is that you need to compile almost all commercial software in a slightly different way when debugging than in the final product that is shipped. Visual Studio is able to consider this because, as you have already seen, it stores details of all the options that it is supposed to pass to the compiler when it has your code compiled. All that Visual Studio has to do to support different types of builds is to store more than one set of such details. The different sets of build information are referred to as configurations. When you create a project, Visual Studio automatically gives you two configurations, called Debug and Release:

➤ The Debug configuration commonly specifies that no optimizations are to take place, extra debugging information is to be present in the executable, and the compiler is to assume that the debug preprocessor symbol `Debug` is present unless it is explicitly `#undefined` in the source code.

➤ The Release configuration specifies that the compiler should optimize the compilation, that there should be no extra debugging information in the executable, and that the compiler should not assume that any particular preprocessor symbol is present.

You can define your own configurations as well. You might want to do this, for example, if you want to set up professional-level builds and enterprise-level builds so that you can ship two versions of the software. In the past, because of issues concerning the Unicode character encodings being supported on Windows NT but not on Windows 95, it was common for C++ projects to feature a Unicode configuration and an MBCS (multi-byte character set) configuration.

Selecting a Configuration

One obvious question is that, because Visual Studio stores details of more than one configuration, how does it determine which one to use when arranging for a project to be built? The answer is that there is always an active configuration, which is the configuration that will be used when you ask Visual Studio to build a project. (Note that configurations are set for each project rather than for each solution.)

By default, when you create a project, the Debug configuration is the active configuration. You can change which configuration is the active one by clicking the Build menu option and selecting the Configuration Manager item. It is also available through a drop-down menu in the main Visual Studio toolbar.

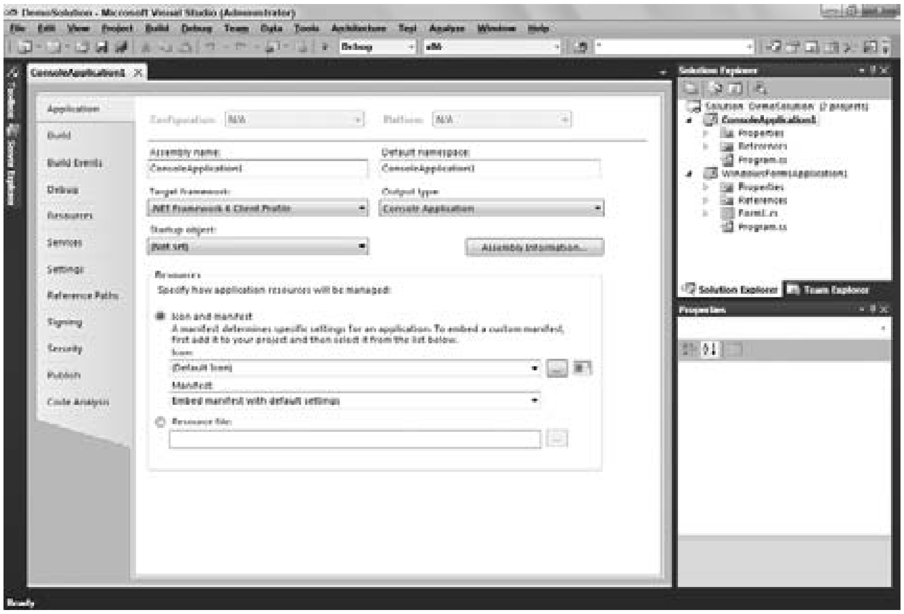
Editing Configurations

In addition to choosing the active configuration, you can also examine and edit the configurations. To do this, you select the relevant project in the Solution Explorer and then select the Properties from the Project menu. This brings up a very sophisticated dialog box. (Alternatively, you can access the same dialog box by right-clicking the name of the project in the Solution Explorer and then selecting Properties from the context menu.)

This dialog contains a tree view, which allows you to select many different general areas to examine or edit. We do not have space to show all of these areas, but we will show a couple of the most important ones.

Figure 16-23 shows a tabbed view of the available properties for a particular application. This screenshot shows the general application settings for the `ConsoleApplication1` project that you created earlier in the chapter.

Among the points to note are that you can select the name of the assembly as well as the type of assembly to be generated. The options here are Console Application, Windows Application, and Class Library. Of course, you can change the assembly type if you want. (Though arguably, if you want, you might wonder why you did not pick the correct project type at the time that you asked Visual Studio to generate the project for you in the first place!)



Configuration: N/A   Platform: N/A

Assembly name: ConsoleApplication1
Default namespace: ConsoleApplication1
Target framework: .NET Framework 4 Client Profile
Output type: Console Application
Startup object: (Not set)

Resources
Specify how application resources will be managed:
Icon and manifest
A manifest determines specific settings for an application. To embed a custom manifest, first add it to your project and then select it from the list below.
Icon: (Default Icon)
Manifest: Embed manifest with default settings
Resource file:

References
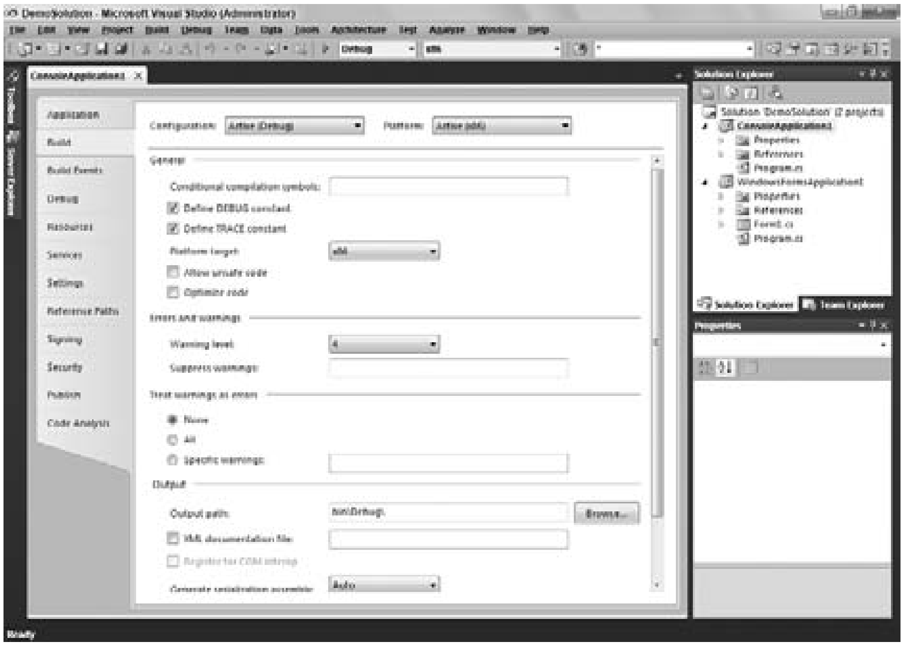
Form1.cs
Program.cs

FIGURE 16-23

Figure 16-24 shows the build configuration properties. You will notice that a list box near the top of the dialog box allows you to specify which configuration you want to look at. You can see — in the case of the Debug configuration — that the compiler assumes that the `DEBUG` and `TRACE` preprocessor symbols have been defined. In addition, the code is not optimized and extra debugging information is generated.

In general, it is not that often that you will need to adjust the configuration settings. However, if you ever do need to use them, you now know the difference between the available configuration properties.



Configuration: Active (Debug)
Platform: Active (x86)

General

Conditional compilation symbols:
[✓] Define DEBUG constant
[✓] Define TRACE constant
Platform target: x86
[ ] Allow unsafe code
[ ] Optimize code

Warning level: 4
Suppress warnings:

Treat warnings as errors

(●) None
( ) All
( ) Specific warnings:

Output

Output path: bin\Debug\
[ ] XML documentation file:
[ ] Register for COM interop
Generate serialization assembly: Auto

FIGURE 16-24

Debugging Your Code

After the long discussion about building and build configurations, you might be surprised to learn that this chapter is not going to spend a great deal of time discussing debugging itself. The reason for that is that the principles and the process of debugging — setting breakpoints and examining the values of variables — is not really significantly different in Visual Studio from any of the various Visual Studio 6 IDEs. Instead, this section briefly reviews the features offered by Visual Studio, focusing on those areas that might be new to some developers. It also discusses how to deal with exceptions, because these can cause problems during debugging.

In C#, as in pre-.NET languages, the main technique involved in debugging is simply setting breakpoints and using them to examine what is going on in your code at a certain point in its execution.

Breakpoints

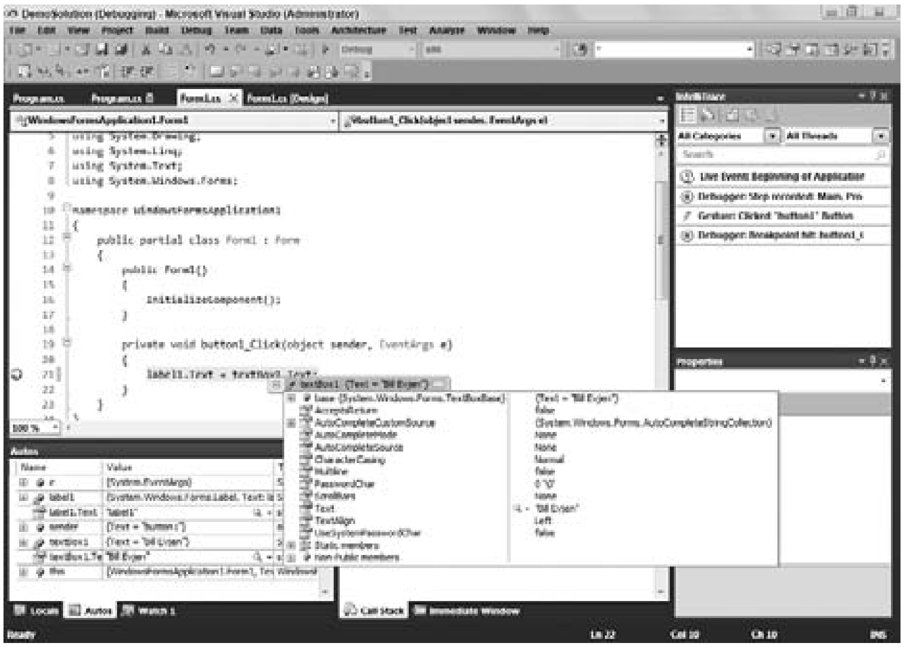
You can set breakpoints from Visual Studio on any line of your code that is actually executed. The simplest way is to click the line in the code editor, within the shaded area toward the far left of the document window (or press the F9 key when the appropriate line is selected). This sets up a breakpoint on that particular line, which causes execution to break and control to be transferred to the debugger as soon as that line is reached in the execution process. As in previous versions of Visual Studio, a breakpoint is indicated by a large circle to the left of the line in the code editor. Visual Studio also highlights the line by displaying the text and background in a different color. Clicking the circle again removes the breakpoint.

If breaking every time at a particular line is not adequate for your particular problem, you can also set conditional breakpoints. To do this, select Debug ➪ Windows ➪ Breakpoints. This brings up a dialog box asking you for details of the breakpoint you want to set. Among the options available, you can:

- Specify that execution should break only after the breakpoint has been passed a certain number of times.
- Specify that the breakpoint should come into effect only every so many times that the line is reached, for example, every 20th time that a line is executed. (This is useful when debugging large loops.)
- Set the breakpoints relative to a variable rather than to an instruction. In this case, the value of the variable will be monitored and the breakpoints will be triggered whenever the value of this variable changes. You might find, however, that using this option slows down your code considerably. Checking whether the value of a variable has changed after every instruction adds a lot of processor time.

Watches

After a breakpoint has been hit, you will usually want to investigate the values of variables. The simplest way to do this is to hover the mouse cursor over the name of the variable in the code editor. This causes a little box that shows the value of that variable to pop up, which can also be expanded to greater detail. This is shown in Figure 16-25.



```
using System.Drawing;
using System.Linq;
using System.Text;
using System.Windows.Forms;

namespace WindowsFormsApplication1
{
    public partial class Form1 : Form
    {
        public Form1()
        {
            InitializeComponent();
        }

        private void button1_Click(object sender, EventArgs e)
        {
            label1.Text = textBox1.Text;
        }
    }
```

```
textBox1 {Text = "Bill Evjen"}
  base {System.Windows.Forms.TextBoxBase}   {Text = "Bill Evjen"}
  AcceptsReturn                             false
  AutoCompleteCustomSource                  {System.Windows.Forms.AutoCompleteStringCollection}
  AutoCompleteMode                          None
  AutoCompleteSource                        None
  CharacterCasing                           Normal
  Multiline                                 false
  PasswordChar                              0 '\0'
  ScrollBars                                None
  Text                                      "Bill Evjen"
  TextAlign                                 Left
  UseSystemPasswordChar                     false
  Static members
  Non-Public members
```

Name	Value
e	{System.EventArgs}
label1	{System.Windows.Forms.Label, Text: label1}
label1.Text	"label1"
sender	{Text = "button1"}
textBox1	{Text = "Bill Evjen"}
textBox1.Text	"Bill Evjen"
this	{WindowsFormsApplication1.Form1, Text: Windows}

FIGURE 16-25

However, you might also prefer to use the Autos window to examine the contents of variables. The Autos window (shown in Figure 16-26) is a tabbed window that appears only when the program is running under the debugger. If you do not see it, try selecting Debug ➪ Windows ➪ Autos.

Variables that are classes or structs are shown with a + icon next to them, which you can click to expand the variable and see the values of its fields.

The three tabs to this window are each designed to monitor different variables:

- **Autos** monitors the last few variables that have been accessed as the program was executing.
- **Locals** monitors variables that are accessible in the method currently being executed.
- **Watch** monitors any variables that you have explicitly specified by typing their names into the Watch window.

FIGURE 16-26

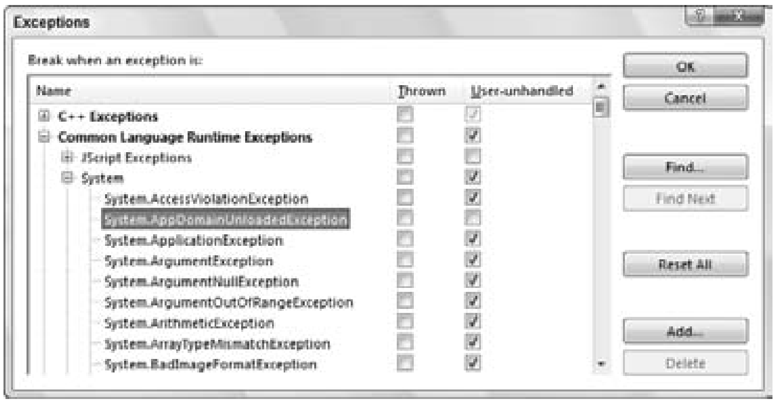
Exceptions

Exceptions are great when you ship your application and for making sure that error conditions are handled in an appropriate way within your application. Used well, they can ensure that your application copes with difficulties well and that the user is never presented with a technical dialog box. Unfortunately, exceptions are not so great when you are trying to debug your application. The problem is twofold:

- If an exception occurs when you are debugging, you often do not want it to be handled automatically — especially if automatically handling it means retiring gracefully and terminating execution! Rather, you want the debugger to help you find why the exception has occurred. Of course, the trouble is that if you have written good, robust, defensive code, your program will automatically handle almost anything — including the bugs that you want to detect!
- If an exception occurs that you have not written a handler for, the .NET runtime will still go off looking for a handler. However, by the time it discovers that there is not one, it will have terminated your program. There will not be a call stack left, and you will not be able to look at the values of any of your variables because they will all have gone out of scope.

Of course, you can set breakpoints in your catch blocks, but that often does not help very much because when the `catch` block is reached, flow of execution will, by definition, have exited the corresponding `try` block. That means that the variables you probably wanted to examine the values of to figure out what has gone wrong will have gone out of scope. You will not even be able to look at the stack trace to find what method was being executed when the `throw` statement occurred — because control will have left that method. Setting the breakpoints at the `throw` statement will of course solve this, except that if you are coding defensively, there will be many `throw` statements in your code. How can you tell which one is the one that threw the exception?

In fact, Visual Studio provides a very neat answer to all of this. If you look into the main Debug menu, you will find a menu item called Exceptions. This item opens the Exceptions dialog box (see Figure 16-27), which allows you to specify what happens when an exception is thrown. You can choose to continue execution or to stop and start debugging — in which case execution stops and the debugger steps in at the `throw` statement itself.



Break when an exception is:

Name	Thrown	User-unhandled
C++ Exceptions	☐	✓
Common Language Runtime Exceptions	☐	✓
JScript Exceptions	☐	☐
System	☐	✓
System.AccessViolationException	☐	✓
System.AppDomainUnloadedException	☐	☐
System.ApplicationException	☐	✓
System.ArgumentException	☐	✓
System.ArgumentNullException	☐	✓
System.ArgumentOutOfRangeException	☐	✓
System.ArithmeticException	☐	✓
System.ArrayTypeMismatchException	☐	✓
System.BadImageFormatException	☐	✓

FIGURE 16-27

What makes this a really powerful tool is that you can customize the behavior according to which class of exception is thrown. For example, in Figure 16-27, we have told Visual Studio to break into the debugger whenever it encounters any exception thrown by a .NET base class, but not to break into the debugger if the exception is an `AppDomainUnloadedException`.

Visual Studio knows about all the exception classes available in the .NET base classes, and about quite a few exceptions that can be thrown outside the .NET environment. Visual Studio is not automatically aware of your own custom exception classes that you write, but you can manually add your exception classes to the list and thereby specify which of your exceptions should cause execution to stop immediately. To do this, just click the Add button (which is enabled when you have selected a top-level node from the tree) and type in the name of your exception class.

REFACTORING TOOLS

Many developers develop their applications first for functionality and then, once the functionality is in place, they *rework* their applications to make them more manageable and more readable. This is called *refactoring*. Refactoring is the process of reworking code for readability, performance, providing type safety, and lining applications up to better adhere to standard OO (object-oriented) programming practices.

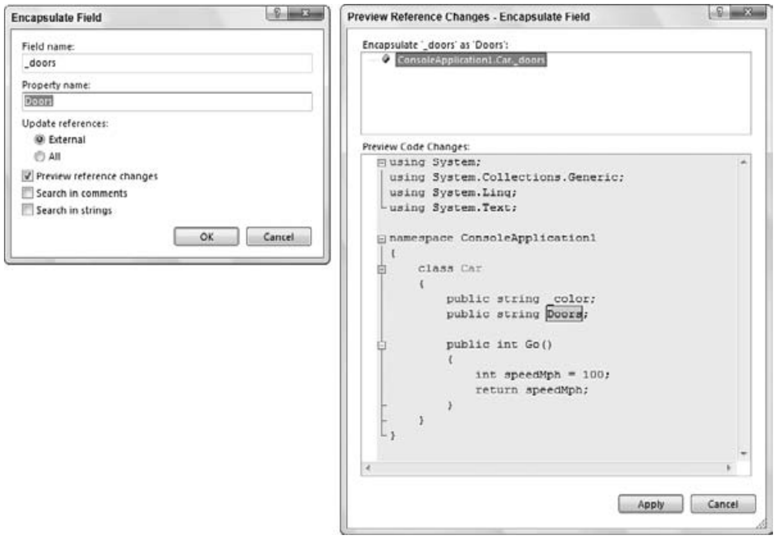
For this reason, the C# environment of Visual Studio 2010 includes a set of refactoring tools. You can find these tools under the Refactoring option in the Visual Studio menu. To show this in action, create a new class called `Car` in Visual Studio:

```
using System;
using System.Collections.Generic;
using System.Text;

namespace ConsoleApplication1
{
    public class Car
    {
        public string _color;
        public string _doors;

        public int Go()
        {
            int speedMph = 100;
            return speedMph;
        }
    }
}
```

Now, suppose that in the idea of refactoring, you want to change the code a bit so that the `color` and the `door` variables are encapsulated in public .NET properties. The refactoring capabilities of Visual Studio 2010 allow you to simply right-click either of these properties in the document window and select Refactor ➪ Encapsulate Field. This will pull up the Encapsulate Field dialog shown in Figure 16-28.



Field name: _doors

Property name: Doors

Update references: (● External) ○ All

[✓] Preview reference changes
[ ] Search in comments
[ ] Search in strings

Encapsulate '_doors' as 'Doors':

ConsoleApplication1.Car._doors

Preview Code Changes:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Text;

namespace ConsoleApplication1
{
    class Car
    {
        public string _color;
        public string Doors;

        public int Go()
        {
            int speedMph = 100;
            return speedMph;
        }
    }
}
```

FIGURE 16-28

From this dialog, you can provide the name of the property and click the OK button. This will turn the selected public field into a private field, while also encapsulating the field in a public .NET property. After you click OK, the code will be reworked into the following (after redoing both fields):

```
namespace ConsoleApplication1
{
    public class Car
    {
        private string _color;

        public string Color
        {
            get { return _color; }
            set { _color = value; }
        }
        private string _doors;

        public string Doors
        {
            get { return _doors; }
            set { _doors = value; }
        }

        public int Go()
        {
            int speedMph = 100;
            return speedMph;
        }
    }
}
```

As you can see, these wizards make it quite simple to refactor your code not just on one page but also for an entire application. Also included are the capabilities to do the following:

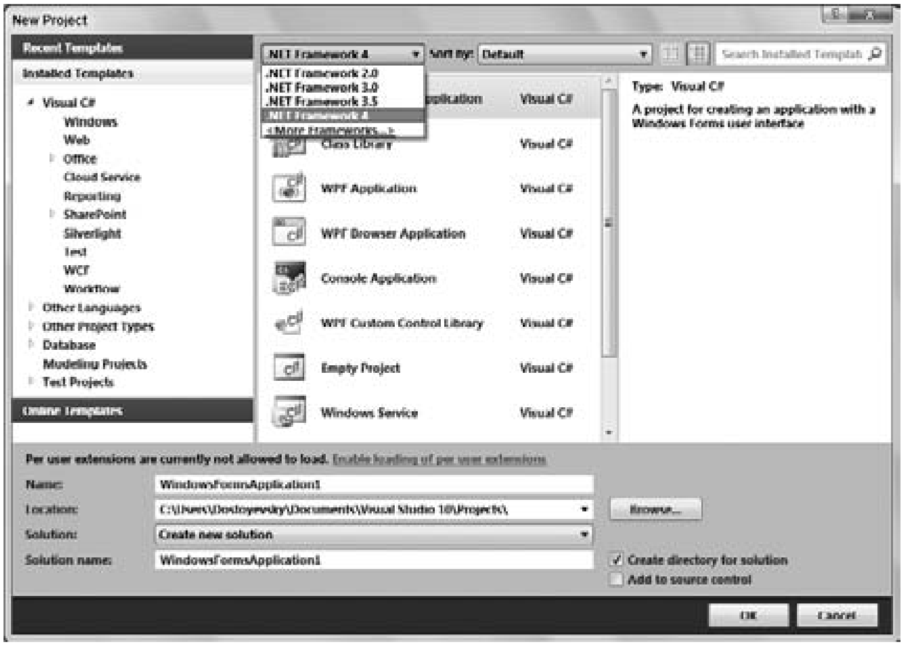
- Rename method names, local variables, fields, and more
- Extract methods from a selection of code
- Extract interfaces based on a set of existing type members
- Promote local variables to parameters
- Rename or reorder parameters

You will find the refactoring capabilities provided by Visual Studio 2010 a great way to get the cleaner, more readable, better-structured code that you are looking for.

MULTI-TARGETING THE .NET FRAMEWORK

Visual Studio 2010 allows you to target the version of the .NET Framework that you want to work with. When you open the New Project dialog and get ready to create a new project, you will notice that there is a drop-down list in the upper-right corner of the dialog that allows you to pick the version of the framework that you are interested in using. This dialog is presented in Figure 16-29.

From this figure, you can see that the drop-down list provides you with the ability to target the .NET Frameworks 2.0, 3.0, 3.5, and 4. When you use the upgrade dialog to upgrade a Visual Studio 2008 solution to Visual Studio 2010, it is important to understand that you are only upgrading the solution to *use* Visual Studio 2010 and that you are not upgrading your project to the .NET Framework 4. Your project will stay on the framework version you were using, but now, you will be able use the new Visual Studio 2010 to work on your project.



Type: Visual C#

A project for creating an application with a Windows Forms user interface

Per user extensions are currently not allowed to load. Enable loading of per user extensions

Name: WindowsFormsApplication1

Location: C:\Users\Devtoyevsky\Documents\Visual Studio 10\Projects\

Solution: Create new solution

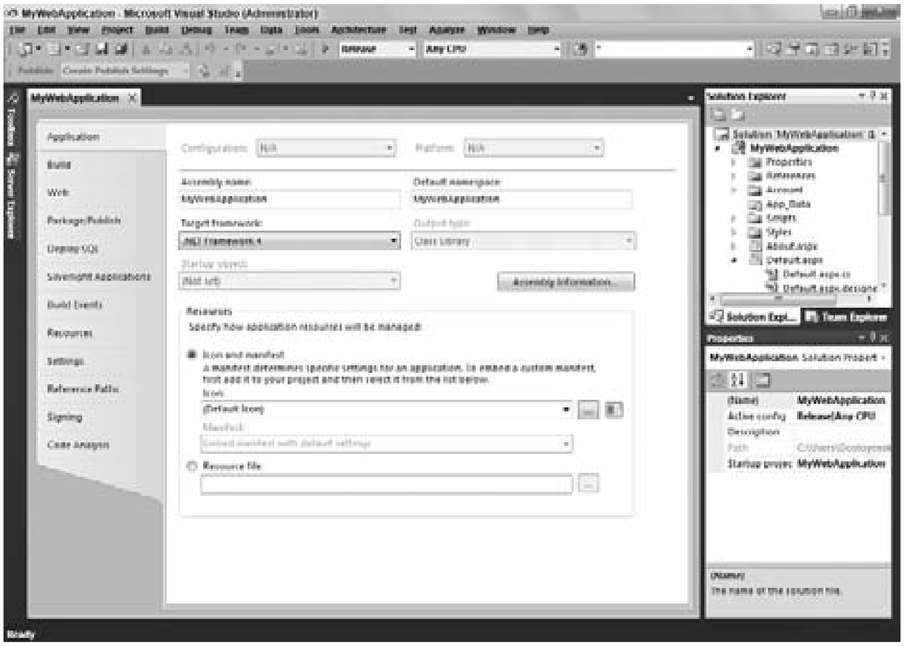
Solution name: WindowsFormsApplication1

[✓] Create directory for solution

[ ] Add to source control

FIGURE 16-29

If you want to change the version of the framework the solution is using, right-click the project and select the properties of the solution. If you are working with an ASP.NET project, you will get a dialog as shown in Figure 16-30.



Configuration: N/A
Platform: N/A
Assembly name: MyWebApplication
Default namespace: MyWebApplication
Target framework: .NET Framework 4
Output type: Class Library
Startup object: (Not set)
Resources
Specify how application resources will be managed:
Icon and manifest
A manifest determines specific settings for an application. To embed a custom manifest, first add it to your project and then select it from the list below.
Icon: (Default Icon)
Manifest: Embed manifest with default settings
Resource file:

(Name)	MyWebApplication
Active config	Release|Any CPU
Description	
Path	C:\Users\...
Startup project	MyWebApplication

FIGURE 16-30

From this dialog, the Application tab will provide you with the ability to change the version of the framework that the application is using.

WPF, WCF, WF, AND MORE

By default, Visual Studio 2005 did not allow you to build applications targeted at the .NET Framework 3.0, which was out during the VS2005 lifetime. The default installation of Visual Studio 2005 was targeted only at the .NET Framework 2.0. To start working with the new technologies targeted at the .NET Framework 3.0, you had to do a few extra installs.

The .NET Framework 3.0 provided you with access to a class library for building application types such as applications that make use of the Windows Presentation Foundation (WPF), the Windows Communication Foundation (WCF), the Windows Workflow Foundation (WF), and Windows CardSpace.

The targeted framework capabilities of Visual Studio 2010 allow you to build these types of applications using either the .NET Framework 3.0, 3.5, or 4.

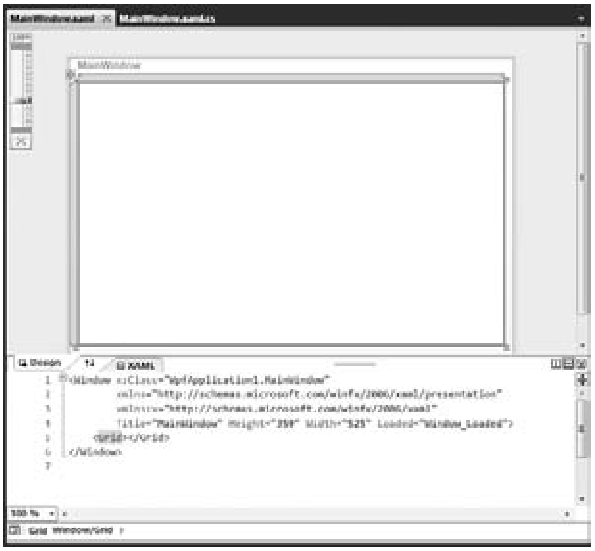
FIGURE 16-31

Building WPF Applications in Visual Studio 2010

One good example of some of the capabilities that the .NET Framework 4 brings to Visual Studio is the WPF Application project type (found in the Windows category). Selecting this project type will create a `MainWindow.xaml` and `MainWindow.xaml.cs` file for you to work from. Everything that is created by default with this project type in the Solution Explorer is presented in Figure 16-31 (shown here with a searchable Properties dialog).

Right away, you will notice options available to you in Visual Studio 2010 in the document window. The default view of the document window after creating this project is presented in Figure 16-32.



```
<Window x:Class="WpfApplication1.MainWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        Title="MainWindow" Height="350" Width="525" Loaded="Window_Loaded">
    <Grid></Grid>
</Window>
```

FIGURE 16-32

The document window has two views — a design view and an XAML view. Making changes in the design view will make the appropriate changes in the XAML view, and vice versa. As with traditional Windows Forms applications, WPF applications also include the ability to use controls that are contained within Visual Studio's toolbox. This toolbox of controls is presented in Figure 16-33.

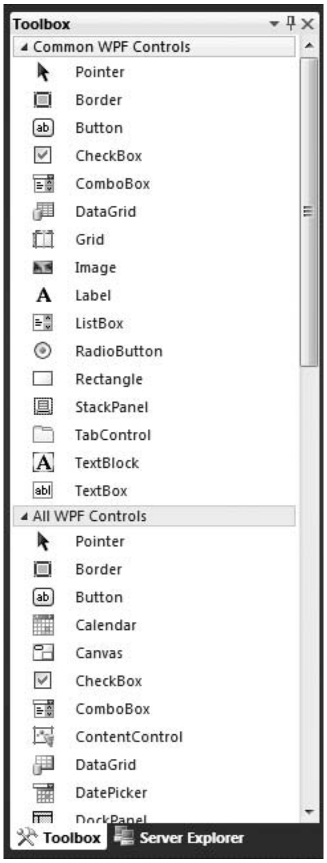


FIGURE 16-33

Building WF Applications in Visual Studio 2010

Another dramatically different application style (when it comes to building the application from within Visual Studio) is the Windows Workflow application type. For an example of this, select the Workflow Console Application project type from the Workflow section of the New Project dialog. This will create a console application as illustrated here with a view of the Solution Explorer (see Figure 16-34).

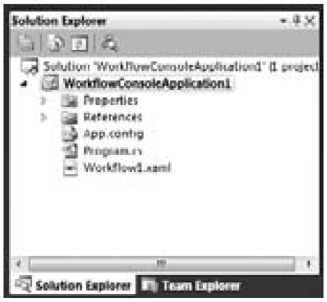

FIGURE 16-34

You will notice when building applications that make use of the Windows Workflow Foundation that there is a heavy dependency on the design view. Looking closely at the workflow (see Figure 16-35), you can see that it is made up of multiple sequential steps and even includes actions based on conditions (such as an `if-else` statement).

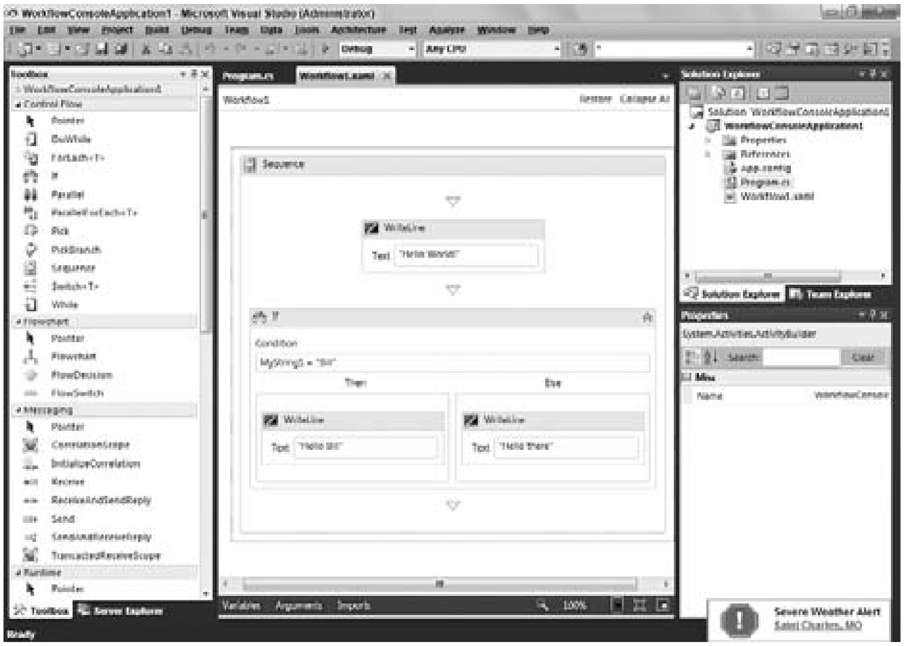

FIGURE 16-35

SUMMARY

This chapter explored one of the most important programming tools in the .NET environment — Visual Studio 2010. The bulk of the chapter examined how this tool facilitates writing code in C# (and C++ and Visual Basic).

Visual Studio 2010 is one of the easiest development environments to work with in the programming world. You will find that Visual Studio makes Rapid Application Development (RAD) easy to achieve, but at the same time, you can dig deep into the mechanics of how your applications are created. This chapter focused on using Visual Studio for everything from refactoring to multi-targeting to reading in Visual Studio 6 projects to debugging. It also covered many of the windows available to Visual Studio.

This chapter also looked at some of the latest projects available to you through the .NET Framework 4. These project types focused on the Windows Presentation Foundation, the Windows Communication Foundation, and the Windows Workflow Foundation.

Chapter 17 presents the deployment situation in detail.

17 Deployment

WHAT'S IN THIS CHAPTER?

- Deployment requirements
- Simple deployment scenarios
- Windows Installer-based projects
- ClickOnce technology

The development process does not end when the source code is compiled and the testing is complete. At that stage, the job of getting the application into the user's hands begins. Whether it's an ASP.NET application, a smart client application, or an application built using the Compact Framework, the software must be deployed to a target environment. The .NET Framework has made deployment much easier than it was in the past. The pains of registering COM components and writing new hives to the registry are all gone.

This chapter looks at the options that are available for application deployment, both from an ASP.NET perspective and from the smart client perspective.

PLANNING FOR DEPLOYMENT

Often, deployment is an afterthought in the development process that can lead to nasty, if not costly, surprises. To avoid grief in deployment scenarios, you should plan the deployment process during the initial design stage. Any special deployment considerations — such as server capacity, desktop security, or where assemblies will be loaded from — should be built into the design from the start, resulting in a much smoother deployment process.

Another issue that you should address early in the development process is the environment in which to test the deployment. Whereas unit testing of application code and of deployment options can be done on the developer's system, the deployment must be tested in an environment that resembles the target system. This is important to eliminate the dependencies that don't exist on a targeted computer. An example of this might be a third-party library that has been installed on the developer's computer early in the project. The target computer might not have this library on it. It can be easy to forget to include it in the deployment package. Testing on the developer's system would not uncover the error because the library already exists. Documenting dependencies can help to eliminate this potential problem.

Deployment processes can be complex for a large application. Planning for the deployment can save time and effort when the deployment process is implemented.

Choosing the proper deployment option must be done with the same care and planning as any other aspect of the system being developed. Choosing the wrong option will make the process of getting the software into the users' hands difficult and frustrating.

Deployment Options

This section provides an overview of the deployment options that are available to .NET developers. Most of these options are discussed in greater detail later in this chapter.

- **Xcopy** — The xcopy utility lets you copy an assembly or group of assemblies to an application folder, cutting down on your development time. Because assemblies are self-discovering (that is, the metadata that describes the assembly is included in the assembly), you do not need to register anything in the registry.

  Each assembly keeps track of what other assemblies it requires to execute. By default, the assembly looks in the current application folder for the dependencies. The process of moving (or probing) assemblies to other folders is discussed later in this chapter.

- **Publishing web sites** — When a web site is published, the entire site is compiled and then copied to a specified location. As a result of precompiling, all source code is removed from the final output and all compile errors can be found and dealt with.
- **Deployment projects** — Visual Studio 2010 has the capability to create setup programs for an application. There are four options based on Microsoft Windows Installer technology:
  - Creating merge modules,
  - Creating a setup for client applications,
  - Creating a setup for web applications, and
  - Creating a setup for Smart Device-based (Compact Framework) applications.

  The ability to create cab files is also available. Deployment projects offer a great deal of flexibility and customization for the setup process. One of these deployment options will be useful for larger applications.

- **ClickOnce technology** — The ClickOnce technology offers a way to build self-updating Windows-based applications. ClickOnce allows an application to be published to a web site, file share, or even a CD. As updates and new builds are made to the application, they can be published to the same location or site by the development team. As the application is used by the end user, it checks the location to see if an update is available. If there is, an update is attempted.

Deployment Requirements

It is instructive to look at the runtime requirements of a .NET-based application. The CLR has certain requirements on the target platform before any managed application can execute.

The first requirement that must be met is the operating system. Currently, the following operating systems can run .NET-based applications:

- Windows XP SP3
- Windows Vista SP1
- Windows 7

The following server platforms are supported:

- Windows 2003 Server Family SP2
- Windows 2008 Server Family (Server Core Role not supported)

The following architectures are supported:

- x86
- x64
- ia64 (some features not supported)

Other requirements are Windows Internet Explorer version 5.01 or later, MDAC version 2.8 or later (if the application is designed to access data), and Internet Information Services (IIS) for ASP.NET applications.

You also must consider hardware requirements when deploying .NET applications. The minimum hardware requirements for both the client and the server are a Pentium 400 MHz and 96 MB RAM

For best performance, increase the amount of RAM — the more RAM the better your .NET application runs. This is especially true for server applications.

Deploying the .NET Runtime

When an application is developed using .NET, there is a dependency on the .NET runtime. This may seem rather obvious, but sometimes the obvious can be overlooked. The following table shows the version number and the filename that would have to be distributed:

.NET VERSION	FILENAME
2.0.50727.42	dotnetfx.exe
3.0.4506.30	dotnetfx3.exe (includes x86 and x64)
3.5.21022.8	dotnetfx35.exe (includes x86, x64, and ia64)
4.0.0.0	dotnetfx40.exe (includes x86, x64, and ia64)

SIMPLE DEPLOYMENT OPTIONS

If deployment is part of an application's original design considerations, deployment can be as simple as copying a set of files to the target computer. For a web application, it can be a simple menu choice in Visual Studio 2010. This section discusses these simple deployment scenarios.

To see how the various deployment options are set up, you must have an application to deploy. The sample download at `www.wrox.com` contains four projects:

- `ClientWinForms`
- `ClientWPF`
- `WebClient`
- `AppSupport`

`ClientWinForms` and `ClientWPF` are smart client applications using `WinForms` and `WPF`, respectively. `WebClient` is a simple web app. `AppSupport` is a class library that contains one simple class that returns a string with the current date and time.

The sample applications use `AppSupport` to fill a label with a string containing the current date. To use the examples, first load and build `AppSupport`. Then, in each of the other applications, set a reference to the newly built `AppSupport.dll`.

Here is the code for the `AppSupport` assembly:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Text;

namespace AppSupport
{
    public class DateService
    {
        public string GetLongDateInfoString()
        {
            return string.Concat("Today's date is ", DateTime.Now.ToLongDateString());
        }

        public string GetShortDateInfoString()
        {
            return string.Concat("Today's date is ", DateTime.Now.ToShortDateString());
        }
    }
}
```

code snippet Dateservice.cs

This simple assembly suffices to demonstrate the deployment options available to you.

Xcopy Deployment

Xcopy deployment is a term used for the process of copying a set of files to a folder on the target machine and then executing the application on the client. The term comes from the DOS command `xcopy.exe`. Regardless of the number of assemblies, if the files are copied into the same folder, the application will execute — rendering the task of editing the configuration settings or registry obsolete.

To see how an xcopy deployment works, execute the following steps:

1. Open the `ClientWinForms` solution (`ClientWinForms.sln`) that is part of the sample download file.
2. Change the target to Release and do a full compile.
3. Use either My Computer or File Explorer to navigate to the project folder `\ClientWinForms\bin\Release` and double-click `ClientWinForms.exe` to run the application.
4. Click the button to see the current date displayed in the two textboxes. This verifies that the application functions properly. Of course, this folder is where Visual Studio placed the output, so you would expect the application to work.
5. Create a new folder and call it `ClientWinFormsTest`. Copy the two files from the release folder to this new folder and then delete the release folder. Again, double-click the `ClientWinForms.exe` file to verify that it's working.

That's all there is to it; xcopy deployment provides the ability to deploy a fully functional application simply by copying the assemblies to the target machine. Just because the example that is used here is simple does not mean that this process cannot work for more complex applications. There really is no limit to the size or number of assemblies that can be deployed using this method. The reason that you might not want to use xcopy deployment is the ability to place assemblies in the Global Assembly Cache (GAC) or the ability to add icons to the Start menu. Also, if your application still relies on a COM library of some type, you will not be able to register the COM components easily.

Xcopy and Web Applications

Xcopy deployment can also work with web applications with the exception of the folder structure. You must establish the virtual directory of your web application and configure the proper user rights. This process is generally accomplished with the IIS administration tool.

After the virtual directory is set up, the web application files can be copied to the virtual directory. Copying a web application's files can be a bit tricky. A couple of configuration files, as well as the images that the pages might be using, need to be accounted for.

Publishing a Web Site

Another deployment option for web projects is to publish the web site. Publishing a web site will precompile the entire site and place the compiled version into a specified location. The location can be a file share, FTP location, or any other location that can be accessed via HTTP. The compilation process strips all source code from the assemblies and creates the DLLs for deployment. This also includes the markup contained in the `.ASPX` source files. Instead of containing the normal markup, the `.ASPX` files contain a pointer to an assembly. Each `.ASPX` file relates to an assembly. This process works regardless of the model: code-behind or single file.

The advantages of publishing a web site are speed and security. Speed is enhanced because all the assemblies are already compiled. Otherwise, the first time a page is accessed there is a delay while the page and dependent code is compiled and cached. The security is enhanced because the source code is not deployed. Also, because everything is precompiled before deployment all compilation errors will be found.

You publish a web site from the Build - Publish menu choice. In the Publish Method drop-down menu, you can choose MSDeploy Publish, FTP, or file system. The FTP option will ask for the FTP address as well as any login credentials that will be needed. The file system option will ask for the path to the target location. The MSDeploy Publish option is the interesting option.

You can define many properties for the deployment of your web site from the Package and Publish tab of the project properties page. You can define what files should be included, including debug information. Database information from the Deploy Sql tab can be included. This information includes connection strings, schema information and database script options.

You can also select packaging options from here. A zip file that contains everything you need to install your web site will be generated. Along with the zip file, three other files will be generated:

- `projectname.deploy.cmd` — A command file used by MSDeploy to install the web site.
- `projectname.SetParameters.xml` — An XML file that contains different parameters to pass to the Web Deployment Tool. This can be used to deploy to different servers or in different environments.
- `projectname.SourceManifest.xml` — Settings used by Visual Studio 2010 to create the package.

Projectname is the name of your project that is being packaged. Packages can be deployed using Visual Studio or by MSBuild.

VISUAL STUDIO 2010 SETUP AND DEPLOYMENT PROJECTS

Xcopy deployment can be easy to use, but there are times when the lack of functionality becomes an issue. To overcome this shortcoming, Visual Studio 2010 has six installer project types. Four of these options are based on the Windows Installer technology. The following table lists the project types.

PROJECT TYPE	DESCRIPTION
Setup Project	Used for the installation of client applications, middle-tier applications, and applications that run as a Windows Service.
Web Setup Project	Used for the installation of web-based applications.
Merge Module Project	Creates `.msm` merge modules that can be used with other Windows Installer-based setup applications.
CAB Project	Creates `.cab` files for distribution through older deployment technologies.
Setup Wizard	Aids in the creation of a deployment project.
Smart Device CAB Project	CAB project for Pocket PC, Smartphone, and other CE-based applications.

Setup and Web Setup Projects are very similar. The key difference is that with Web Setup the project is deployed to a virtual directory on a web server, whereas with Setup Project it is deployed to a folder structure. Both project types are based on Windows Installer and have all the features of a Windows Installer-based setup program.

Merge Module Project is generally used when you have created a component or library of functionality that is included in a number of deployment projects. By creating a merge module, you can set any configuration items specific to the component and without having to worry about them in the creation of the main deployment project.

The Cab Project type simply creates `.cab` files for the application. `.cab` files are used by older installation technologies as well as some web-based installation processes. The Setup Wizard project type steps through the process of creating a deployment project, asking specific questions along the way.

The following sections discuss how to create each of these deployment projects, what settings and properties can be changed, and what customization you can add.

What is Windows Installer?

Windows Installer is a service that manages the installation, update, repair, and removal of applications on most Windows operating systems. It is part of Windows ME, Windows 2000, Windows XP, Windows Vista, and Windows 7, and is available for Windows 95, Windows 98, and Windows NT 4.0. The current version of Windows Installer is 4.5.

Windows Installer tracks the installation of applications in a database. When an application has to be uninstalled, you can easily track and remove the registry settings that were added, the files that were copied to the hard drive, and the desktop and Start menu icons that were added. If a particular file is still referenced by another application, the installer leaves it on the hard drive so that the other application doesn't break. The database also makes it possible to perform repairs. If a registry setting or a DLL associated with an application becomes corrupt or is accidentally deleted, you can repair the installation. During a repair, the installer reads the database from the last install and replicates that installation.

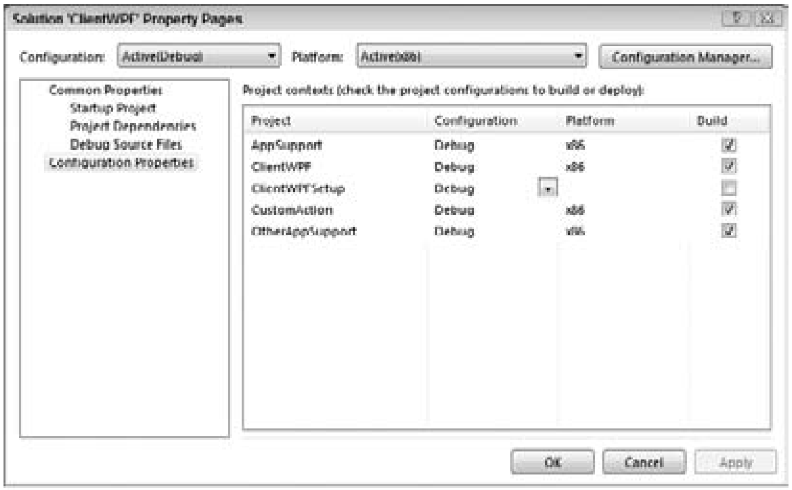
The deployment projects in Visual Studio 2010 give you the ability to create a Windows Installation package. The deployment projects give you access to most of what you will need to do to install a given application. However, if you need even more control, check out the Windows Installer SDK, which is part of the Platform SDK — it contains documentation on creating custom installation packages for your application. The following sections deal with creating these installation packages using the Visual Studio 2010 deployment projects.

Creating Installers

Creating installation packages for client applications or for web applications is not that difficult. One of the first tasks is to identify all the external resources your application requires, including configuration files, COM components, third-party libraries, and controls and images. Including a list of dependencies in the project documentation was discussed earlier. This is where having that documentation can prove to be very useful. Visual Studio 2010 can do a reasonable job of interrogating an assembly and retrieving the dependencies for it, but you still have to audit the findings to make sure that nothing is missing.

Another concern might be when in the overall process the install package is created. If you have an automated build process set up, you can include the building of the installation package upon a successful build of the project. Automating the process greatly reduces the chance for errors in what can be a time-consuming and complicated process for large projects.

What you can do is to include the deployment project with the project solution. The Solution Property Pages dialog box has a setting for Configuration Properties. You can use this setting to select the projects that will be included for your various build configurations. If you select the Build check box under Release builds but not for the Debug builds, the installation package will be created only when you are creating a release build. This is the process used in the following examples. Figure 17-1 shows the Solution Property Pages dialog box of the `ClientWPF` solution. Notice that the Debug configuration is displayed and that the Build check box is unchecked for the setup project.



Project contexts (check the project configurations to build or deploy):

Project	Configuration	Platform	Build
AppSupport	Debug	x86	✓
ClientWPF	Debug	x86	✓
ClientWPFSetup	Debug		
CustomAction	Debug	x86	✓
OtherAppSupport	Debug	x86	✓

FIGURE 17-1

Simple Client Application

In the following example, you create an installer for the `ClientWinForms` solution (which is included in the sample download, together with the completed installer projects). This will show how having the installer project in a separate solution works. Later we'll take a look at the `ClientWPF` which has the installer project in the same solution.

Before you get started creating the deployment project, make sure that you have a release build of the application that will be deployed.

Next, create a new project in Visual Studio 2010. In the New Project dialog box, select Setup and Deployment Projects on the left. On the right, select Setup Project and assign it a name of your choice (for example, `ClientWinFormsSetup`).

In the Solution Explorer window, click the project and then the Properties window. You will see a list of properties. These properties are displayed during the setup of your application. Some of these properties are also displayed in the Add/Remove Programs Control Panel applet. Because most of these properties are visible to users during the installation process (or when they are looking at your installation in Add or Remove Programs), setting them correctly adds a professional touch to your application.

The list of properties is important, especially if your application will be deployed commercially. The following table describes the properties and the values that you should enter:

PROJECT PROPERTY	DESCRIPTION
`AddRemoveProgramsIcon`	The icon that appears in the Add/Remove dialog box.
`Author`	The author of the application. Generally this property setting is the same as the manufacturer. It displays on the Summary page of the Properties dialog of the `msi` package, as well as the Contact field of the SupportInfo page on the Add/Remove dialog box.
`Description`	A freeform text field that describes the application or component that is being installed. This information is displayed on the Summary page of the Properties dialog of the `msi` package, as well as the Comment field of the SupportInfo page on the Add/Remove dialog box.
`DetectNewerInstalled Version`	A Boolean value that, when set to `true`, checks to see if a newer version of the application is already installed. If so, the installation process will stop.
`InstallAllUsers`	Boolean value that, when set to `true`, will install that application for all users of the computer. If set to `false`, only the current user will have access.
`Keywords`	Keywords that can be used to search for the `.msi` file on the target computer. This information is displayed on the Summary page of the Properties dialog box of the `msi` package.
`Localization`	The locale used for string resources and registry settings. This affects the user interface of the installer.
`Manufacturer`	Name of the company that manufactured the application or component. Typically, this is the same information as specified in the `Author` property. This information is displayed on the Summary page of the Properties dialog box of the `msi` package as well as the Publisher field of the SupportInfo page in the Add/Remove dialog box. It is used as part of the default installation path of the application.
`ManufacturerURL`	The URL for a web site that relates to the application or component being installed.
`PostBuildEvent`	A command that is executed after the build ends.
`PreBuildEvent`	A command that is executed before the build begins.
`ProductCode`	A string GUID that is unique to this application or component. Windows Installer uses this property to identify the application for subsequent upgrades or installs.
`ProductName`	A name that describes the application. Used as the description of an application in the Add/Remove dialog box as well as part of the default install path: `C:\Program Files\Manufacturer\ProductName`.
`RemovePrevious-Versions`	Boolean value that, if set to `true`, will check for a previous version of the application. If yes, the uninstall function of the previous version is called before installation continues. This property uses `ProductCode` and `UpgradeCode` to determine if uninstall should occur. `UpgradeCode` should be the same; `ProductCode` should be different.
`RunPostBuildEvent`	When the `PostBuildEvent` should be run. Options are On successful build or Always.

PROJECT PROPERTY	DESCRIPTION
`SearchPath`	A string that represents the search path for dependent assemblies, files, or merge modules. Used when the installer package is built on the development machine.
`Subject`	Additional information regarding the application. This information is displayed on the Summary page of the Properties dialog box of the `msi` package.
`SupportPhone`	A phone number for support of the application or component. This information is displayed in the Support Information field of the SupportInfo page on the Add/Remove dialog box.
`SupportURL`	A URL for support of the application or component. This information is displayed in the Support Information field of the SupportInfo page in the Add/Remove dialog box.
`TargetPlatform`	Supports the 32- or 64-bit versions of Windows.
`Title`	The title of the installer. This is displayed on the Summary page of the Properties dialog box of the `msi` package.
`UpgradeCode`	A string GUID that represents a shared identifier of different versions of the same application. The `UpgradeCode` should not change for different versions or different language versions of the application. Used by `DetectNewerInstalledVersion` and `RemovePreviousVersion`.
`Version`	The version number of the installer, `.cab` file, or merge module. Note that this is not the version of the application being installed.

After you have set the properties, you can start to add assemblies. In this example, the only assembly you have to add is the main executable (`ClientWinForms.exe`). To do this, you can either right-click the project in the Solution Explorer or select Add from the Project menu. You have four options:

➤ Project Output — You explore this option in the next example.

➤ File — This is used for adding a readme text file or any other file that is not part of the build process.

➤ Merge Module — A merge module that was created separately.

➤ Assembly — Use this option to select an assembly that is part of the installation.

Choose Assembly for this example. You will be presented with the Component Selector dialog box, which resembles the dialog box you use for adding references to a project. Browse to the `\bin\release` folder of your application. Select `ClientWinForms.exe` and click OK in the Component Selector dialog box. You can now see `ClientWinForms.exe` listed in the Solution Explorer of the deployment project. In the Detected Dependencies section, you can see that Visual Studio interrogated `ClientWinForms.exe` to find the assemblies on which it depends; in this case, `AppSupport.dll` is included automatically. You would continue this process until all the assemblies in your application are accounted for in the Solution Explorer of the deployment project.

Next, you have to determine where the assemblies will be deployed. By default, the File System editor is displayed in Visual Studio 2010. The File System editor is split into two panes: the left pane shows the hierarchical structure of the file system on the target machine; the right pane provides a detail view of the selected folder. The folder names might not be what you expect to see, but keep in mind that these are for the target machine. For example, the folder labeled User's Programs Menu maps to the folder on the target client that contains the user's Program Menu. This will vary depending on the version of Windows being used.

You can add other folders at this point, either special folders or a custom folder. To add a special folder, make sure that File System on Target Machine is highlighted in the left pane, and select Action menu on the main menu. The Add Special Folder menu choice provides a list of folders that can be added. For example, if you want to add a folder under the Application folder, you can select the Application Folder folder in the left pane of the editor and then select the Action menu. This time, there will be an Add menu that enables you to create the new folder. Rename the new folder and it will be created for you on the target machine.

One of the special folders that you might want to add is a folder for the GAC. `AppSupport.dll` can be installed to the GAC if it is used by several different applications. To add an assembly to the GAC, it does have to have a strong name. The process for adding the assembly to the GAC is to add the GAC from the Special Folder menu as described previously and then drag the assembly that you want in the GAC from the current folder to the Global Assembly Cache folder. If you try to do this with an assembly that is not strongly named, the deployment project will not compile.

If you select Application Folder, you see on the right pane that the assemblies that you added are automatically added to the Application folder. You can move the assemblies to other folders, but keep in mind that the assemblies have to be able to find each other. (For more details on probing, see Chapter 18, "Assemblies.")

If you want to add a shortcut to the application on the user's desktop or to the Start menu, drag the items to the appropriate folders. To create a desktop shortcut, go to the Application folder. On the right side of the editor select the application. Go to the Action menu and select the Create Shortcut item to create a shortcut to the application. After the shortcut is created, drag it to the User's Desktop folder. Now when the application is installed, the shortcut will appear on the desktop. Typically, it is up to the user to decide if he or she wants a desktop shortcut to the application.

The process of asking the user for input and taking conditional steps is explored later in this chapter. The same process can be followed to create an item in the Start menu. Also, if you look at the properties for the shortcut that you just created, you will see that you can configure the basic shortcut properties such as Arguments and what icon to use. The application icon is the default icon.

Before you build the deployment project, you might have to check some project properties. If you select Project menu, then ClientWinFormsSetup Properties, you will see the project Property Pages dialog box. These are properties that are specific to a current configuration. After selecting the configuration in the Configuration drop-down, you can change the properties listed in the following table.

PROPERTY	DESCRIPTION
Output filename	The name of the `.msi` or `.msm` file that is generated when the project is compiled.
Package files	This property enables you to specify how the files are packaged. Your options are: As loose uncompressed files — All the deployment files are stored in the same directory as the `.msi` file. In setup file — Files are packaged in the `.msi` file (default setting). In cabinet file(s) — Files are in one or more `.cab` files in the same directory. When this is selected the CAB file size option becomes available.
Prerequisites URL	Allows you to specify where prerequisites such as the .NET Framework or Windows Installer can be found. Clicking the Settings button will display a dialog that has a list of items such as Windows Installer 4.5, the .NET Framework, and SQL Express 2008. There is also an option for choosing where the prerequisites can be downloaded from.
Compression	This specifies the compression style for the files included. Your options are: Optimized for speed — Larger files but faster installation time (default setting). Optimized for size — Smaller files but slower installation time. None — No compression applied.
CAB size	This is enabled when the Package file setting is set to In CAB files. Unlimited creates one single CAB file; custom allows you to set the maximum size for each `.cab` file.
Authenticode signature	When this is checked, the deployment project output is signed using Authenticode; the default setting is unchecked.

After you have set the project properties, you should be able to build the deployment project and create the setup for the `ClientWinForms` application. After you build the project, you can test the installation by right-clicking the project name in the Solution Explorer. This lets you access an Install and Uninstall choice in the context menu. If you have done everything correctly, you should be able to install and uninstall `ClientWinForms` successfully.

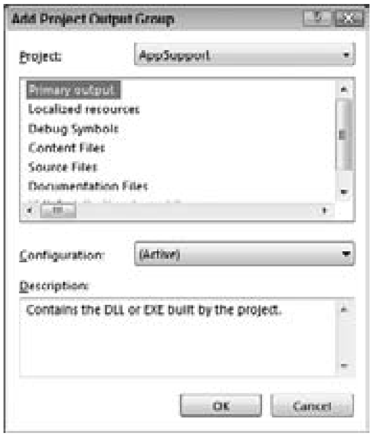
Same Solution Project

The previous example works well for creating a deployment package, but it does have a couple of downsides. For example, what happens when a new assembly is added to the original application? The deployment project will not automatically recognize any changes; you will have to add the new assemblies and verify that any new dependencies are covered. In smaller applications (like the example), this isn't that big of a deal.

However, when you're dealing with an application that contains dozens or maybe hundreds of assemblies, this can become quite tedious to maintain. Visual Studio 2010 has a simple way of resolving this potential headache. Include the deployment project in your application's solution. You can then capture the output of the main project as your deployment assemblies. You can look at the `ClientWPF` as an example.

Open the `ClientWPF` solution in Visual Studio 2010. Add a new project using Solution Explorer. Select Deployment and Setup Projects and then select Setup Project, following the steps outlined in the previous section. You can name this project `ClientWPFSetup`. In the previous example, you added the assemblies by selecting Add ➪ Assemblies from the Project menu. This time, select Add ➪ Project Output from the Project menu. This opens the Add Project Output Group dialog box (see Figure 17-2).

The top part of the dialog box has a drop-down list box that shows all the projects in the current solution. Select the main startup project. Then select the items that you want to include in your project from the following list. Your options are Documentation, Primary output, Localized resources, Debug symbols, Content files, and Source files.



Project: AppSupport

Configuration: (Active)

Description:

Contains the DLL or EXE built by the project.

FIGURE 17-2

First, select Primary Output. This includes the output and all dependencies when the application is built. Another drop-down list box lists the valid configurations: Debug and Release, plus any custom configurations you might have added. This also determines what outputs are picked up. For deployment, you will most likely want to use the Release configuration.

After you make these selections, a new item is added to your deployment project in Solution Explorer. The name of the item is Primary output from `ClientWPF (Release .NET)`. You will also see the file `AppSupport.dll` listed under the dependencies. As before, no need to search for the dependent assemblies.

At this point, all the various project properties discussed in the previous section still apply. You can change the Name, Manufacturer, `.cab` file size, and other properties. After setting the properties, do a release build of the solution and test the installation. Everything should work as expected.

To see the advantage of adding the deployment package to the applications solution, add a new project to the solution. In the example it is called `OtherAppSupport`. In it is a simple test method that returns the string "This is the message." Set a reference in `ClientWPF` to the newly added project, and do another release build of the solution. You should see that the deployment project picked up the new assembly without you having to do anything. You can also right-click the Detected Dependencies section of the installer project and select Refresh Dependencies. If you had been using a standalone deployment project, the newly added project would not have been picked up.

Simple Web Application

Creating an installation package for a web application is not that different from creating a client install package. The download examples include a `WebClient` that also utilizes the `AppSupport.dll` assembly. You can create the deployment project the same way that the client deployment projects are created, either standalone or in the same solution. In this example, the deployment project is built in the same solution.

Start the `WebClient` solution and add a new deployment and setup project. This time, be sure to choose Web Setup Project in the Templates window. If you look at the properties view for the project, you will see that all the same properties exist for web applications that existed for client applications. The only addition is `RestartWWWService`. This is a Boolean value that will restart IIS during the install. If you're using ASP.NET components and not replacing any ATL or ISAPI DLLs, you shouldn't have to do this.

If you look at the File System editor, you will notice that there is only one folder. The Web Application folder will be your virtual directory. By default, the name of the directory is the name of the deployment project, and it is located below the web root directory. The following table explains the properties that can be set from the installer. The properties discussed in the previous section are not included.

PROPERTY	DESCRIPTION
`AllowDirectoryBrowsing`	A Boolean value that, if `true`, allows an HTML listing of the files and subfolders of the virtual directory. Maps to the Directory browsing property of IIS.
`AllowReadAccess`	A Boolean value that, if `true`, allows users to read or download files. Maps to the Read property of IIS.
`AllowScriptSourceAccess`	A Boolean value that, if `true`, allows users to access source code, including scripts. Maps to Script source access in IIS.
`AllowWriteAccess`	A Boolean value that, if `true`, allows users to change content in write-enabled files. Maps to the Write property of IIS.
`ApplicationProtection`	Determines the protection level of applications that are run on the server. The valid values are: Low — Applications run in the same process as web services. Medium — Applications run in same process but not the same as web services. High — Application runs in its own process. Maps to the Application Protection property in IIS. Has no effect if the `IsApplication` property is `false`.
`AppMappings`	A list of application names and document or data files that are associated with the applications. Maps to the Application Mappings property of IIS.
`Condition`	A Windows Installer condition that must be met for the item to be installed.
`DefaultDocument`	The default or startup document when the user first browses to the site.
`ExecutePermissions`	The level of permissions that a user has to execute applications. The valid values are: None — Only static content can be accessed. ScriptsOnly — Only scripts can be accessed. Includes ASP. ScriptsAndExecutables — Any files can be accessed. Maps to Execute Permissions in IIS.
`Index`	Boolean value that, if `true`, would allow indexing of the content for Microsoft Indexing Service. Maps to the Index this resource property of IIS.

PROPERTY	DESCRIPTION
`IsApplication`	Boolean value that, if `true`, instructs IIS to create the application root for the folder.
`LogVisits`	Boolean value that, if `true`, logs visits to the web site in a log file. Maps to the Log Visits property of IIS.
`Property`	The named property that can be accessed at installation time.
`VirtualDirectory`	The virtual directory for the application. This is relative to the web server.

You might notice that most of these properties are properties of IIS and can be set in the IIS Administrator tool. So, the logical assumption is that to set these properties in the installer, the installer will need to run with administrator privileges. The settings made here can compromise security, so the changes should be well documented.

Other than these properties, the process of creating the deployment package is very similar to the previous client example. The main difference between the two projects is the ability to modify IIS from the installation process. As you can see, you have a great deal of control over the IIS environment.

Client from Web Server

Another installation scenario is either running the install program from a web site or actually running the application from a web site. Both of these are attractive options if you must deploy an application to a large number of users. By deploying from a web site, you eliminate the need for a distribution medium such as CD-ROMs, DVDs, or even floppy disks. By running the application from a web site or even a network share, you eliminate the need to distribute a setup program at all.

Running an installer from a web site is fairly simple. You use the Web Bootstrapper project compile option. You will be asked to provide the URL of the setup folder. This is the folder in which the setup program is going to look for the `.msi` and other files necessary for the setup to work. After you set this option and compile the deployment package, you can copy it to the web site that you specify in the Setup folder URL property. At this point, when the user navigates to the folder, she will be able to either run the setup or download it and then run it. In both instances, the user must be able to connect to the same site to finish the installation.

CLICKONCE

ClickOnce is a deployment technology that allows applications to be self-updating. Applications are published to a file share, web site, or media such as a CD. When published, ClickOnce apps can be automatically updated with minimal user input.

ClickOnce also solves the security permission problem. Normally, to install an application the user needs Administrative rights. With ClickOnce, a user can install and run an application with only the absolute minimum permissions required to run the application.

ClickOnce Operation

ClickOnce applications have two XML-based manifest files associated with them. One is the application manifest, and the other is the deployment manifest. These two files describe everything that is required to deploy an application.

The application manifest contains information about the application such as permissions required, assemblies to include, and other dependencies. The deployment manifest is about the deployment of the app. Items such as the location of the application manifest are contained in the deployment manifest. The complete schemas for the manifests are in the .NET SDK documentation.

ClickOnce has some limitations. Assemblies cannot be added to the GAC, for example. The following table compares ClickOnce and Windows Installer.

FEATURE	CLICKONCE	WINDOWS INSTALLER
Application installation location	ClickOnce application cache	Program Files folder
Install for multiple users	No	Yes
Install shared files	No	Yes
Install drivers	No	Yes
Install to the GAC	No	Yes
Add application to the Startup group	No	Yes
Add application to the Favorites menu	No	Yes
Register file types	No	Yes
Access registry	No. The HKLM can be accessed with Full Trust permissions.	Yes
Binary patching of files	Yes	No
Install assemblies on demand	Yes	No

Some situations certainly exist where using Windows Installer is clearly a better choice, however, ClickOnce can be used for a large number of applications.

Publishing a ClickOnce Application

Everything that ClickOnce needs to know is contained in the two manifest files. The process of publishing an application for ClickOnce deployment is simply generating the manifests and placing the files in the proper location. The manifest files can be generated in Visual Studio 2010. There is also a command-line tool (`mage.exe`) and a version with a GUI (`mageUI.exe`).

You can create the manifest files in Visual Studio 2010 in two ways. At the bottom of the Publish tab on the Project Properties dialog are two buttons. One is the Publish Wizard and the other is Publish Now. The Publish Wizard asks several questions about the deployment of the application and then generates the manifest files and copies all the needed files to the deployment location. The Publish Now button uses the values that have been set in the Publish tab to create the manifest files and copies the files to the deployment location.

To use the command-line tool, `mage.exe`, the values for the various ClickOnce properties must be passed in. Manifest files can be both created and updated using `mage.exe`. Typing **mage.exe -help** at the command prompt gives the syntax for passing in the values required.

The GUI version of `mage.exe` (`mageUI.exe`) is similar in appearance to the Publish tab in Visual Studio 2010. An application and deployment manifest file can be created and updated using the GUI tool.

ClickOnce applications appear in the Add/Remove Control Panel applet just as any other installed application. One big difference is that the user is presented with the choice of either uninstalling the application or rolling back to the previous version. ClickOnce keeps the previous version in the ClickOnce application cache.

ClickOnce Settings

Several properties are available for both manifest files. The most important property is where the application should be deployed from. The dependencies for the application must be specified. The Publish tab has an Application Files button that shows a dialog for entering all the assemblies required by the application. The Prerequisite button displays a list of common prerequisites that can be installed along with the application. You have the choice of installing the prerequisites from the same location that the application is being published to or optionally having the prerequisites installed from the vendor's web site.

The Update button displays a dialog that has the information about how the application should be updated. As new versions of an application are made available, ClickOnce can be used to update the application. Options include to check for updates every time the application starts or to check in the background. If the background option is selected, a specified period of time between checks can be entered. Options for allowing the user to be able to decline or accept the update are available. This can be used to force an update in the background so that the user is never aware that the update is occurring. The next time the application is run, the new version will be used instead of the older version. A separate location for the update files can be used as well. This way the original installation package can be located in one location and installed for new users, and all the updates can be staged in another location.

The application can be set up so that it will run in either online or offline mode. In offline mode the application can be run from the Start menu and acts as if it were installed using the Windows Installer. Online mode means that the application will run only if the installation folder is available.

Application Cache for ClickOnce Files

Applications distributed with ClickOnce are not installed in the Program Files folder. Instead, they are placed in an application cache that resides in the Local Settings folder under the current user's Documents and Settings folder. Controlling this aspect of the deployment means that multiple versions of an application can reside on the client PC at the same time. If the application is set to run online, every version that the user has accessed is retained. For applications that are set to run locally, the current and previous versions are retained.

Because of this, it is a very simple process to roll back a ClickOnce application to its previous version. If the user goes to the Add/Remove Programs Control Panel applet, the dialog presented will contain the choice of removing the ClickOnce application or rolling back to the previous version. An Administrator can change the manifest file to point to the previous version. If the administrator does this, the next time the user runs that application, a check will be made for an update. Instead of finding new assemblies to deploy, the application will restore the previous version without any interaction from the user.

Application Security

Applications deployed over the Internet or an intranet have a lower security or trust setting than applications that have been installed to the local drive. For example, by default, if an application is launched or deployed from the Internet it is in the Internet Security Zone. This means that it cannot access the file system, among other things. If the application is installed from a file share, it will run in the Intranet Zone.

If your ClickOnce application requires a higher level of trust than the default, the user will be prompted to grant the permissions required for the application to run. These permissions are set in the `trustInfo` element of the application manifest. Only the permissions asked for in this setting will be granted. So, if an application asks for file access permissions, Full Trust will not be granted, only the specific permissions requested.

Another option is to use Trusted Application Deployment. Trusted Application Deployment is a way to grant permissions on an enterprise-wide basis without having to prompt the user. A trust license issuer is identified to each client machine. This is done with public key cryptography. Typically, an organization will have only one issuer. It is important to keep the private key for the issuer in a safe, secure location.

A trust license is requested from the issuer. The level of trust that is being requested is part of the trust license configuration. A public key used to sign the application must also be supplied to the license issuer. The license created contains the public key used to sign the application and the public key of the license issuer. This trust license is then embedded in the deployment manifest. The last step is to sign the deployment manifest with your own key pair. The application is now ready to deploy.

When the client opens the deployment manifest the Trust Manager will determine if the ClickOnce application has been given a higher trust. The issuer license is looked at first. If it is valid, the public key in the license is compared to the public key that was used to sign the application. If these match, the application is granted the requested permissions.

VISUAL STUDIO 2010 EDITORS

The installation processes discussed so far are very powerful and can do quite a bit. But there is much more that you can control in the installation process. For example, you can use the various editors in Visual Studio 2010 to build conditional installations or add registry keys and custom dialog boxes. The `SampleClientSetupSolution` example has all these advanced options enabled.

File System Editor

The File System editor enables you to specify where in the target the various files and assemblies that make up the application will be deployed. By default, a standard set of deployment folders is displayed. You can add any number of custom and special folders with the editor. This is also where you would add desktop and Start menu shortcuts to the application. Any file that must be part of the deployment must be referenced in the File System editor.

Registry Editor

The Registry editor allows you to add keys and data to the registry. When the editor is first displayed, a standard set of main keys is displayed:

- `HKEY_CLASSES_ROOT`
- `HKEY_CURRENT_USER`
- `HKEY_LOCAL_MACHINE`
- `HKEY_USERS`

`HKEY_CURRENT_USER` and `HKEY_LOCAL_MACHINE` contain additional entries in the Software/[Manufacturer] key where Manufacturer is the information you entered in the `Manufacturer` property of the deployment project.

To add additional keys and values, highlight one of the main keys on the left side of the editor. Select Action from the main menu and then select New. Select the key or the value type that you want to add. Repeat this step until you have all the registry settings that you want. If you select the Registry on Target Machine item on the left pane and then select the Action menu, you will see an Import option, which enables you to import an already defined `*.reg` file.

To create a default value for a key you must first enter a value for the key, and then select the value name in the right or value pane. Select Rename from the File menu and delete the name. Press Enter and the value name is replaced with (Default).

You can also set some properties for the subkeys and values in the editor. The only one that hasn't been discussed already is the `DeleteAtUninstall` property. A well-designed application should remove all keys that have been added by the application at uninstall time. The default setting is not to delete the keys.

One thing to keep in mind is that the preferred method for maintaining application settings is to use XML-based configuration files. These files offer a great deal more flexibility and are much easier to restore and back up than registry entries.

File Types Editor

The File Types editor is used to establish associations between files and applications. For example, when you double-click a file with the `.doc` extension, the file is opened in Word. You can create these same associations for your application.

To add an association, execute the following steps:

1. Select File Types on Target Machine from the Action menu.
2. Then select Add File Type. In the properties window, you can now set the name of the association.
3. In the `Extension` property, add the file extension that should be associated with the application. Do not enter the periods; you can separate multiple extensions with a semicolon, like this: **ex1;ex2**.
4. In the Command property, select the Ellipsis button.
5. Now, select the file (typically an executable) that you want to associate with the specified file types. Keep in mind that any one extension should be associated with only one application.

By default, the editor shows &Open as the Document Action. You can add others. The order in which the actions appear in the editor is the order in which they will appear in the context menu when the user right-clicks the file type. Keep in mind that the first item is always the default action. You can set the `Arguments` property for the actions. This is the command-line argument used to start the application.

User Interface Editor

Sometimes you might want to ask the user for more information during the installation process. The User Interface editor is used to specify properties for a set of predefined dialog boxes. The editor is separated into two sections, Install and Admin. One is for the standard installation and the other is used for an administrator's installation. Each section is broken up into three subsections: Start, Progress, and End. These subsections represent the three basic stages of the installation process (see Figure 17-3).

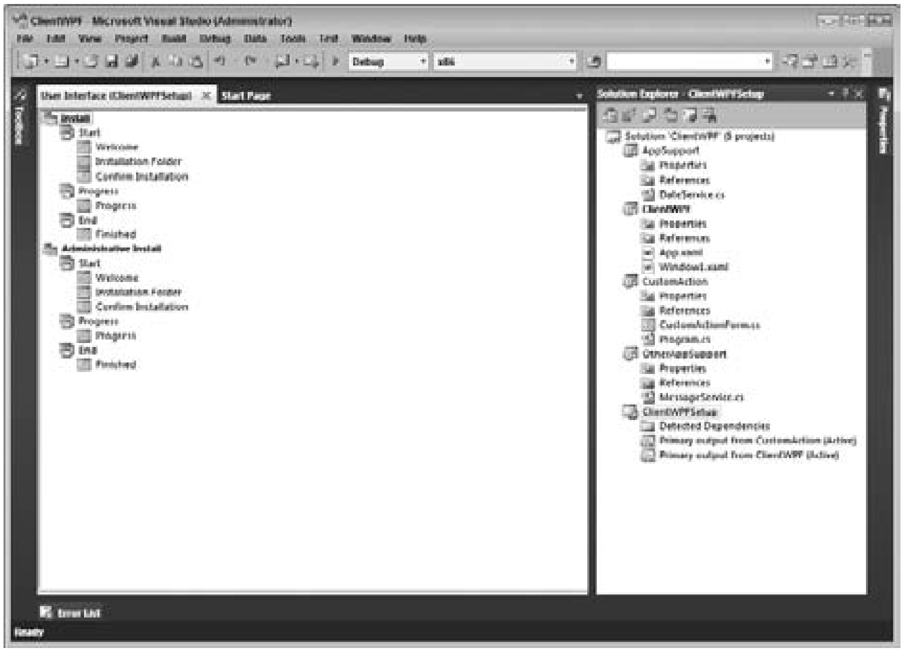


FIGURE 17-3

The following table lists the types of dialog boxes that you can add to the project.

DIALOG BOX	DESCRIPTION
Check Boxes	Contains up to four check boxes. Each check box has a `Label`, `Value`, and `Visible` property.
Confirm Installation	Gives the user the ability to confirm the various settings before installation takes place.
Customer Information	Has edit fields for the collection name, organization name, and serial number. Organization name and serial number are optional.
Finished	Displayed at the end of the setup process.
Installation Address	For web applications, displays a dialog box so that users can choose an alternative installation URL.
Installation Folder	For client applications, displays a dialog box so that users can select an alternative installation folder.
License Agreement	Displays the license agreement that is located in a file specified by the `LicenseFile` property.
Progress	Displays a progress indicator during the installation process that shows the current installation status.
Radio Buttons	Contains up to four radio buttons. Each radio button has a `Label` and `Value` property.
Read Me	Shows the readme information contained in the file specified by the `ReadMe` property.
Register User	Executes an application that will guide the user through the registration process. This application must be supplied in the setup project.
Splash	Displays a bitmap image.
Text Boxes	Contains up to four text box fields. Each text box has a `Label`, `Value`, and `Visible` property.
Welcome	Contains two properties: the `WelcomeText` property and the `CopyrightWarning`. Both are string properties.

Each of these dialog boxes also contains a property for setting the banner bitmap, and most have a property for banner text. You can also change the order in which the dialog boxes appear by dragging them up or down in the editor window.

Now that you can capture some of this information, the question is, how do you make use of it? This is where the `Condition` property that appears on most of the objects in the project comes in. The `Condition` property must evaluate to true for the installation step to proceed. For example, say the installation comes with three optional installation components. In this case, you would add a dialog box with three check boxes. The dialog should be somewhere after the Welcome and before the Confirm Installation dialog box. Change the `Label` property of each check box to describe the action. The first action could be “Install Component A,” the second could be “Install Component B,” and so on. In the File System editor, select the file that represents Component A. Assuming that the name of the check box on the dialog box is CHECKBOXA1, the `Condition` property of the file would be `CHECKBOXA1=Checked` — that is, if CHECKBOXA1 is checked, install the file; otherwise, don’t install it.

Custom Actions Editor

The Custom Actions editor allows you to define custom steps that will take place during certain phases of the installation. Custom actions are created beforehand and consist of a DLL, EXE, script, or Installer class. The action would contain special steps to perform that can’t be defined in the standard deployment project. The actions will be performed at four specific points in the deployment. When the editor is first started, you will see the four points in the project (see Figure 17-4):

➤ Install — Actions will be executed at the end of the installation phase.
➤ Commit — Actions will be executed after the installation has finished and no errors have been recorded.
➤ Rollback — Actions occur after the rollback phase has completed.
➤ Uninstall — Actions occur after uninstall has completed.

FIGURE 17-4

To add an action, you first select the phase of the installation in which you want the action to occur. Select the Add Custom Action menu option from the Action menu to open the File System dialog box. This means that the component that contains the action must be part of the deployment project. Because it will be executing on the target machine it has to be deployed; therefore, it should be listed in the File System editor.

After you have added the action, you can select one or more of the properties listed in the following table.

ARGUMENTS	COMMAND-LINE ARGUMENTS
`Condition`	A Windows Installer condition that must be evaluated and result in true for the action to execute.
`CustomDataAction`	Custom data that will be available to the action.
`EntryPoint`	The entry point for the custom DLL that contains the action. If the action is contained in an executable, this property does not apply.
`InstallerClass`	A Boolean value that, if true, specifies that the action is a .NET `ProjectInstaller` class.
`Name`	Name of the action. Defaults to the filename of the action.
`SourcePath`	The path to action on the development machine.

Because the action is code that you develop outside the deployment project, you have the freedom to add just about anything that adds a professional touch to your application. The thing to remember is that such an action happens after the phase it is associated with is complete. If you select the Install phase, the action will not execute until after the install phase has completed. If you want to make determinations before the process, you will want to create a launch condition.

Launch Conditions Editor

The Launch Conditions editor allows you to specify that certain conditions must be met before installation can continue. Launch conditions are organized into types of conditions. The basic launch conditions are File Search, Registry Search, and Windows Installer Search. When the editor is first started you see two groups (see Figure 17-5): Search Target Machine and Launch Conditions. Typically, a search is conducted, and, based on the success or failure of that search, a condition is executed. This happens by setting the `Property` property of the search. The `Property` property can be accessed by the installation process. It can be checked in the `Condition` property of other actions, for example. You can also add a launch condition in the editor. In this condition, you set the `Condition` property to the value of the `Property` property in the search. In the condition, you can specify a URL that will download the file, registry key, or installer component that was being searched for. Notice in Figure 17-5 that a .NET Framework condition is added by default.

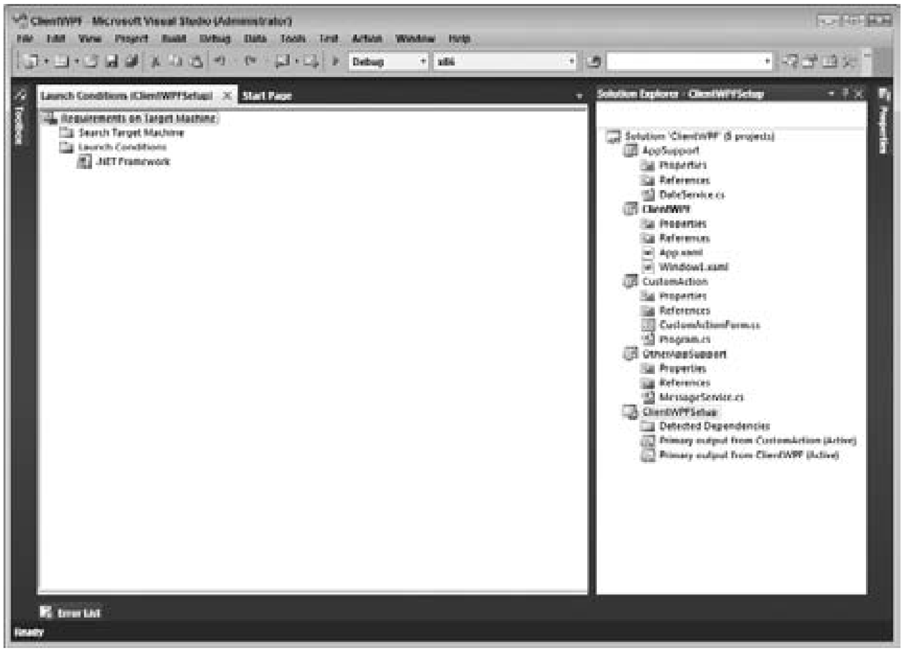

FIGURE 17-5

File Search will search for a file or type of file. You can set many different file-related properties that determine how files are searched, including filename, folder location, various date values, version information, and size. You can also set the number of subfolders that are searched.

Registry Search allows you to search for keys and values. It also allows you to set the root key for searching.

Windows Installer Search looks for the specified Installer component. The search is conducted by GUID.

The Launch Conditions editor provides two prepackaged launch conditions: the .NET Framework Launch Condition, which allows you to search for a specific version of the runtime, and a search for a specific version of MDAC, which uses the registry search to find the relevant MDAC registry entries.

SUMMARY

Deploying software has become difficult for developers of desktop software. As web sites have grown more complex, the deployment of server-based software has become more difficult. This chapter looked at the options and capabilities that Visual Studio 2010 and version 3.5 of the .NET Framework provide to help make deployment easier and less error-prone.

After reading this chapter, you should be able to create a deployment package that resolves almost any deployment issue that you might have. Client applications can be deployed locally or via the Internet or an intranet. The extensive features of deployment projects and the ways that deployment projects can be configured were covered. You can also use no-touch deployment and ClickOnce to deploy applications. The security features of ClickOnce will make this a secure and efficient way of deploying client applications. Using deployment projects to install web applications can make the process of configuring IIS much easier as well. Publishing a web site provides the added benefit of precompiling the application.

PART III
Foundation

18 Assemblies

WHAT'S IN THIS CHAPTER?

- An overview of assemblies
- Creating assemblies
- Using application domains
- Sharing assemblies
- Versioning

An *assembly* is the .NET term for a deployment and configuration unit. This chapter discusses exactly what assemblies are, how they can be applied, and why they are such a useful feature.

This chapter teaches you how to create assemblies dynamically, how to load assemblies into appdomains, and how to share assemblies between different applications. The chapter also covers versioning, which is an important aspect of sharing assemblies.

WHAT ARE ASSEMBLIES?

Assemblies are the deployment units of .NET applications. .NET applications consist of one or more assemblies. .NET executables with the usual extension EXE or DLL are known by the term *assembly*. What's the difference between an assembly and a native DLL or EXE? Although they both have the same file extension, .NET assemblies include metadata that describes all the types that are defined in the assembly with information about its members — methods, properties, events, and fields.

The metadata of .NET assemblies also provides information about the files that belong to the assembly, version information, and the exact information about assemblies that are used. .NET assemblies are the answer to the DLL hell we've seen previously with native DLLs.

Assemblies are self-describing installation units, consisting of one or more files. One assembly could be a single DLL or EXE that includes metadata, or it can be made of different files, for example, resource files, modules, and an EXE.

Assemblies can be private or shared. With simple .NET applications, using just private assemblies is the best way to work. No special management, registration, versioning, and so on is needed with private assemblies. The only application that could have version problems with private assemblies is your own application. Other applications are not influenced because they have their own copies of the assemblies. The private components you use within your application are installed at the same time as the application itself. Private assemblies are located in the same directory as the application or subdirectories thereof. This way you shouldn't have any versioning problems with the application. No other application will ever overwrite your private assemblies. Of course, it is still a good idea to use version numbers for private assemblies, too. This helps a lot with code changes, but it's not a requirement of .NET.

With shared assemblies, several applications can use the same assembly and have a dependency on it. Shared assemblies reduce the need for disk and memory space. With shared assemblies, many rules must be fulfilled — a shared assembly must have a version number and a unique name, and usually it's installed in the *global assembly cache* (GAC). The GAC allows you to share different versions of the same assembly on a system.

Assembly Features

The assembly features can be summarized as follows:

- Assemblies are *self-describing*. It's no longer necessary to pay attention to registry keys for apartments, to get the type library from some other place, and so on. Assemblies include metadata that describes the assembly. The metadata includes the types exported from the assembly and a manifest; the next section describes the function of a manifest.
- *Version dependencies* are recorded inside an assembly manifest. Storing the version of any referenced assemblies in the manifest makes it possible to easily find deployment faults because of wrong versions available. The version of the referenced assembly that will be used can be configured by the developer and the system administrator. Later in this chapter, you learn which version policies are available and how they work.
- Assemblies can be loaded *side by side*. Beginning with Windows 2000, you have a side-by-side feature where different versions of the same DLL can be used on a system. Did you ever check the directory `<windows>\winsxs`? .NET allows different versions of the same assembly to be used inside a single process! How is this useful? If assembly `A` references version 1 of the shared assembly `Shared`, and assembly `B` uses version 2 of the shared assembly `Shared`, and you are using both assembly `A` and `B`, you need both versions of the shared assembly `Shared` in your application — and with .NET both versions are loaded and used. The .NET 4 runtime even allows multiple CLR versions (2 and 4) inside one process. This allows, for example, loading plugins with different CLR requirements. While there's no direct .NET way to communicate between objects in different CLR versions inside one process, you can use other techniques, for example COM.
- Application isolation is ensured by using *application domains*. With application domains a number of applications can run independently inside a single process. Faults in one application cannot directly affect other applications inside the same process.
- Installation can be as easy as copying the files that belong to an assembly. An xcopy can be enough. This feature is named *ClickOnce deployment*. However, there are cases in which ClickOnce deployment cannot be applied, and a normal Windows installation is required. Deployment of applications is discussed in Chapter 17, "Deployment."

Assembly Structure

An assembly consists of assembly metadata describing the complete assembly, type metadata describing the exported types and methods, MSIL code, and resources. All these parts can be inside of one file or spread across several files.

In the first example (see Figure 18-1), the assembly metadata, type metadata, MSIL code, and resources are all in one file — `Component.dll`. The assembly consists of a single file.

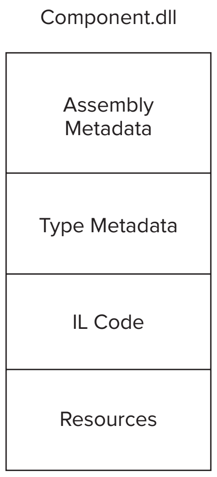

FIGURE 18-1

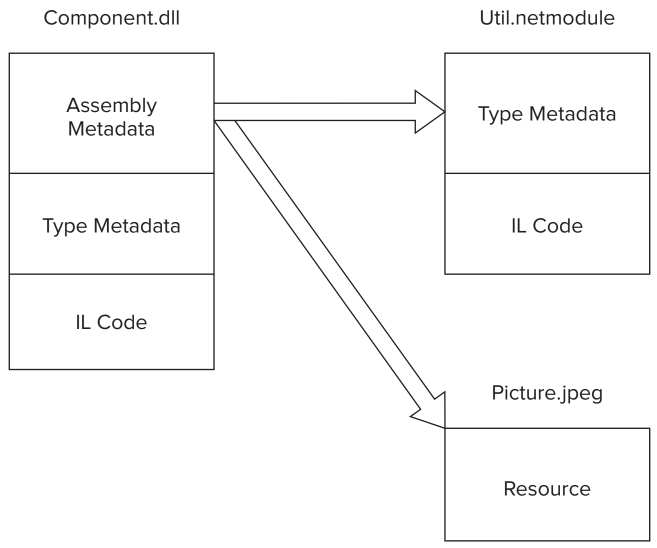

FIGURE 18-2

Assembly Manifests

An important part of an assembly is a *manifest,* which is part of the metadata. It describes the assembly with all the information that's needed to reference it and lists all its dependencies. The parts of the manifest are as follows:

- **Identity** — Name, version, culture, and public key.
- **A list of files** — Files belonging to this assembly. A single assembly must have at least one file but may contain a number of files.
- **A list of referenced assemblies** — All assemblies used from the assembly are documented inside the manifest. This reference information includes the version number and the public key, which is used to uniquely identify assemblies. The public key is discussed later in this chapter.
- **A set of permission requests** — These are the permissions needed to run this assembly. You can find more information about permissions in Chapter 21, "Security."
- **Exported types** — These are included if they are defined within a module and the module is referenced from the assembly; otherwise, they are not part of the manifest. A module is a unit of reuse. The type description is stored as metadata inside the assembly. You can get the structures and classes with the properties and methods from the metadata. This replaces the type library that was used with COM to describe the types. For the use of COM clients, it's easy to generate a type library from the manifest. The reflection mechanism uses the information about the exported types for late binding to classes. See Chapter 14, "Reflection," for more information about reflection.

Namespaces, Assemblies, and Components

You might be a little bit confused by the meanings of namespaces, types, assemblies, and components. How does a namespace fit into the assembly concept? The namespace is completely independent of an assembly. You can have different namespaces in a single assembly, but the same namespace can be spread across assemblies. The namespace is just an extension of the type name — it belongs to the name of the type.

For example, the assemblies `mscorlib` and `system` contain the namespace `System.Threading` among many other namespaces. Although the assemblies contain the same namespaces, you will not find the same class names.

Private and Shared Assemblies

Assemblies can be shared or private. A *private assembly* is found either in the same directory as the application, or within one of its subdirectories. With a private assembly, it's not necessary to think about naming conflicts with other classes or versioning problems. The assemblies that are referenced during the build process are copied to the application directory. Private assemblies are the usual way to build assemblies, especially when applications and components are built within the same company.

Although it is still possible to have naming conflicts with private assemblies (multiple private assemblies may be part of the application and they could have conflicts, or a name in a private assembly might conflict with a name in a shared assembly used by the application), naming conflicts are greatly reduced. If you find you'll be using multiple private assemblies or working with shared assemblies in other applications, it's a good idea to utilize well-named namespaces and types to minimize naming conflicts.

When using *shared assemblies,* you have to be aware of some rules. The assembly must be unique and, therefore, must also have a unique name, called a *strong name*. Part of the strong name is a mandatory version number. Shared assemblies will mostly be used when a vendor, different from that of the application, builds the component, or when a large application is split into subprojects. Also, some technologies, such as .NET Enterprise Services, require shared assemblies in specific scenarios.

Satellite Assemblies

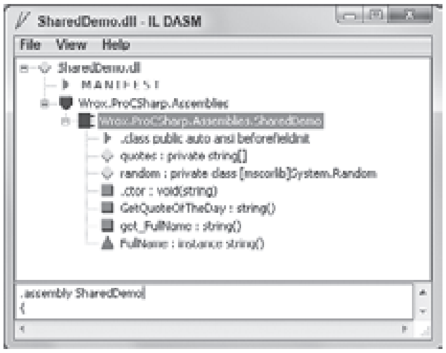
A satellite assembly is an assembly that only contains resources. This is extremely useful for localization. Because an assembly has a culture associated, the resource manager looks for satellite assemblies containing the resources of a specific culture.

You can read more about satellite assemblies in Chapter 22, "Localization."

Viewing Assemblies

You can view assemblies by using the command-line utility `ildasm`, the MSIL disassembler. You can open an assembly by starting `ildasm` from the command line with the assembly as an argument or by selecting the File➪Open menu.

Figure 18-3 shows `ildasm` opening the example that you will build a little later in the chapter, `SharedDemo.dll`. `ildasm` shows the manifest and the `SharedDemo` type in the `Wrox.ProCSharp.Assemblies` namespace. When you open the manifest, you can see the version number and the assembly attributes, as well as the referenced assemblies and their versions. You can see the MSIL code by opening the methods of the class.



```
SharedDemo.dll
  MANIFEST
  Wrox.ProCSharp.Assemblies
    Wrox.ProCSharp.Assemblies.SharedDemo
      .class public auto ansi beforefieldinit
      quotes : private string[]
      random : private class [mscorlib]System.Random
      .ctor : void(string)
      GetQuoteOfTheDay : string()
      get_FullName : string()
      FullName : instance string()
```

```
.assembly SharedDemo
{
```

FIGURE 18-3

In addition to using `ildasm`*, the .NET Reflector is another great tool to use to analyze assemblies. The .NET Reflector allows type and member search, and call and callee graphs, and decompiles IL code to C#, C++, or Visual Basic. You can download this tool from* `www.redgate.com/products/reflector`.

CREATING ASSEMBLIES

Now that you know what assemblies are, it is time to build some. Of course, you have already built assemblies in previous chapters, because a .NET executable counts as an assembly. This section looks at special options for assemblies.

Creating Modules and Assemblies

All C# project types in Visual Studio create an assembly. Whether you choose a DLL or EXE project type, an assembly is always created. With the command-line C# compiler csc, it's also possible to create modules. A module is a DLL without assembly attributes (so it's not an assembly, but it can be added to assemblies at a later time). The command:

```
csc /target:module hello.cs
```

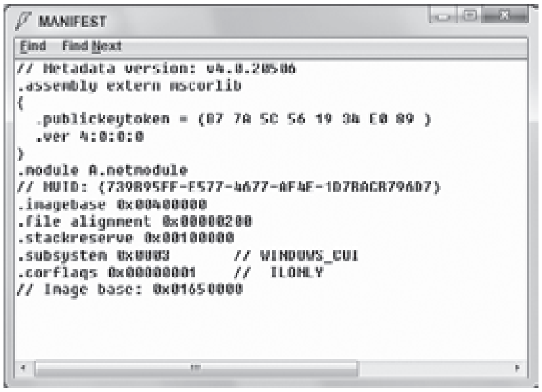
creates a module `hello.netmodule`. You can view this module using `ildasm`.

A module also has a manifest, but there is no `.assembly` entry inside the manifest (except for the external assemblies that are referenced) because a module has no assembly attributes. It's not possible to configure versions or permissions with modules; that can be done only at the assembly scope. You can find references to assemblies in the manifest of the module. With the `/addmodule` option of `csc`, it's possible to add modules to existing assemblies.

To compare modules to assemblies, create a simple class `A` and compile it by using the following command:

```
csc /target:module A.cs
```

The compiler generates the file `A.netmodule`, which doesn't include assembly information (as you can see using `ildasm` to look at the manifest information). The manifest of the module shows the referenced assembly `mscorlib` and the `.module` entry in Figure 18-4.



```
// Metadata version: v4.0.20506
.assembly extern mscorlib
{
  .publickeytoken = (B7 7A 5C 56 19 34 E0 89 )
  .ver 4:0:0:0
}
.module A.netmodule
// MVID: {739895FF-F577-4677-AF4F-1D7BACB796D7}
.imagebase 0x00400000
.file alignment 0x00000200
.stackreserve 0x00100000
.subsystem 0x0003       // WINDOWS_CUI
.corflags 0x00000001    //  ILONLY
// Image base: 0x01650000
```

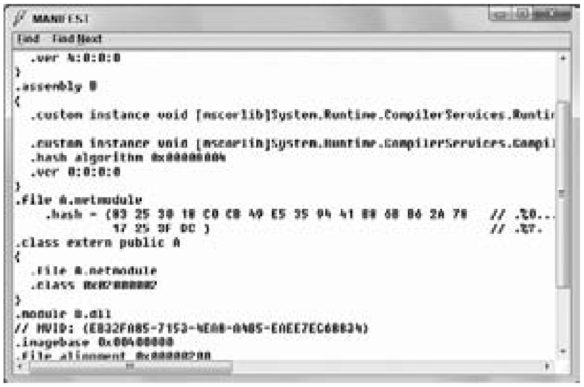
FIGURE 18-4

Next, create an assembly B, which includes the module `A.netmodule`. It's not necessary to have a source file to generate this assembly. The command to build the assembly is:

```
csc /target:library /addmodule:A.netmodule /out:B.dll
```

Looking at the assembly using `ildasm`, you can find only a manifest. In the manifest, the assembly `mscorlib` is referenced. Next, you see the assembly section with a hash algorithm and the version. The number of the algorithm defines the type of the algorithm that was used to create the hash code of the assembly. When creating an assembly programmatically it is possible to select the algorithm. Part of the manifest is a list of all modules belonging to the assembly. In Figure 18-5 you see `.file A.netmodule`, which belongs to the assembly. Classes exported from modules are part of the assembly manifest; classes exported from the assembly itself are not.

What's the purpose of modules? Modules can be used for faster startup of assemblies because not all types are inside a single file. The modules are loaded only when needed. Another reason to use modules is if you want to create an assembly with more than one programming language. One module could be written using Visual Basic, another module could be written using C#, and these two modules could be included in a single assembly.



```
  .ver 4:0:0:0
}
.assembly B
{
  .custom instance void [mscorlib]System.Runtime.CompilerServices.Runti

  .custom instance void [mscorlib]System.Runtime.CompilerServices.Compi
  .hash algorithm 0x00008004
  .ver 0:0:0:0
}
.file A.netmodule
    .hash = (83 25 30 18 C0 C8 49 E5 35 94 41 89 68 86 2A 78   // .%0...
             97 25 3F DC )                                      // .%?.
.class extern public A
{
  .file A.netmodule
  .class 0x02000002
}
.module B.dll
// MVID: {E832FA85-7153-4EA8-A485-EAEE7EC68834}
.imagebase 0x00400000
.file alignment 0x00000200
```

FIGURE 18-5

Assembly Attributes

When creating a Visual Studio project, the source file `AssemblyInfo.cs` is generated automatically. You can find this file below Properties in Solution Explorer. You can use the normal source code editor to configure the assembly attributes in this file. This is the file generated from the project template:

```
using System.Reflection;
using System.Runtime.CompilerServices;
using System.Runtime.InteropServices;
//
// General Information about an assembly is controlled through the following
// set of attributes. Change these attribute values to modify the information
// associated with an assembly.
//
[assembly: AssemblyTitle("DomainTest")]
[assembly: AssemblyDescription("")]
[assembly: AssemblyConfiguration("")]
[assembly: AssemblyCompany("")]
[assembly: AssemblyProduct("DomainTest")]
[assembly: AssemblyCopyright("Copyright @ 2010")]
[assembly: AssemblyTrademark("")]
[assembly: AssemblyCulture("")]

// Setting ComVisible to false makes the types in this assembly not visible
// to COM components.  If you need to access a type in this assembly from
// COM, set the ComVisible attribute to true on that type.
[assembly: ComVisible(false)]

// The following GUID is for the ID of the typelib if this project is exposed
// to COM
[assembly: Guid("ae0acc2c-0daf-4bb0-84a3-f9f6ac48bfe9")]

//
// Version information for an assembly consists of the following four
// values:
//
//      Major Version
//      Minor Version
//      Build Number
//      Revision
//
[assembly: AssemblyVersion("1.0.0.0")]
[assembly: AssemblyFileVersion("1.0.0.0")]
```

This file is used for configuration of the assembly manifest. The compiler reads the assembly attributes to inject the specific information into the manifest.

The `assembly:` prefix with the attribute marks an assembly-level attribute. Assembly-level attributes are, in contrast to the other attributes, not attached to a specific language element. The arguments that can be used for the assembly attribute are classes of the namespaces `System.Reflection`, `System.Runtime.CompilerServices`, and `System.Runtime.InteropServices`.

You can read more about attributes and how to create and use custom attributes in Chapter 14.

The following table contains a list of assembly attributes defined within the `System.Reflection` namespace.

ASSEMBLY ATTRIBUTE	DESCRIPTION
`AssemblyCompany`	Specifies the company name.
`AssemblyConfiguration`	Specifies build information such as retail or debugging information.
`AssemblyCopyright` and `AssemblyTrademark`	Hold the copyright and trademark information.
`AssemblyDefaultAlias`	Can be used if the assembly name is not easily readable (such as a GUID when the assembly name is created dynamically). With this attribute an alias name can be specified.
`AssemblyDescription`	Describes the assembly or the product. Looking at the properties of the executable file this value shows up as Comments.
`AssemblyProduct`	Specifies the name of the product where the assembly belongs.
`AssemblyTitle`	Used to give the assembly a friendly name. The friendly name can include spaces. With the file properties you can see this value as Description.
`AssemblyCulture`	Defines the culture of the assembly. This attribute is important for satellite assemblies.
`AssemblyInformationalVersion`	This attribute isn't used for version checking when assemblies are referenced; it is for information only. It is very useful to specify the version of an application that uses multiple assemblies. Opening the properties of the executable you can see this value as the Product Version.
`AssemblyVersion`	This attribute gives the version number of the assembly. Versioning is discussed later in this chapter.
`AssemblyFileVersion`	This attribute defines the version of the file. The value shows up with the Windows file properties dialog, but it doesn't have any influence on the .NET behavior.

Here's an example of how these attributes might be configured:

```
[assembly: AssemblyTitle("Professional C#")]
[assembly: AssemblyDescription("Sample Application")]
[assembly: AssemblyConfiguration("Retail version")]
[assembly: AssemblyCompany("Wrox Press")]
[assembly: AssemblyProduct("Wrox Professional Series")]
[assembly: AssemblyCopyright("Copyright (C) Wrox Press 2010")]
[assembly: AssemblyTrademark("Wrox is a registered trademark of " +
     "John Wiley & Sons, Inc.")]
[assembly: AssemblyCulture("")]

[assembly: AssemblyVersion("1.0.0.0")]
[assembly: AssemblyFileVersion("1.0.0.0")]
```

With Visual Studio 2010, you can configure these attributes with the project properties, Application settings, and Assembly Information, as you can see in Figure 18-6.

FIGURE 18-6

Creating and Loading Assemblies Dynamically

During development time, you add a reference to an assembly so that it gets included with the assembly references, and the types of the assembly are available to the compiler. During runtime the referenced assembly is loaded as soon as a type of the assembly is instantiated or a method of the type is used. Instead of using this automatic behavior, you can also load assemblies programmatically. To load assemblies programmatically, you can use the class `Assembly` with the static method `Load()`. This method is overloaded where you can pass the name of the assembly using `AssemblyName`, the name of the assembly, or a byte array.

It is also possible to create an assembly on the fly, as shown with the next example. This sample demonstrates how C# code can be entered in a text box, a new assembly is dynamically created by starting the C# compiler, and the compiled code is invoked.

To compile C# code dynamically, you can use the class `CSharpCodeProvider` from the namespace `Microsoft.CSharp`. Using this class, you can compile code and generate assemblies from a DOM tree, from a file, and from source code.

The UI of the application is created by using WPF. You can see the design view of the UI in Figure 18-7. The window is made up of a `TextBox` to enter C# code, a `Button`, and a `TextBlock` WPF control that spans all columns of the last row to display the result, as shown in Figure 18-7.

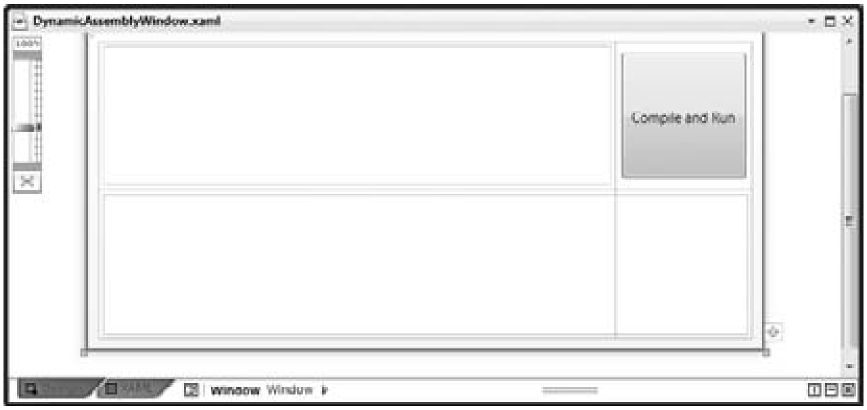

FIGURE 18-7

To dynamically compile and run C# code, the class `CodeDriver` defines the method `CompileAndRun()`. This method compiles the code from the text box and starts the generated method.

```
using System;
using System.CodeDom.Compiler;
using System.IO;
using System.Reflection;
using System.Text;
using Microsoft.CSharp;

namespace Wrox.ProCSharp.Assemblies
{

   public class CodeDriver
   {
      private string prefix =
         "using System;" +
         "public static class Driver" +
         "{" +
         "   public static void Run()" +
         "   {";

      private string postfix =
         "   }" +
         "}";

      public string CompileAndRun(string input, out bool hasError)
      {
         hasError = false;
         string returnData = null;

         CompilerResults results = null;
         using (var provider = new CSharpCodeProvider())
         {
            var options = new CompilerParameters();
            options.GenerateInMemory = true;

            var sb = new StringBuilder();
            sb.Append(prefix);
            sb.Append(input);
            sb.Append(postfix);

            results = provider.CompileAssemblyFromSource(
                  options, sb.ToString());
         }

         if (results.Errors.HasErrors)
         {
            hasError = true;
            var errorMessage = new StringBuilder();
            foreach (CompilerError error in results.Errors)
            {
               errorMessage.AppendFormat("{0} {1}", error.Line,
                     error.ErrorText);
            }
            returnData = errorMessage.ToString();
         }
         else
         {
            TextWriter temp = Console.Out;
            var writer = new StringWriter();
            Console.SetOut(writer);
            Type driverType = results.CompiledAssembly.GetType("Driver");

            driverType.InvokeMember("Run", BindingFlags.InvokeMethod |
                  BindingFlags.Static | BindingFlags.Public,
                  null, null, null);
```

```
                Console.SetOut(temp);

                returnData = writer.ToString();
            }

            return returnData;
        }
    }
}
```

code snippet DynamicAssembly/CodeDriver.cs

The method `CompileAndRun()` requires a string input parameter where one or multiple lines of C# code can be passed. Because every method that is called must be included in a method and a class, the variables `prefix` and `postfix` define the structure of the dynamically created class `Driver` and the method `Run()` that surround the code from the parameter. Using a `StringBuilder`, the `prefix`, `postfix`, and the code from the `input` variable are merged to create a complete class that can be compiled. Using this resultant string, the code is compiled with the `CSharpCodeProvider` class. The method `CompileAssemblyFromSource()` dynamically creates an assembly. Because this assembly is just needed in memory, the compiler parameter option `GenerateInMemory` is set.

If the source code that was passed contains some errors, these will show up in the `Errors` collection of `CompilerResults`. The errors are returned with the return data, and the variable `hasError` is set to `true`.

If the source code compiles successfully, the `Run()` method of the new `Driver` class is invoked. The invocation of this method is done using reflection. From the newly compiled assembly that can be accessed using `CompilerResults.CompiledType`, the new class `Driver` is referenced by the `driverType` variable. Then the `InvokeMember()` method of the `Type` class is used to invoke the method `Run()`. Because this method is defined as a public static method, the `BindingFlags` must be set accordingly. To see a result of the program that is written to the console, the console is redirected to a `StringWriter` to finally return the complete output of the program with the `returnData` variable.

Running the code with the `InvokeMember()` *method makes use of .NET reflection. Reflection is discussed in Chapter 14.*

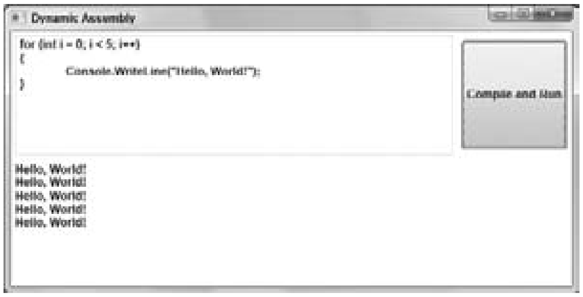
The `Click` event of the WPF button is connected to the `Compile_Click()` method where the `CodeDriver` class is instantiated, and the `CompileAndRun()` method is invoked. The input is taken from the `TextBox` named `textCode`, and the result is written to the `TextBlock textOutput`.

```
private void Compile_Click(object sender, RoutedEventArgs e)
{
    var driver = new CodeDriver ();
    bool isError;
    textOutput.Text = driver.CompileAndRun(textCode.Text, out isError);
    if (isError)
    {
        textOutput.Background = Brushes.Red;
    }
}
```

code snippet DynamicAssembly/DynamicAssemblyWindow.xaml.cs

Now you can start the application; enter C# code in the `TextBox` as shown in Figure 18-8, and compile and run the code.

The program as written so far has the disadvantage that every time you click the Compile and Run button, a new assembly is created and loaded, and the program always needs more and more memory. You cannot unload an assembly from the application. To unload assemblies, application domains are needed.



```
for (int i = 0; i < 5; i++)
{
        Console.WriteLine("Hello, World!");
}
```

```
Hello, World!
Hello, World!
Hello, World!
Hello, World!
Hello, World!
```

FIGURE 18-8

APPLICATION DOMAINS

Before .NET, processes were used as isolation boundaries, with every process having its private virtual memory; an application running in one process could not write to the memory of another application and thereby crash the other application. The process was used as an isolation and security boundary between applications. With the .NET architecture, you have a new boundary for applications: *application domains*. With managed IL code, the runtime can ensure that access to the memory of another application inside a single process can't happen. Multiple applications can run in a single process within multiple application domains (see Figure 18-9).

An assembly is loaded into an application domain. In Figure 18-9, you can see process 4711 with two application domains. In application domain A, objects one and two are instantiated, object one in assembly one, and object two in assembly two. The second application domain in process 4711 has an instance one. To minimize memory consumption, the code of assemblies is only loaded once into an application domain. Instance and static members are not shared among application domains. It's not possible to directly access objects within another application domain; a proxy is needed instead. So in Figure 18-9, the object one in application domain B cannot directly access the objects one or two in application domain A without a proxy.

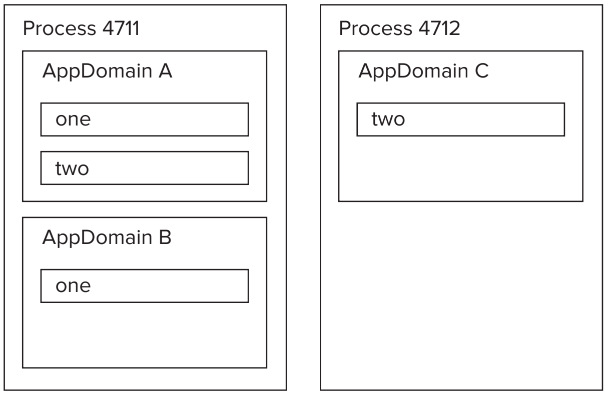


FIGURE 18-9

The `AppDomain` class is used to create and terminate application domains, load and unload assemblies and types, and enumerate assemblies and threads in a domain. In this section, you program a small example to see application domains in action.

First, create a C# console application called `AssemblyA`. In the `Main()` method add a `Console.WriteLine()` so that you can see when this method is called. In addition, add the class `Demo` with a constructor with two `int` values as arguments, which will be used to create instances with the `AppDomain` class. The `AssemblyA.exe` assembly will be loaded from the second application that will be created:

```
using System;

namespace Wrox.ProCSharp.Assemblies
{
   public class Demo
   {
      public Demo(int val1, int val2)
      {
         Console.WriteLine("Constructor with the values {0}, {1}" +
               " in domain {2} called", val1, val2,
               AppDomain.CurrentDomain.FriendlyName);
      }
   }

   class Program
   {
      static void Main()
      {
         Console.WriteLine("Main in domain {0} called",
               AppDomain.CurrentDomain.FriendlyName);
      }
   }
}
```

code snippet AssemblyA/Program.cs

Running the application produces this output:

```
Main in domain AssemblyA.exe called.
```

The second project you create is again a C# console application: `DomainTest`. First, display the name of the current domain using the property `FriendlyName` of the `AppDomain` class. With the `CreateDomain()` method, a new application domain with the friendly name `New AppDomain` is created. Next, load the assembly `AssemblyA` into the new domain and call the `Main()` method by calling `ExecuteAssembly()`:

```
using System;
using System.Reflection;

namespace Wrox.ProCSharp.Assemblies
{
   class Program
   {
      static void Main()
      {
         AppDomain currentDomain = AppDomain.CurrentDomain;
         Console.WriteLine(currentDomain.FriendlyName);
         AppDomain secondDomain = AppDomain.CreateDomain("New AppDomain");
         secondDomain.ExecuteAssembly("AssemblyA.exe");
      }
   }
}
```

code snippet DomainTest/Program.cs

Before starting the program `DomainTest.exe`, reference the assembly `AssemblyA.exe` with the `DomainTest` project. Referencing the assembly with Visual Studio 2010 copies the assembly to the project directory, so that the assembly can be found. If the assembly cannot be found, a `System.IO.FileNotFoundException` exception is thrown.

When `DomainTest.exe` is run, you get the following console output. `DomainTest.exe` is the friendly name of the first application domain. The second line is the output of the newly loaded assembly in the `New`

AppDomain. With a process viewer, you will not see the process AssemblyA.exe executing because there's no new process created. AssemblyA is loaded into the process DomainTest.exe.

```
DomainTest.exe
Main in domain New AppDomain called
```

Instead of calling the Main() method in the newly loaded assembly, you can also create a new instance. In the following example, replace the ExecuteAssembly() method with a CreateInstance(). The first argument is the name of the assembly, AssemblyA. The second argument defines the type that should be instantiated: Wrox.ProCSharp.Assemblies.AppDomains.Demo. The third argument, true, means that case is ignored. System.Reflection.BindingFlags.CreateInstance is a binding flag enumeration value to specify that the constructor should be called:

```
AppDomain secondDomain = AppDomain.CreateDomain("New AppDomain");
// secondDomain.ExecuteAssembly("AssemblyA.exe");
secondDomain.CreateInstance("AssemblyA", "Wrox.ProCSharp.Assemblies.Demo",
   true, BindingFlags.CreateInstance, null, new object[] {7, 3},
   null, null);
```

code snippet DomainTest/Program.cs

The results of a successful run of the application are as follows:

```
DomainTest.exe
Constructor with the values 7, 3 in domain New AppDomain called
```

Now you have seen how to create and call application domains. In runtime hosts, application domains are created automatically. ASP.NET creates an application domain for each web application that runs on a web server. Internet Explorer creates application domains in which managed controls will run. For applications, it can be useful to create application domains if you want to unload an assembly. You can unload assemblies only by terminating an application domain.

Application domains are an extremely useful construct if assemblies are loaded dynamically, and the requirement exists to unload assemblies after use. Within the primary application domain, it is not possible to get rid of loaded assemblies. However, it is possible to end application domains where all assemblies loaded just within the application domain are cleaned from the memory.

With this knowledge about application domains, it is now possible to change the WPF program created earlier. The new class CodeDriverInAppDomain creates a new application domain using AppDomain .CreateDomain. Inside this new application domain, the class CodeDriver is instantiated using CreateInstanceAndUnwrap(). Using the CodeDriver instance, the CompileAndRun() method is invoked before the new app-domain is unloaded again.

```
using System;
using System.Runtime.Remoting;

namespace Wrox.ProCSharp.Assemblies
{
   public class CodeDriverInAppDomain
   {
      public string CompileAndRun(string code, out bool hasError)
      {
         AppDomain codeDomain = AppDomain.CreateDomain("CodeDriver");

         CodeDriver codeDriver = (CodeDriver)
```

```
                codeDomain.CreateInstanceAndUnwrap("DynamicAssembly",
                    "Wrox.ProCSharp.Assemblies.CodeDriver");

            string result = codeDriver.CompileAndRun(code, out hasError);

            AppDomain.Unload(codeDomain);

            return result;
        }
    }
}
```

code snippet DynamicAssembly/CodeDriverInAppDomain.cs

The class `CodeDriver` itself now is used both in the main app-domain and in the new app-domain, that's why it is not possible to get rid of the code that this class is using. If you would like to do that, you can define an interface that is implemented by the `CodeDriver` and just use the interface in the main app-domain. However, here this is not an issue because there's only the need to get rid of the dynamically created assembly with the `Driver` class.

To access the class `CodeDriver` from a different app-domain, the class `CodeDriver` must derive from the base class `MarshalByRefObject`. Only classes that derive from this base type can be accessed across another app-domain. In the main app-domain, a proxy is instantiated to invoke the methods of this class across an inter-appdomain channel.

```
using System;
using System.CodeDom.Compiler;
using System.IO;
using System.Reflection;
using System.Text;
using Microsoft.CSharp;

namespace Wrox.ProCSharp.Assemblies
{

    public class CodeDriver: MarshalByRefObject
    {
```

code snippet DynamicAssembly/CodeDriver.cs

The `Compile_Click()` event handler can now be changed to use the `CodeDriverInAppDomain` class instead of the `CodeDriver` class:

```
        private void Compile_Click(object sender, RoutedEventArgs e)
        {
            var driver = new CodeDriverInAppDomain();
            bool isError;
            textOutput.Text = driver.CompileAndRun(textCode.Text, out isError);
            if (isError)
            {
                textOutput.Background = Brushes.Red;
            }
        }
```

code snippet DynamicAssembly/DynamicAssemblyWindow.xaml.cs

Now you can click the Compile and Run button of the application any number of times, and the generated assembly is always unloaded.

You can see the loaded assemblies in an app-domain with the `GetAssemblies()` *method of the* `AppDomain` *class.*

SHARED ASSEMBLIES

Assemblies can be isolated for use by a single application — not sharing an assembly is the default. When using shared assemblies there are specific requirements that must be followed.

This section explores all that's needed for sharing assemblies. Strong names are required for uniquely identifying a share assembly. Strong names are created by signing the assembly. This section also explains the process of delayed signing. Shared assemblies are typically installed into the global assembly cache (GAC). You will read about how to use the GAC.

Strong Names

The goals for a shared assembly name are that it must be globally unique and it must be possible to protect the name. At no time can any other person create an assembly using the same name.

COM solved the first problem by using a globally unique identifier (GUID). The second problem, however, still existed because anyone could steal the GUID and create a different object with the same identifier. Both problems are solved with *strong names* of .NET assemblies.

A strong name is made of these items:

➤ The *name* of the assembly itself.

➤ A *version number*. This allows it to use different versions of the same assembly at the same time. Different versions can also work side by side and can be loaded concurrently inside the same process.

➤ A *public key* guarantees that the strong name is unique. It also guarantees that a referenced assembly cannot be replaced from a different source.

➤ A *culture*. Cultures are discussed in Chapter 22.

A shared assembly must have a strong name to uniquely identify the assembly.

A strong name is a simple text name accompanied by a version number, a public key, and a culture. You wouldn't create a new public key with every assembly, but you'd have one in your company, so the key uniquely identifies your company's assemblies.

However, this key cannot be used as a trust key. Assemblies can carry Authenticode signatures to build up a trust. The key for the Authenticode signature can be a different one from the key used for the strong name.

For development purposes, a different public key can be used and later be exchanged easily with the real key. This feature is discussed later in the section "Delayed Signing of Assemblies."

To uniquely identify the assemblies in your companies, a useful namespace hierarchy should be used to name your classes. Here is a simple example showing how to organize namespaces: Wrox Press can use the major namespace `Wrox` for its classes and namespaces. In the hierarchy below the namespace, the namespaces must be organized so that all classes are unique. Every chapter of this book uses a different namespace of the form `Wrox.ProCSharp.<Chapter>`; this chapter uses `Wrox.ProCSharp.Assemblies`. So, if there is a class `Hello` in two different chapters, there's no conflict because of different namespaces. Utility classes that are used across different books can go into the namespace `Wrox.Utilities`.

A company name commonly used as the first part of the namespace is not necessarily unique, so something more must be used to build a strong name. For this the public key is used. Because of the public/private key principle in strong names, no one without access to your private key can destructively create an assembly that could be unintentionally called by the client.

Integrity Using Strong Names

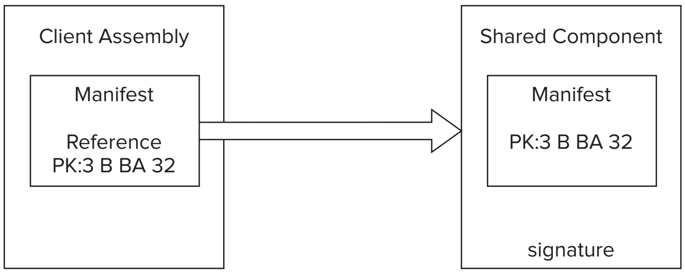

FIGURE 18-10

Global Assembly Cache

The *global assembly cache* (GAC) is, as the name implies, a cache for globally available assemblies. Most shared assemblies are installed inside this cache; otherwise, a shared directory (also on a server) can be used.

The GAC is located in the directory `<windows>\assembly`. Inside this directory, you can find multiple `GACxxx` directories and a `NativeImages_<runtime version>` directory. The `GACxxx` directories contain shared assemblies. `GAC_MSIL` contains the assemblies with pure .NET code; `GAC_32` contains the assemblies that are specific to a 32-bit platform. On a 64-bit system, you can also find the directory `GAC_64` with assemblies specific for 64 bit. The directory `GAC` is for backward compatibility with .NET 1.0 and 1.1. In the directory `NativeImages_<runtime version>`, you can find the assemblies compiled to native code. If you go deeper in the directory structure, you will find directory names that are similar to the assembly names, and below that, a version directory and the assemblies themselves. This allows the installation of different versions of the same assembly.

`gacutil.exe` is a utility to install, uninstall, and list assemblies using the command line. The following list explains some of the `gacutil` options:

- `gacutil /l` lists all assemblies from the assembly cache.
- `gacutil /i mydll` installs the shared assembly `mydll` into the assembly cache. With the option `/f` you can force the installation to the GAC even if the assembly is already installed. This is useful if you changed the assembly but didn't change the version number.
- `gacutil /u mydll` uninstalls the assembly `mydll`.

For production you should use an installer program to install shared assemblies to the GAC. Deployment is covered in Chapter 17.

Creating a Shared Assembly

In the next example, you create a shared assembly and a client that uses it.

Creating shared assemblies is not much different from creating private assemblies. Create a simple Visual C# class library project with the name `SharedDemo`. Change the namespace to `Wrox.ProCSharp.Assemblies` and the class name to `SharedDemo`. Enter the following code. In the constructor of the class, all lines of a file are read into an array. The name of the file is passed as an argument to the constructor. The method `GetQuoteOfTheDay()` just returns a random string of the array.

```
using System;
using System.IO;

namespace Wrox.ProCSharp.Assemblies
{
   public class SharedDemo
   {
      private string[] quotes;
      private Random random;

      public SharedDemo(string filename)
      {
         quotes = File.ReadAllLines(filename);
         random = new Random();
      }

      public string GetQuoteOfTheDay()
      {
         int index = random.Next(1, quotes.Length);
         return quotes[index];
      }
   }
}
```

code snippet SharedDemo/SharedDemo.cs

Create a Strong Name

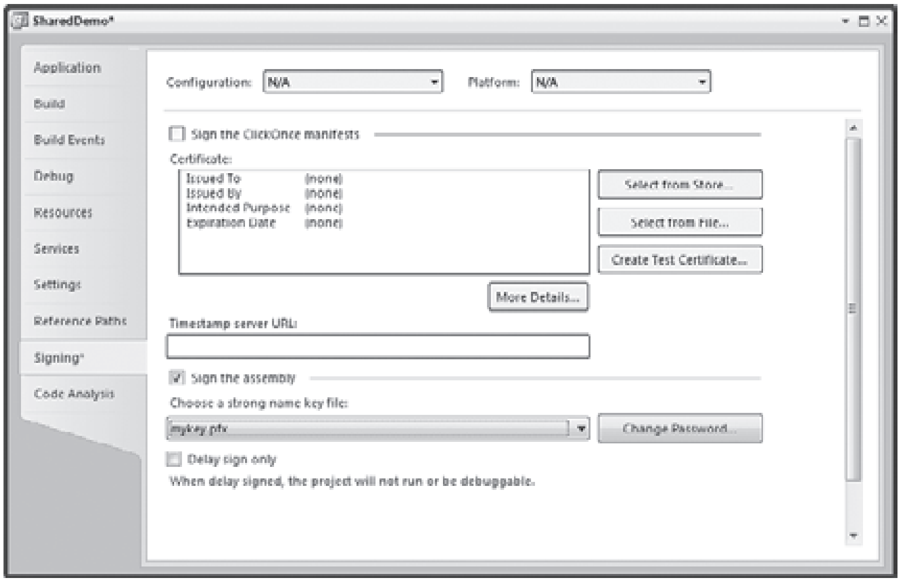
A strong name is needed to share this assembly. You can create such a name with the *strong name tool* (`sn`):

```
sn -k mykey.snk
```

The strong name utility generates and writes a public/private key pair, and writes this pair to a file; here the file is `mykey.snk`.

With Visual Studio 2010, you can sign the assembly with the project properties by selecting the Signing tab, as shown in Figure 18-11. You can also create keys with this tool. However, you should not create a key file for every project. Just a few keys for the complete company can be used instead. It is useful to create different keys depending on security requirements (see Chapter 21).

Setting the signing option with Visual Studio adds the `/keyfile` option to the compiler setting. Visual Studio also allows you to create a keyfile that is secured with a password. Such a file has the file extension `.pfx` (see Figure 18-11).



Configuration: N/A   Platform: N/A

☐ Sign the ClickOnce manifests

Certificate:

```
Issued To          (none)
Issued By          (none)
Intended Purpose   (none)
Expiration Date    (none)
```

Timestamp server URL:

☑ Sign the assembly

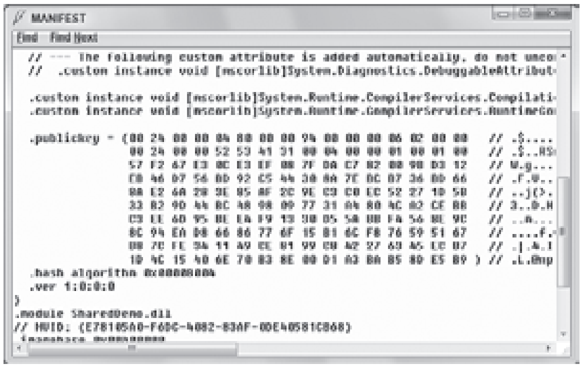
Choose a strong name key file: mykey.pfx

☐ Delay sign only

When delay signed, the project will not run or be debuggable.

FIGURE 18-11

After rebuilding, the public key can be found inside the manifest. You can verify this using `ildasm`, as shown in Figure 18-12.



```
  // --- The following custom attribute is added automatically, do not unco
  //  .custom instance void [mscorlib]System.Diagnostics.DebuggableAttribut

  .custom instance void [mscorlib]System.Runtime.CompilerServices.Compilati
  .custom instance void [mscorlib]System.Runtime.CompilerServices.RuntimeCo

                1D 4C 15 40 6E 70 83 8E 00 01 A3 BA 85 80 E5 B9 ) // .L.@np
  .hash algorithm 0x00008004
  .ver 1:0:0:0
}
.module SharedDemo.dll
// MVID: {E78105A0-F6DC-4082-83AF-0DE40581C868}
```

FIGURE 18-12

Installing the Shared Assembly

With a public key in the assembly, you can now install it in the global assembly cache using the global assembly cache tool `gacutil` with the `/i` option. The `/f` option forces you to write the assembly to the GAC, even if it is already there.

```
gacutil /i SharedDemo.dll /f
```

Then you can use the Global Assembly Cache Viewer or `gacutil /l SharedDemo` to check the version of the shared assembly and see if it is successfully installed.

Using the Shared Assembly

To use the shared assembly, create a C# console application called `Client`. Change the name of the namespace to `Wrox.ProCSharp.Assemblies`. The shared assembly can be referenced in the same way as a private assembly: by using the Project → Add Reference menu.

With shared assemblies the reference property `Copy Local` *can be set to* `false`*. This way the assembly is not copied to the directory of the output files but will be loaded from the GAC instead.*

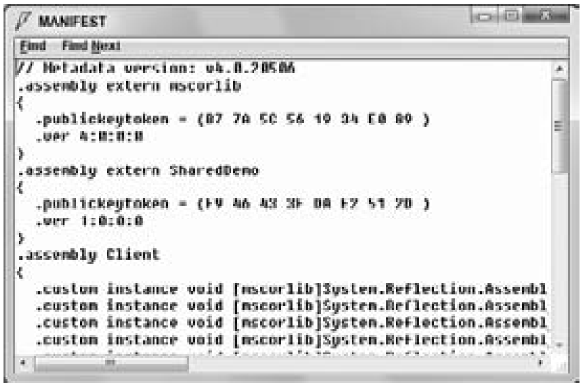
Add the file `quotes.txt` to the project items, and set the property `Copy to Output Directory` to `Copy if newer`.

Here's the code for the `Client` application:

```
using System;
namespace Wrox.ProCSharp.Assemblies
{
   class Program
   {
      static void Main()
      {
          var quotes = new SharedDemo("Quotes.txt");
          for (int i=0; i < 3; i++)
          {
             Console.WriteLine(quotes.GetQuoteOfTheDay());
             Console.WriteLine();
          }
      }
   }
}
```

code snippet Client/Program.cs

Looking at the manifest in the client assembly using `ildasm` (see Figure 18-13), you can see the reference to the shared assembly `SharedDemo`: `.assembly extern SharedDemo`. Part of this referenced information is the version number, discussed next, and the token of the public key.



```
// Metadata version: v4.0.20506
.assembly extern mscorlib
{
  .publickeytoken = (B7 7A 5C 56 19 34 E0 89 )
  .ver 4:0:0:0
}
.assembly extern SharedDemo
{
  .publickeytoken = (F9 46 43 3F 0A E2 51 7D )
  .ver 1:0:0:0
}
.assembly Client
{
  .custom instance void [mscorlib]System.Reflection.Assembl
  .custom instance void [mscorlib]System.Reflection.Assembl
  .custom instance void [mscorlib]System.Reflection.Assembl
  .custom instance void [mscorlib]System.Reflection.Assembl
```

FIGURE 18-13

The token of the public key can also be seen within the shared assembly using the strong name utility: `sn -T` shows the token of the public key in the assembly, and `sn -Tp` shows the token and the public key. Pay attention to the use of the uppercase T!

The result of your program with a sample quotes file is shown here:

```
"We don't like their sound. And guitar music is on the way out." — Decca Recording,
Co., in rejecting the Beatles, 1962

"The ordinary 'horseless carriage' is at present a luxury for the wealthy; and
although its price will probably fall in the future, it will never come into as
common use as the bicycle." — The Literary Digest, 1889

"Landing and moving around the moon offers so many serious problems for human
beings that it may take science another 200 years to lick them", Lord Kelvin
(1824–1907)
```

Delayed Signing of Assemblies

The private key of a company should be safely stored. Most companies don't give all developers access to the private key; only a few security people have it. That's why the signature of an assembly can be added at a later date, such as before distribution. When the assembly attribute `AssemblyDelaySign` is set to `true`, no signature is stored in the assembly, but enough free space is reserved so that it can be added later. Without using a key, you cannot test the assembly and install it in the GAC; however, you can use a temporary key for testing purposes, and replace this key with the real company key later.

The following steps are required to delay signing of assemblies:

1. Create a public/private key pair with the strong name utility `sn`. The generated file `mykey.snk` includes both the public and private keys.

   ```
   sn -k mykey.snk
   ```

2. Extract the public key to make it available to developers. The option `–p` extracts the public key of the keyfile. The file `mykeypub.snk` only holds the public key.

   ```
   sn -p mykey.snk mykeypub.snk
   ```

   All developers in the company can use this keyfile `mykeypub.snk` and compile the assembly with the `/delaysign+` option. This way the signature is not added to the assembly, but it can be added afterward. In Visual Studio 2010, the delay sign option can be set with a check box in the Signing settings.

3. Turn off the verification of the signature, because the assembly doesn't have a signature:

   ```
   sn -Vr SharedDemo.dll
   ```

4. Before distribution the assembly can be re-signed with the `sn` utility. Use the `–R` option to re-sign previously signed or delayed signed assemblies. Re-signing of the assembly can be done by the person who does the deployment package for the application and has access to the private key that is used for distribution.

   ```
   sn -R MyAssembly.dll mykey.snk
   ```

The signature verification should be turned off only during the development process. Never distribute an assembly without verification, because it would be possible for this assembly to be replaced by a malicious one.

Re-signing of assemblies can be automated by defining the tasks in an MSBuild file. This is discussed in Chapter 16, "Visual Studio 2010."

References

Assemblies in the GAC can have references associated with them. These references are responsible for the fact that a cached assembly cannot be deleted if it is still needed by an application. For example, if a shared assembly is installed by a Microsoft installer package (`.msi` file), it can only be deleted by uninstalling the application, not by deleting it directly from the GAC. Trying to delete the assembly from the GAC results in the error message "`Assembly <name> could not be uninstalled because it is required by other applications.`"

A reference to the assembly can be set by using the `gacutil` utility with the option `/r`. The option `/r` requires a reference type, a reference ID, and a description. The type of the reference can be one of three options: `UNINSTALL_KEY`, `FILEPATH`, or `OPAQUE`. `UNINSTALL_KEY` is used by MSI when a registry key is defined that is also needed for the uninstallation. A directory can be specified with `FILEPATH`. A useful directory would be the root directory of the application. The `OPAQUE` reference type allows you to set any type of reference.

The command line

```
gacutil /i shareddemo.dll /r FILEPATH c:\ProCSharp\Assemblies\Client "Shared Demo"
```

installs the assembly `shareddemo` in the GAC with a reference to the directory of the client application. Another installation of the same assembly can happen with a different path, or an `OPAQUE` ID like in this command line:

```
gacutil /i shareddemo.dll /r OPAQUE 4711 "Opaque installation"
```

Now, the assembly is in the GAC only once, but it has two references. To delete the assembly from the GAC, both references must be removed:

```
gacutil /u shareddemo /r OPAQUE 4711 "Opaque installation"
gacutil /u shareddemo /r FILEPATH c:\ProCSharp\Assemblies\Client "Shared Demo"
```

To remove a shared assembly, the option `/u` *requires the assembly name without the file extension DLL. On the contrary, the option* `/i` *to install a shared assembly requires the complete filename including the file extension.*

Chapter 17 deals with deployment of assemblies, where the reference count is being dealt with in an MSI package.

Native Image Generator

With the native image generator, `Ngen.exe`, you can compile the IL code to native code at installation time. This way the program can start faster because the compilation during runtime is no longer necessary. Comparing precompiled assemblies to assemblies where the JIT compiler needs to run is not different from a performance view after the IL code is compiled. The only improvement you get with the native image generator is that the application starts faster because there's no need to run JIT. Reducing the startup time of the application might be enough reason for using the native image generator. In case you create a native image from the executable, you should also create native images from all the DLLs that are loaded by the executable. Otherwise, the JIT compiler still needs to run.

The `ngen` utility installs the native image in the native image cache. The physical directory of the native image cache is `<windows>\assembly\NativeImages<RuntimeVersion>`.

With `ngen install myassembly`, you can compile the MSIL code to native code and install it into the native image cache. This should be done from an installation program if you would like to put the assembly in the native image cache.

With `ngen`, you can also display all assemblies from the native image cache with the option `display`. If you add an assembly name to the `display` option, you get the information about all installed versions of this assembly and the assemblies that are dependent on the native assembly:

```
C:\>ngen display System.AddIn
Microsoft (R) CLR Native Image Generator - Version 4.0.21006.1
Copyright (c) Microsoft Corporation.  All rights reserved.

NGEN Roots:

System.AddIn, Version=3.5.0.0, Culture=Neutral, PublicKeyToken=b77a5c561934e089,
 processorArchitecture=msil
System.AddIn, Version=4.0.0.0, Culture=neutral, PublicKeyToken=b77a5c561934e089

NGEN Roots that depend on "System.AddIn":

C:\Program Files (x86)\Common Files\Microsoft Shared\VSTA\Pipeline.v10.0\
AddInSideAdapters\Microsoft.VisualStudio.Tools.Applications.AddInAdapter.v9.0.dll
C:\Program Files (x86)\Common Files\Microsoft Shared\VSTA\Pipeline.v10.0\
AddInSideAdapters\Microsoft.VisualStudio.Tools.Office.AddInAdapter.v9.0.dll
...
```

If the security of the system changes, it's not sure if the native image has the security requirements it needs for running the application. This is why the native images become invalid with a system configuration change. With the command `ngen update`, all native images are rebuilt to include the new configurations.

Installing .NET 4 also installs the Native Runtime Optimization Service. This service can be used to defer compilation of native images and regenerates native images that have been invalidated.

The command `ngen install myassembly /queue` can be used by an installation program to defer compilation of `myassembly` to a native image using the Native Image Service. `ngen update /queue` regenerates all native images that have been invalidated. With the `ngen queue` options `pause`, `continue`, and `status` you can control the service and get status information.

You might ask why the native images cannot be created on the developer system, and you just distribute the native image to the production system. The reason is that the native image generator takes care of the CPU that is installed with the target system and compiles the code optimized for the CPU type. During installation of the application, the CPU is known.

CONFIGURING .NET APPLICATIONS

COM components are used in the registry to configure components. Configuration of .NET applications is done by using configuration files. With registry configurations, an xcopy deployment is not possible. Configuration files can simply be copied. The configuration files use XML syntax to specify startup and runtime settings for applications.

This section explores the following:

- What you can configure using the XML base configuration files
- How you can redirect a strongly named referenced assembly to a different version
- How you can specify the directory of assemblies to find private assemblies in subdirectories and shared assemblies in common directories or on a server

Configuration Categories

The configuration can be grouped into these categories:

- **Startup settings** enable you to specify the version of the required runtime. It's possible that different versions of the runtime could be installed on the same system. The version of the runtime can be specified with the `<startup>` element.
- **Runtime settings** enable you to specify how garbage collection is performed by the runtime and how the binding to assemblies works. You can also specify the version policy and the code base with these settings. You take a more detailed look into the runtime settings later in this chapter.
- **WCF settings** are used to configure applications using WCF. You deal with these configurations in Chapter 43, "Windows Communication Foundation."
- **Security settings** are introduced in Chapter 21 and configuration for cryptography and permissions is done there.

These settings can be provided in three types of configuration files:

- **Application configuration files** include specific settings for an application, such as binding information to assemblies, configuration for remote objects, and so on. Such a configuration file is placed into the same directory as the executable; it has the same name as the executable with a `.config` extension appended. ASP.NET configuration files are named `web.config`.
- **Machine configuration files** are used for system-wide configurations. You can also specify assembly binding and remoting configurations here. During a binding process, the machine configuration file is consulted before the application configuration file. The application configuration can override settings

from the machine configuration. The application configuration file should be the preferred place for application-specific settings so that the machine configuration file stays smaller and more manageable. A machine configuration file is located in `%runtime_install_path%\config\Machine.config`.

- **Publisher policy files** can be used by a component creator to specify that a shared assembly is compatible with older versions. If a new assembly version just fixes a bug of a shared component, it is not necessary to put application configuration files in every application directory that uses this component; the publisher can mark it as compatible by adding a publisher policy file instead. In case the component doesn't work with all applications, it is possible to override the publisher policy setting in an application configuration file. In contrast to the other configuration files, publisher policy files are stored in the GAC.

How are these configuration files used? How a client finds an assembly (also called *binding*) depends on whether the assembly is private or shared. Private assemblies must be in the directory of the application or in a subdirectory thereof. A process called *probing* is used to find such an assembly. If the assembly doesn't have a strong name, the version number is not used with probing.

Shared assemblies can be installed in the GAC or placed in a directory, on a network share, or on a web site. You specify such a directory with the configuration of the `codeBase` shortly. The public key, version, and culture are all important aspects when binding to a shared assembly. The reference of the required assembly is recorded in the manifest of the client assembly, including the name, the version, and the public key token. All configuration files are checked to apply the correct version policy. The GAC and code bases specified in the configuration files are checked, followed by the application directories, and probing rules are then applied.

Binding to Assemblies

You've already seen how to install a shared assembly to the GAC. Instead of installing a shared assembly to the GAC, you can configure a specific shared directory by using configuration files. This feature can be used if you want to make the shared components available on a server. Another possible scenario arises if you want to share an assembly between your applications, but you don't want to make it publicly available in the GAC, so you put it into a shared directory instead.

There are two ways to find the correct directory for an assembly: the `codeBase` element in an XML configuration file, or through probing. The `codeBase` configuration is available only for shared assemblies, and probing is done for private assemblies.

<codeBase>

The `<codeBase>` can be configured with an application configuration file. The following application configuration file redirects the search for the assembly `SharedDemo` to load it from the network:

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <runtime>
    <assemblyBinding xmlns="urn:schemas-microsoft-com:asm.v1">
      <dependentAssembly>
        <assemblyIdentity name="SharedDemo" culture="neutral"
              publicKeyToken="f946433fdae2512d" />
        <codeBase version="1.0.0.0"
              href="http://www.christiannagel.com/WroxUtils/SharedDemo.dll" />
      </dependentAssembly>
    </assemblyBinding>
  </runtime>
</configuration>
```

The `<codeBase>` element has the attributes `version` and `href`. With `version`, the original referenced version of the assembly must be specified. With `href`, you can define the directory from which the assembly should be loaded. In the example, a path using the HTTP protocol is used. A directory on a local system or a share is specified by using `href="file://C:/WroxUtils/SharedDemo.dll"`.

<probing>

When the `<codeBase>` is not configured and the assembly is not stored in the GAC, the runtime tries to find an assembly through probing. The .NET runtime tries to find assemblies with either a `.dll` or an `.exe` file extension in the application directory or in one of its subdirectories that has the same name as the assembly searched for. If the assembly is not found here, the search continues. You can configure search directories with the `<probing>` element in the `<runtime>` section of application configuration files. This XML configuration can also be done easily by selecting the properties of the application with the .NET Framework Configuration tool. You can configure the directories where the probing should occur by using the search path in the .NET Framework configuration.

The XML file produced has these entries:

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
   <runtime>
      <assemblyBinding xmlns="urn:schemas-microsoft-com:asm.v1">
         <probing privatePath="bin;utils;" />
      </assemblyBinding>
   </runtime>
</configuration>
```

The `<probing>` element has just a single required attribute: `privatePath`. This application configuration file tells the runtime that assemblies should be searched for in the base directory of the application, followed by the `bin` and the `util` directory. Both directories are subdirectories of the application base directory. It's not possible to reference a private assembly outside the application base directory or a subdirectory thereof. An assembly outside of the application base directory must have a shared name and can be referenced using the `<codeBase>` element, as you saw earlier.

VERSIONING

For private assemblies, versioning is not important because the referenced assemblies are copied with the client. The client uses the assembly it has in its private directories.

This is, however, different for shared assemblies. This section looks at the traditional problems that can occur with sharing. With shared components, more than one client application can use the same component. The new version can break existing clients when updating a shared component with a newer version. You can't stop shipping new versions because new features will be requested and introduced with new versions of existing components. You can try to program carefully to be backward compatible, but that's not always possible.

A solution to this dilemma could be an architecture that allows installation of different versions of shared components, with clients using the version that they referenced during the build process. This solves a lot of problems but not all of them. What happens if you detect a bug in a component that's referenced from the client? You would like to update this component and make sure that the client uses the new version instead of the version that was referenced during the build process.

Therefore, depending on the type in the fix of the new version, you sometimes want to use a newer version, and you also want to use the older referenced version. The .NET architecture enables both scenarios.

In .NET, the original referenced assembly is used by default. You can redirect the reference to a different version by using configuration files. Versioning plays a key role in the binding architecture — how the client gets the right assembly where the components live.

Version Numbers

Assemblies have a four-part version number, for example, `1.1.400.3300`. The parts are `<Major>.<Minor>.<Build>.<Revision>`.

How these numbers are used depends on your application configuration.

A good policy is to change the major or minor number on changes incompatible with the previous version, but just the build or revision number with compatible changes. This way, it can be assumed that redirecting an assembly to a new version where just the build and revision have changed is safe.

With Visual Studio 2010, you can define the version number of the assembly with the assembly information in the project settings. The project settings write the assembly attribute `[AssemblyVersion]` to the file `AssemblyInfo.cs`:

```
[assembly: AssemblyVersion("1.0.0.0")]
```

Instead of defining all four version numbers, you can also place an asterisk in the third or fourth place:

```
[assembly: AssemblyVersion("1.0.*")]
```

With this setting, the first two numbers specify the major and minor version, and the asterisk (`*`) means that the build and revision numbers are auto-generated. The build number is the number of days since January 1, 2000, and the revision is the number of seconds since midnight divided by two. Though the automatic versioning might help during development time, before shipping it is a good practice to define a specific version number.

This version is stored in the `.assembly` section of the manifest.

Referencing the assembly in the client application stores the version of the referenced assembly in the manifest of the client application.

Getting the Version Programmatically

To make it possible to check the version of the assembly that is used from the client application, add the read-only property `FullName` to the `SharedDemo` class created earlier to return the strong name of the assembly. For easy use of the `Assembly` class, you have to import the `System.Reflection` namespace:

```
public string FullName
{
   get
   {
      return Assembly.GetExecutingAssembly().FullName;
   }
}
```

code snippet SharedDemo/SharedDemo.cs

The `FullName` property of the `Assembly` class holds the name of the class, the version, the locality, and the public key token, as you see in the following output, when calling `FullName` in your client application.

In the client application, just add a call to `FullName` in the `Main()` method after creating the shared component:

```
static void Main()
{
   var quotes = new SharedDemo("Quotes.txt");
   Console.WriteLine(quotes.FullName);
```

code snippet Client/Program.cs

Be sure to register the new version of the shared assembly `SharedDemo` again in the GAC, using `gacutil`. If the referenced version cannot be found, you will get a `System.IO.FileLoadException`, because the binding to the correct assembly failed.

With a successful run, you can see the full name of the referenced assembly:

```
SharedDemo, Version=1.0.0.0, Culture=neutral, PublicKeyToken= f946433fdae2512d
```

This client program can now be used to test different configurations of this shared component.

Binding to Assembly Versions

With a configuration file, you can specify that the binding should happen to a different version of a shared assembly. Assume that you create a new version of the shared assembly `SharedDemo` with major and minor versions 1.1. Maybe you don't want to rebuild the client but just want the new version of the assembly to be used with the existing client instead. This is useful in cases where either a bug is fixed with the shared assembly or you just want to get rid of the old version because the new version is compatible.

By running `gacutil.exe`, you can see that the versions 1.0.0.0 and 1.0.3300.0 are installed for the `SharedDemo` assembly:

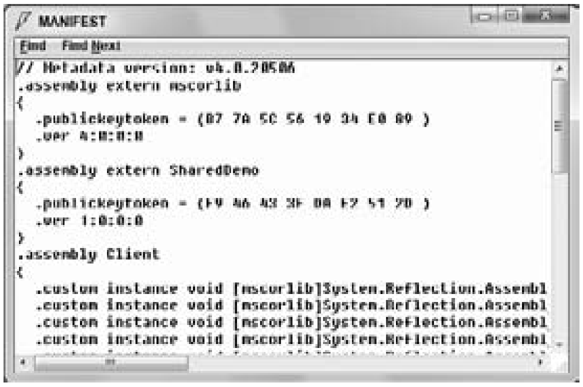
```
> gacutil -l SharedDemo

Microsoft (R) .NET Global Assembly Cache Utility.  Version 4.0.21006.1
Copyright (c) Microsoft Corporation.  All rights reserved.

The Global Assembly Cache contains the following assemblies:
  SharedDemo, Version=1.0.0.0, Culture=neutral, PublicKeyToken=f946433fdae2512d,
 processorArchitecture=x86
  SharedDemo, Version=1.0.3300.0, Culture=neutral, PublicKeyToken=f946433fdae251
2d, processorArchitecture=x86

Number of items = 2
```

Figure 18-14 shows the manifest of the client application where the client references version 1.0.0.0 of the assembly `SharedDemo`.



```
// Metadata version: v4.0.20506
.assembly extern mscorlib
{
  .publickeytoken = (B7 7A 5C 56 19 34 E0 89 )
  .ver 4:0:0:0
}
.assembly extern SharedDemo
{
  .publickeytoken = (F9 46 43 3F DA E2 51 2D )
  .ver 1:0:0:0
}
.assembly Client
{
  .custom instance void [mscorlib]System.Reflection.Assembl
  .custom instance void [mscorlib]System.Reflection.Assembl
  .custom instance void [mscorlib]System.Reflection.Assembl
  .custom instance void [mscorlib]System.Reflection.Assembl
```

FIGURE 18-14

Now, again, an application configuration file is needed. As before, the assembly that is redirected needs to be specified with the `<assemblyIdentity>` element. This element identifies the assembly using the name, culture, and public key token. For a redirect to a different version, the `<bindingRedirect>` element is used. The `oldVersion` attribute specifies what version of the assembly should be redirected to a new version. With `oldVersion` you can specify a range like the one shown that all assemblies from version 1.0.0.0 to 1.0.3300.0 should be redirected. The new version is specified with the `newVersion` attribute.

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
   <runtime>
      <assemblyBinding xmlns="urn:schemas-microsoft-com:asm.v1">
         <dependentAssembly>
            <assemblyIdentity name="SharedDemo" culture="neutral"
                  publicKeyToken="f946433fdae2512d" />
            <bindingRedirect oldVersion="1.0.0.0-1.0.3300.0"
                  newVersion="1.0.3300.0" />
            </dependentAssembly>
```

```
        </assemblyBinding>
    </runtime>
</configuration>
```

code snippet Client/App.config

Publisher Policy Files

Using assemblies shared from the GAC allows you to use publisher policies to override versioning issues. Assume that you have an assembly used by some applications. What can be done if a critical bug is found in the shared assembly? You have seen that it is not necessary to rebuild all the applications that use this shared assembly, because you can use configuration files to redirect to the new version of this shared assembly. Maybe you don't know all the applications that use this shared assembly, but you want to get the bug fix to all of them. In that case, you can create publisher policy files to redirect all applications to the new version of the shared assembly.

Publisher policy files apply only to shared assemblies installed in the GAC.

To set up publisher policies, you have to do the following:

- Create a publisher policy file
- Create a publisher policy assembly
- Add the publisher policy assembly to the GAC

Create a Publisher Policy File

A publisher policy file is an XML file that redirects an existing version or version range to a new version. The syntax used here is the same as that used for application configuration files, so you can use the file you created earlier to redirect the old versions 1.0.0.0 through 1.0.3300.0 to the new version 1.0.3300.0.

Rename the previously created file to `mypolicy.config` to use it as a publisher policy file.

Create a Publisher Policy Assembly

To associate the publisher policy file with the shared assembly, it is necessary to create a publisher policy assembly and to put it into the GAC. The tool that can be used to create such files is the assembly linker `al`. The option `/linkresource` adds the publisher policy file to the generated assembly. The name of the generated assembly must start with policy, followed by the major and minor version number of the assembly that should be redirected, and the filename of the shared assembly. In this case the publisher policy assembly must be named `policy.1.0.SharedDemo.dll` to redirect the assemblies `SharedDemo` with the major version 1 and minor version 0. The key that must be added to this publisher key with the option `/keyfile` is the same key that was used to sign the shared assembly `SharedDemo` to guarantee that the version redirection is from the same publisher.

```
al /linkresource:mypolicy.config /out:policy.1.0.SharedDemo.dll
/keyfile:.\.\mykey.snk
```

Add the Publisher Policy Assembly to the GAC

The publisher policy assembly can now be added to the GAC with the utility `gacutil`:

```
gacutil -i policy.1.0.SharedDemo.dll
```

Do not forget the `-f` option if the same policy file was already published. Now remove the application configuration file that was placed in the directory of the client application and start the client application. Although the client assembly references 1.0.0.0, you use the new version 1.0.3300.0 of the shared assembly because of the publisher policy.

Overriding Publisher Policies

With a publisher policy, the publisher of the shared assembly guarantees that a new version of the assembly is compatible with the old version. As you know, from changes of traditional DLLs, such guarantees don't always hold. Maybe all except one application is working with the new shared assembly. To fix the one application that has a problem with the new release, the publisher policy can be overridden by using an application configuration file.

You can disable the publisher policy by adding the XML element `<publisherPolicy>` with the attribute `apply="no"`.

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <runtime>
    <assemblyBinding xmlns="urn:schemas-microsoft-com:asm.v1">
      <dependentAssembly>
        <assemblyIdentity name="SharedDemo" culture="neutral"
              publicKeyToken="f946433fdae2512d" />
        <publisherPolicy apply="no" />
      </dependentAssembly>
    </assemblyBinding>
  </runtime>
</configuration>
```

code snippet Client/App.config

By disabling the publisher policy, you can configure different version redirection in the application configuration file.

Runtime Version

Installing and using multiple versions is not only possible with assemblies but also with the .NET runtime (CLR). The versions 1.0, 1.1, 2.0, and 4.0 (and later versions) of the CLR can be installed on the same operating system side by side. Visual Studio 2010 targets applications running on CLR 2.0 with .NET 2.0, 3.0, and 3.5 and CLR 4.0 with .NET 4.

If the application is built with CLR 2.0, it might run without changes on a system where only CLR version 4.0 is installed. The reverse is not true, if the application is built with CLR 4.0, it cannot run on a system where only CLR 2.0 is installed.

In an application configuration file, it's not just possible to redirect versions of referenced assemblies; you can also define the required version of the runtime. You can specify the version that's required for the application in an application configuration file. The element `<supportedRuntime>` marks the runtime versions that are supported by the application. The order of `<supportedRuntime>` elements defines the preference if multiple runtime versions are available on the system. The configuration here prefers the .NET 4 runtime and also supports 2.0. Remember, for this to be possible, the application must be built with the target framework .NET 2.0, 3.0 or 3.5.

```
<?xml version="1.0"?>
<configuration>
   <startup>
      <supportedRuntime version="v4.0.21006" />
      <supportedRuntime version="v2.0.50727" />
   </startup>
</configuration>
```

SUMMARY

Assemblies are the new installation unit for the .NET platform. Microsoft learned from problems with previous architectures and did a complete redesign to avoid the old problems. This chapter discussed the features of assemblies: they are self-describing, and no type library and registry information is needed.

Version dependencies are exactly recorded so that with assemblies, the DLL hell of old DLLs no longer exists. Because of these features, development, deployment, and administration have become a lot easier.

You learned the differences between private and shared assemblies and saw how shared assemblies can be created. With private assemblies, you don't have to pay attention to uniqueness and versioning issues because these assemblies are copied and only used by a single application. Sharing assemblies requires you to use a key for uniqueness and to define the version. You looked at the GAC, which can be used as an intelligent store for shared assemblies.

You can have faster application startups by using the native image generator. With this the JIT compiler does not need to run because the native code is created during installation time.

You looked at overriding versioning issues to use a version of an assembly different from the one that was used during development; this is done through publisher policies and application configuration files. Finally, you learned how probing works with private assemblies.

The chapter also discussed loading assemblies dynamically and creating assemblies during runtime. If you want to get more information on this, you should read about the plugin model of .NET 4 in Chapter 28, "Managed Extensibility Framework." To use a plugin model with the advantage of app-domains, see coverage of the `System.Addin` namespace in Chapter 50, "Add-Ins."

19

Instrumentation

WHAT'S IN THIS CHAPTER?

- Code contracts
- Tracing
- Event logging
- Performance monitoring

This chapter helps you to get live information about your running application to find the issues that your application might have during production or to monitor resources needed to adapt earlier to higher user loads. This is where the namespace `System.Diagnostics` comes into play.

One way to mark errors in your application, of course, is by throwing exceptions. However, an application might not fail that badly, but still not behave as expected. The application might be running well on most systems, but might have a problem on a few. On the live system, you can change the log behavior by changing a configuration value and get detailed live information about what's going on in the application. This can be done with *tracing*.

If there are problems with applications, the system administrator needs to be informed. With the Event Viewer, the system administrator can both interactively monitor problems with applications and be informed about specific events that happen by adding subscriptions. The *event-logging* mechanism allows you to write information about the application.

To analyze resources needed from applications, monitor applications with specified time intervals, and plan for a different application distribution or the extension of system resources, the system administrator can use the Performance Monitor. You can write live data from your application by using *performance counts*.

New in .NET 4 are classes that offer design-by-contract in the namespace `System.Diagnostics.Contracts`. With these classes, you can define preconditions, postconditions, and invariants that can be checked during runtime but also with a static contract analyzer.

This chapter explains these facilities and demonstrates how you can use them from your applications.

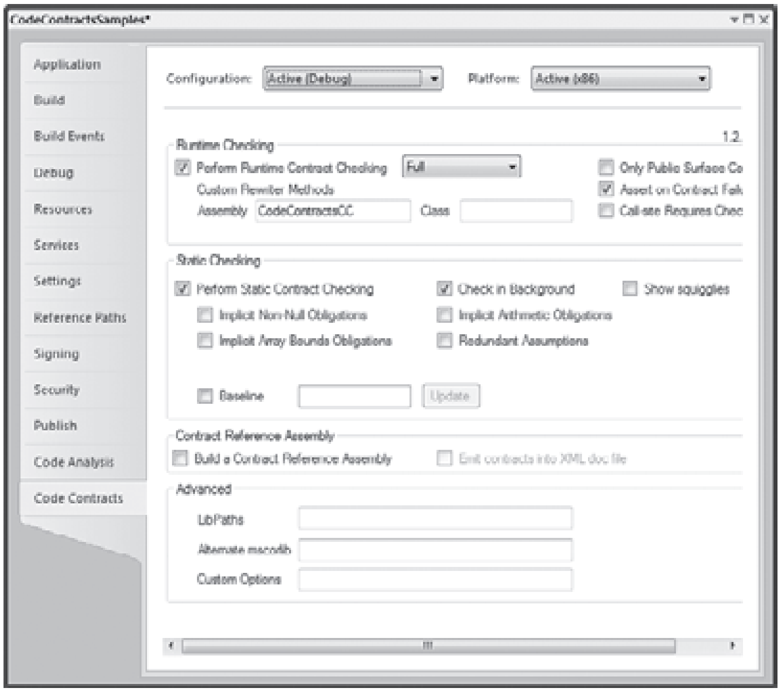
CODE CONTRACTS

Design-by-contracts is an idea from the Eiffel programming language. Now .NET 4 includes classes for static and runtime checks of code within the namespace `System.Diagnostics.Contracts` that can be used by all .NET languages.

With this functionality you can define preconditions, postconditions, and invariants within a method. The preconditions lists what requirements the parameters must fulfill, the postconditions define the requirements on returned data, and the invariants define the requirements of variables within the method itself.

Contract information can be compiled both into the debug and the release code. It is also possible to define a separate contract assembly, and many checks can also be made statically without running the application. You can also define contracts on interfaces that cause the implementations of the interface to fulfill the contracts. Contract tools can rewrite the assembly to inject contract checks within the code for runtime checks, check the contracts during compile time, and add contract information to the generated XML documentation.

Figure 19-1 shows the project properties for the code contracts in Visual Studio 2010. Here, you can define what level of runtime checking should be done, indicate if assert dialogs should be opened on contract failures, and configure static checking. Setting the Perform Runtime Contract Checking to Full defines the symbol `CONTRACTS_FULL`. Because many of the contract methods are annotated with the attribute `[Conditional("CONTRACTS_FULL")]`, all runtime checks are only done with this setting.



Configuration: Active (Debug) Platform: Active (x86)

1.2

LibPaths
Alternate mscorlib
Custom Options

FIGURE 19-1

To work with code contracts you can use classes that are available with .NET 4 in the namespace `System.Diagnostics.Contracts`*. However, there's no tool included with Visual Studio 2010. You need to download an extension to Visual Studio from Microsoft DevLabs:* `http://msdn.microsoft.com/en-us/devlabs/dd491992.aspx`*. For static analysis with this tool, the Visual Studio Team System is required; for runtime analysis, Visual Studio Standard edition is enough.*

Code contracts are defined with the `Contract` class. All contract requirements that you define in a method, no matter if they are preconditions or postconditions, must be placed at the beginning of the method. You can also assign a global event handler to the event ContractFailed that is invoked for every failed contract during runtime. Invoking SetHandled() with the ContractFailedEventArgs parameter e stops the standard behavior of failures that would throw an exception.

```
Contract.ContractFailed += (sender, e) =>
{
    Console.WriteLine(e.Message);
    e.SetHandled();
};
```

code snippet CodeContractsSamples/Program.cs

Preconditions

Preconditions check the parameters that are passed to a method. Requires() and Requires<TException>() are preconditions that can be defined with the Contract class. With the Requires() method, a Boolean value must be passed, and an optional message string with the second parameter that is shown when the condition does not succeed. The following sample requires that the argument *min* be lower than or equal to the argument *max*.

```
static void MinMax(int min, int max)
{
     Contract.Requires(min <= max);
    //...
}
```

code snippet CodeContractsSamples/Program.cs

The following contract throws an ArgumentNullException if the argument o is null. The exception is not thrown if an event handler that sets the ContractFailed event to handled. Also, if the Assert on Contract Failure is configured, Trace.Assert() is done to stop the program instead of throwing the exception defined.

```
static void Preconditions(object o)
{
    Contract.Requires<ArgumentNullException>(o != null,
        "Preconditions, o may not be null");
    //...
```

Requires<TException>() is not annotated with the attribute [Conditional("CONTRACTS_FULL")], and it also doesn't have a condition on the DEBUG symbol, so this runtime check is done in any case. Requires<TException>() throws the defined exception if the condition is not fulfilled.

With a lot of legacy code, arguments are often checked with if statements and throw an exception if a condition is not fulfilled. With code contracts, it is not necessary to rewrite the verification; just add one line of code:

```
static void PrecondtionsWithLegacyCode(object o)
{
    if (o == null) throw new ArgumentNullException("o");
    Contract.EndContractBlock();
```

The EndContractBlock() defines that the preceding code should be handled as a contract. If other contract statements are used as well, the EndContractBlock() is not necessary.

For checking collections that are used as arguments, the Contract class offers Exists() and ForAll() methods. ForAll() checks every item in the collection if the condition succeeds. In the example, it is checked if every item in the collection has a value smaller than 12. With the Exists() method, it is checked if any one element in the collection succeeds the condition.

```
static void ArrayTest(int[] data)
{
    Contract.Requires(Contract.ForAll(data, i => i < 12));
```

Both the methods `Exists()` and `ForAll()` have an overload where you can pass two integers, *`fromInclusive`* and *`toExclusive`*, instead of `IEnumerable<T>`. A range from the numbers (excluding *`toExclusive`*) is passed to the delegate `Predicate<int>` defined with the third parameter. `Exists()` and `ForAll()` can be used with preconditions, postconditions, and also invariants.

Postconditions

Postconditions define guarantees about shared data and return values after the method has completed. Although they define some guarantees on return values, they must be written at the beginning of a method; all contract requirements must be at the beginning of the method.

`Ensures()` and `EnsuresOnThrow<TException>()` are postconditions. The following contract ensures that the variable `sharedState` is lower than 6 at the end of the method. The value can change in between.

```
private static int sharedState = 5;
static void Postcondition()
{
    Contract.Ensures(sharedState < 6);
    sharedState = 9;
    Console.WriteLine("change sharedState invariant {0}", sharedState);
    sharedState = 3;
    Console.WriteLine("before returning change it to a valid value {0}",
                      sharedState);
}
```

code snippet CodeContractsSamples/Program.cs

With `EnsuresOnThrow<TException>()`, it is guaranteed that a shared state succeeds a condition if a specified exception is thrown.

To guarantee a return value, the special value `Result<T>` can be used with an `Ensures()` contract. Here, the result is of type `int` as is also defined with the generic type `T` for the `Result()` method. The `Ensures()` contract guarantees that the *`return`* value is lower than 6.

```
static int ReturnValue()
{
    Contract.Ensures(Contract.Result<int>() < 6);
    return 3;
}
```

You can also compare a value to an old value. This is done with the `OldValue<T>()` method that returns the original value on method entry for the variable passed. The following ensures that the contract defines that the result returned (`Contract.Result<int>()`) is larger than the old value from the argument *`x`* (`Contract.OldValue<int>(x)`).

```
static int ReturnLargerThanInput(int x)
{
    Contract.Ensures(Contract.Result<int>() > Contract.OldValue<int>(x));
    return x + 3;
}
```

If a method returns values with the `out` modifier instead of just with the `return` statement, conditions can be defined with `ValueAtReturn()`. The following contract defines that the *x* variable must be larger than 5 and smaller than 20 on return, and with the *y* variable modulo 5 must equal 0 on return.

```
static void OutParameters(out int x, out int y)
{
    Contract.Ensures(Contract.ValueAtReturn<int>(out x) > 5 &&
                     Contract.ValueAtReturn<int>(out x) < 20);
    Contract.Ensures(Contract.ValueAtReturn<int>(out y) % 5 == 0);
    x = 8;
    y = 10;
}
```

Invariants

Invariants define contracts for variables during the method lifetime. `Contract.Requires()` defines input requirements, `Contract.Ensures()` defines requirements on method end. `Contract.Invariant()` defines conditions that must succeed during the whole lifetime of the method.

```
static void Invariant(ref int x)
{
    Contract.Invariant(x > 5);
    x = 3;
    Console.WriteLine("invariant value: {0}", x);
    x = 9;
}
```

code snippet CodeContractsSamples/Program.cs

Contracts for Interfaces

With interfaces you can define methods, properties, and events that a class that derives from the interface must implement. With the interface declaration you cannot define how the interface must be implemented. Now this is possible using code contracts.

Take a look at the following interface. The interface `IPerson` defines `FirstName`, `LastName`, and `Age` properties, and the method `ChangeName()`. What's special with this interface is just the attribute `ContractClass`. This attribute is applied to the interface `IPerson` and defines that the `PersonContract` class is used as the code contract for this interface.

```
[ContractClass(typeof(PersonContract))]
public interface IPerson
{
    string FirstName { get; set; }
    string LastName { get; set; }
    int Age { get; set; }
    void ChangeName(string firstName, string lastName);
}
```

code snippet CodeContractsSamples/IPerson.cs

The class `PersonContract` implements the interface `IPerson` and defines code contracts for all the members. The attribute `PureAttribute` means that the method or property may not change state of a class instance. This is defined with the `get` accessors of the properties but can also be defined with all methods that are not allowed to change state. The `FirstName` and `LastName` `get` accessors also define that the result must be a string with `Contract.Result()`. The `get` accessor of the `Age` property defines a postcondition and ensures that the returned value is between 0 and 120. The `set` accessor of the `FirstName` and `LastName` properties requires that the value passed is not null. The `set` accessor of the `Age` property defines a precondition that the passed value is between 0 and 120.

```
[ContractClassFor(typeof(IPerson))]
public sealed class PersonContract : IPerson
{
    string IPerson.FirstName
    {
        [Pure] get { return Contract.Result<String>(); }
        set { Contract.Requires(value != null); }
    }
    string IPerson.LastName
    {
        [Pure] get { return Contract.Result<String>(); }
        set { Contract.Requires(value != null); }
    }
```

```
        int IPerson.Age
        {
            [Pure]
            get
            {
                Contract.Ensures(Contract.Result<int>() >= 0 &&
                                 Contract.Result<int>() < 121);
                return Contract.Result<int>();
            }
            set
            {
                Contract.Requires(value >= 0 && value < 121);
            }
        }
        void IPerson.ChangeName(string firstName, string lastName)
        {
            Contract.Requires(firstName != null);
            Contract.Requires(lastName != null);
        }
    }
```

code snippet CodeContractsSamples/PersonContract.cs

Now a class implementing the `IPerson` interface must fulfill all the contract requirements. The class `Person` is a simple implementation of the interface that fulfills the contract.

```
    public class Person : IPerson
    {
        public Person(string firstName, string lastName)
        {
            this.FirstName = firstName;
            this.LastName = lastName;
        }

        public string FirstName { get; private set; }
        public string LastName { get; private set; }
        public int Age { get; set; }

        public void ChangeName(string firstName, string lastName)
        {
            this.FirstName = firstName;
            this.LastName = lastName;
        }
    }
```

code snippet CodeContractsSamples/Person.cs

When using the class `Person`, the contract must also be fulfilled. For example, it's not allowed to assign null to a property:

```
            var p = new Person { FirstName = "Tom", LastName = null }; // contract error
```

code snippet CodeContractsSamples/Program.cs

It's also not allowed to assign an invalid value to the `Age` property:

```
            var p = new Person { FirstName = "Tom", LastName = "Turbo" };
            p.Age = 133;  // contract error
```

TRACING

With tracing, you can see messages from the running application. To get information about a running application, you can start the application in the debugger. During debugging, you can walk through the application step by step and set breakpoints at specific lines and when you reach specific conditions. The problem with debugging is that a program with release code can behave differently from a program with debug code. For example, while the program is stopping at a breakpoint, other threads of the application are suspended as well. Also, with a release build, the compiler-generated output is optimized and, thus, different effects can occur. There is a need to have information from a release build as well. Trace messages are written with both debug and release code.

A scenario showing how tracing helps is described here. After an application is deployed, it runs on one system without problems, while on another system intermediate problems occur. When you turn on verbose tracing, the system with the problems gives you detailed information about what's happening inside the application. The system that is running without problems has tracing configured just for error messages redirected to the Windows event log system. Critical errors are seen by the system administrator. The overhead of tracing is very small, because you configure a trace level only when needed.

The tracing architecture has four major parts:

- ➤ The *source* is the originator of the trace information. You use the source to send trace messages.
- ➤ The *switch* defines the level of information to log. For example, you can request just error information or detailed verbose information.
- ➤ Trace *listeners* define where the trace messages should be written to.
- ➤ Listeners can have *filters* attached. The filter defines what trace messages should be written by the listener. This way, you can have different listeners for the same source that write different levels of information.

Figure 19-2 shows the major classes for tracing and how they are connected, in a Visual Studio class diagram. The `TraceSource` uses a switch to define what information to log. The `TraceSource` has a `TraceListenerCollection` associated with it, which trace messages are forwarded to. The collection consists of `TraceListener` objects, and every listener has a `TraceFilter` connected.

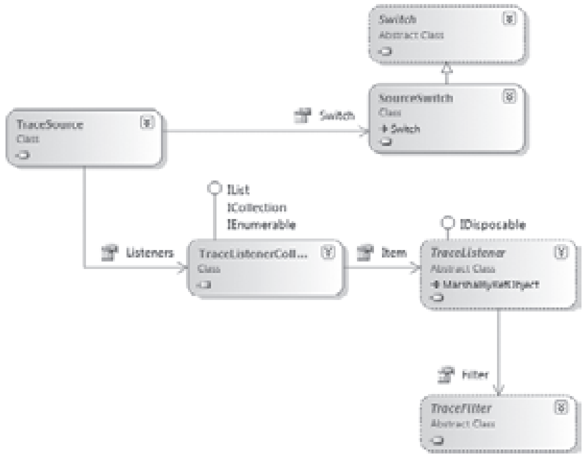

FIGURE 19-2

Trace Sources

You can write trace messages with the `TraceSource` class. Tracing requires the `Trace` flag of the compiler settings. With a Visual Studio project, the `Trace` flag is set by default with debug and release builds, but you can change it through the `Build` properties of the project.

To write trace messages, you need to create a new `TraceSource` instance. In the constructor, the name of the trace source is defined. The method `TraceInformation()` writes an information message to the trace output. Instead of just writing informational messages, the `TraceEvent()` method requires an enumeration value of type `TraceEventType` to define the type of the trace message. `TraceEventType.Error` specifies the message as an error message. You can define it with a trace switch to see only error messages. The second argument of the `TraceEvent()` method requires an identifier. The ID can be used within the application itself. For example, you can use `id 1` for entering a method and `id 2` for exiting a method. The method `TraceEvent()` is overloaded, so the `TraceEventType` and the ID are the only required parameters. Using the third parameter of an overloaded method, you can pass the message written to the trace. `TraceEvent()` also supports passing a format string with any number of parameters in the same way as `Console.WriteLine()`. `TraceInformation()` does nothing more than invoke `TraceEvent()` with an identifier of 0. `TraceInformation()` is just a simplified version of `TraceEvent()`. With the `TraceData()` method, you can pass any object, for example, an exception instance, instead of a message. To make sure that data is written by the listeners and does not stay in memory, you need to do a `Flush()`. If the source is no longer needed, you can invoke the `Close()` method that closes all listeners associated with the trace source. `Close()` does a `Flush()` as well.

```
public class Program
{
    internal static TraceSource trace =
        new TraceSource("Wrox.ProCSharp.Instrumentation");

    static void TraceSourceDemo1()
    {
        trace.TraceInformation("Info message");

        trace.TraceEvent(TraceEventType.Error, 3, "Error message");
        trace.TraceData(TraceEventType.Information, 2, "data1", 4, 5);
        trace.Flush();
        trace.Close();
    }
```

code snippet TracingDemo/Program.cs

You can use different trace sources within your application. It makes sense to define different sources for different libraries, so that you can turn on different trace levels for different parts of your application. To use a trace source, you need to know its name. A commonly used name for the trace source is the same name as the assembly name.

The `TraceEventType` enumeration that is passed as an argument to the `TraceEvent()` method defines the following levels to specify the severity of the problem: `Verbose`, `Information`, `Warning`, `Error`, and `Critical`. `Critical` defines a fatal error or application crash; `Error` defines a recoverable error. Trace messages at the `Verbose` level give you detailed debugging information. `TraceEventType` also defines action levels `Start`, `Stop`, `Suspend`, and `Resume`. These levels define timely events inside a logical operation.

The code, as it is written now, does not display any trace message because the switch associated with the trace source is turned off.

Trace Switches

To enable or disable trace messages, you can configure a trace switch. Trace switches are classes that are derived from the abstract base class `Switch`. Derived classes are `BooleanSwitch`, `TraceSwitch`, and `SourceSwitch`. The class `BooleanSwitch` can be turned on and off, and the other two classes provide a range level. One range is defined by the `SourceLevels` enumeration. To configure trace switches, you must know the values associated with the `SourceLevels` enumeration. `SourceLevels` defines the values `Off`, `Error`, `Warning`, `Info`, and `Verbose`.

You can associate a trace switch programmatically by setting the `Switch` property of the `TraceSource`. Here, the switch associated is of type `SourceSwitch`, has the name `Wrox.ProCSharp.Instrumentation`, and has the level `Verbose`:

```
internal static SourceSwitch traceSwitch =
    new SourceSwitch("Wrox.ProCSharp.Instrumentation")
        { Level = SourceLevels.Verbose };
internal static TraceSource trace =
    new TraceSource("Wrox.ProCSharp.Instrumentation")
        { Switch = traceSwitch };
```

code snippet TracingDemo/Program.cs

Setting the level to `Verbose` means that all trace messages should be written. If you set the value to `Error`, only error messages should show up. Setting the value to `Information` means that error, warning, and info messages are shown. By writing the trace messages once more, you can see the messages while running the debugger in the Output window.

Usually, you would want to change the switch level, not by recompiling the application, but instead by changing the configuration. The trace source can be configured in the application configuration file. Tracing is configured within the `<system.diagnostics>` element. The trace source is defined with the `<source>` element as a child element of `<sources>`. The name of the source in the configuration file must exactly match the name of the source in the program code. Here, the trace source has a switch of type `System.Diagnostics.SourceSwitch` associated with the name `MySourceSwitch`. The switch itself is defined within the `<switches>` section, and the level of the switch is set to `verbose`.

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <system.diagnostics>
    <sources>
      <source name="Wrox.ProCSharp.Instrumentation" switchName="MySourceSwitch"
          switchType="System.Diagnostics.SourceSwitch" />
    </sources>
    <switches>
      <add name="MySourceSwitch" value="Verbose"/>
    </switches>
  </system.diagnostics>
</configuration>
```

code snippet TracingDemo/App.config

Now, you can change the trace level just by changing the configuration file without the need to recompile the code. After the configuration file is changed, you must restart the application.

Currently, trace messages are written to just the Output window of Visual Studio while you are running it in a debug session. Adding trace listeners changes this.

Trace Listeners

By default, trace information is written to the Output window of the Visual Studio debugger. Just by changing the application's configuration, you can redirect the trace output to different locations.

Where the tracing results should be written to is defined by trace listeners. A trace listener is derived from the abstract base class `TraceListener`. NET comes with several trace listeners to write the trace events to different targets. For file-based trace listeners, the base class `TextWriterTraceListener` is used, along with the derived classes `XmlWriterTraceListener` to write to XML files and `DelimitedListTraceListener` to write to delimited files. Writing to the event log is done with either the `EventLogTraceListener` or the `EventProviderTraceListener`. `EventProviderTraceListener` uses the event file format that is new since Windows Vista. You can also combine web tracing with `System.Diagnostics` tracing and use the `WebPageTraceListener` to write `System.Diagnostics` tracing to the Web trace file, `trace.axd`.

.NET Framework delivers many listeners to which trace information can be written. In case the listeners don't fulfill your requirements, you can create a custom listener by deriving a class from the base class `TraceListener`. With a custom listener, you can, for example, write trace information to a Web service, write messages to your mobile phone, and so on. I guess it's not that interesting to receive hundreds of messages on your phone in your spare time. And with verbose tracing this can become really expensive.

You can configure a trace listener programmatically by creating a listener object and assigning it to the `Listeners` property of the `TraceSource` class. However, usually it is more interesting to just change a configuration to define a different listener.

You can configure listeners as child elements of the `<source>` element. With the listener, you define the type of the listener class and use `initializeData` to specify where the output of the listener should go. The configuration here defines the `XmlWriterTraceListener` to write to the file `demotrace.xml`, and the `DelimitedListTraceListener` to write to the file `demotrace.txt`:

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <system.diagnostics>
    <sources>
      <source name="Wrox.ProCSharp.Tracing" switchName="MySourceSwitch"
          switchType="System.Diagnostics.SourceSwitch">
        <listeners>
          <add name="xmlListener"
              type="System.Diagnostics.XmlWriterTraceListener"
              traceOutputOptions="None"
              initializeData="c:/logs/mytrace.xml" />

          <add name="delimitedListener" delimiter=":"
              type="System.Diagnostics.DelimitedListTraceListener"
              traceOutputOptions="DateTime, ProcessId"
              initializeData="c:/logs/mytrace.txt" />
        </listeners>
      </source>
    </sources>
    <switches>
      <add name="MySourceSwitch" value="Verbose"/>
    </switches>
  </system.diagnostics>
</configuration>
```

code snippet TracingDemo/App.config

With the listener, you can also specify what additional information should be written to the trace log. This information is defined with the `traceOutputOptions` XML attribute and is defined by the `TraceOptions` enumeration. The enumeration defines `Callstack`, `DateTime`, `LogicalOperationStack`, `ProcessId`, `ThreadId`, and `None`. The information needed can be added with comma separation to the `traceOutputOptions` XML attribute, as shown with the delimited trace listener.

The delimited file output from the `DelimitedListTraceListener`, including the process ID and date/time, is shown here:

```
"Wrox.ProCSharp.Instrumentation":Information:0:"Info message"::
    5288:""::"2009-10-11T10:35:55.8479950Z"::
"Wrox.ProCSharp.Instrumentation":Error:3:"Error message"::5288:""::
    "2009-10-11T10:35:55.8509257Z"::
"Wrox.ProCSharp.Instrumentation":Information:2::
    "data1","4","5":5288:""::"2009-10-11T10:35:55.8519026Z"::
```

The XML output from the `XmlWriterTraceListener` always contains the name of the computer, the process ID, the thread ID, the message, the time created, the source, and the activity ID. Other fields, such as the call stack, logical operation stack, and timestamp, depend on the trace output options.

You can use the `XmlDocument` *and* `XPathNavigator` *classes to analyze the content from the XML file. These classes are covered in Chapter 33, "Manipulating XML."*

If a listener should be used by multiple trace sources, you can add the listener configuration to the element `<sharedListeners>`, which is independent of the trace source. The name of the listener that is configured with a shared listener must be referenced from the listeners of the trace source:

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <system.diagnostics>
    <sources>
      <source name="Wrox.ProCSharp.Tracing" switchName="MySourceSwitch"
          switchType="System.Diagnostics.SourceSwitch">
        <listeners>
          <add name="xmlListener"
              type="System.Diagnostics.XmlWriterTraceListener"
              traceOutputOptions="None"
              initializeData="c:/logs/mytrace.xml" />
          <add name="delimitedListener" />
        </listeners>
      </source>
    </sources>
    <sharedListeners>
      <add  name="delimitedListener" delimiter=":"
           type="System.Diagnostics.DelimitedListTraceListener"
           traceOutputOptions="DateTime, ProcessId"
           initializeData="c:/logs/mytrace.txt" />
    </sharedListeners>
    <switches>
      <add name="MySourceSwitch" value="Verbose"/>
    </switches>
  </system.diagnostics>
</configuration>
```

code snippet TracingDemo/app.config

Filters

Every listener has a `Filter` property that defines whether the listener should write the trace message. For example, multiple listeners can be used with the same trace source. One of the listeners writes verbose messages to a log file, and another listener writes error messages to the event log. Before a listener writes a trace message, it invokes the `ShouldTrace()` method of the associated filter object to decide if the trace message should be written.

A filter is a class that is derived from the abstract base class `TraceFilter`. .NET 4 offers two filter implementations: `SourceFilter` and `EventTypeFilter`. With the source filter, you can specify that trace messages are to be written only from specific sources. The event type filter is an extension of the switch functionality. With a switch, it is possible to define, according to the trace severity level, if the event source should forward the trace message to the listeners. If the trace message is forwarded, the listener now can use the filter to decide if the message should be written.

The changed configuration now defines that the delimited listener should write trace messages only if the severity level is of type warning or higher, because of the defined `EventTypeFilter`. The XML listener specifies a `SourceFilter` and accepts trace messages only from the source `Wrox.ProCSharp.Tracing`. If you have a large number of sources defined to write trace messages to the same listener, you can change the configuration for the listener to concentrate on trace messages from a specific source.

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <system.diagnostics>
    <sources>
      <source name="Wrox.ProCSharp.Tracing" switchName="MySourceSwitch"
          switchType="System.Diagnostics.SourceSwitch">
        <listeners>
          <add name="xmlListener" />
          <add name="delimitedListener" />
        </listeners>
      </source>
    </sources>
    <sharedListeners>
          <add name="delimitedListener" delimiter=":"
              type="System.Diagnostics.DelimitedListTraceListener"
              traceOutputOptions="DateTime, ProcessId"
              initializeData="c:/logs/mytrace.txt">
            <filter type="System.Diagnostics.EventTypeFilter"
                initializeData="Warning" />
          </add>
          <add name="xmlListener"
              type="System.Diagnostics.XmlWriterTraceListener"
              traceOutputOptions="None"
              initializeData="c:/logs/mytrace.xml">
            <filter type="System.Diagnostics.SourceFilter"
                initializeData="Wrox.ProCSharp.Instrumentation" />
          </add>
    </sharedListeners>
    <switches>
      <add name="MySourceSwitch" value="Verbose"/>
    </switches>
  </system.diagnostics>
</configuration>
```

code snippet TracingDemo/App.config

The tracing architecture can be extended. Just as you can write a custom listener derived from the base class `TraceListener`, you can create a custom filter derived from `TraceFilter`. With that capability, you can create a filter that specifies to write trace messages, for example, depending on the time, depending on an exception that occurred lately, or depending on the weather.

Correlation

With trace logs, you can see the relation of different methods in several ways. To see the call stack of the trace events, just a configuration is needed to track the call stack with the XML listener. You can also define a logical call stack that can be shown in the log messages. And you can define activities to map trace messages.

To show the call stack and the logical call stack with the trace messages, the `XmlWriterTraceListener` can be configured to the corresponding `traceOuputOptions`. The MSDN documentation gives details on all the other options you can configure for tracing with this listener.

```
<sharedListeners>
  <add name="xmlListener" type="System.Diagnostics.XmlWriterTraceListener"
       traceOutputOptions="LogicalOperationStack, Callstack"
       initializeData="c:/logs/mytrace.xml">
  </add>
</sharedListeners>
```

code snippet TracingDemo/App.config

To see correlation and logical call stack in action, in the Main method a new activity ID is assigned to the `CorrelationManager` by setting the `ActivityID` property. Events of type `TraceEventType.Start` and `TraceEventType.Stop` are done at the beginning and end of the `Main` method. Also, a logical operation named "`Main`" is started and stopped with the `StartLogicalOperation()` and `StopLogicalOperation()` methods.

```
static void Main()
{
    // start a new activity
    if (Trace.CorrelationManager.ActivityId == Guid.Empty)
    {
        Guid newGuid = Guid.NewGuid();
        Trace.CorrelationManager.ActivityId = newGuid;
    }
    trace.TraceEvent(TraceEventType.Start, 0, "Main started");

    // start a logical operation
    Trace.CorrelationManager.StartLogicalOperation("Main");

    TraceSourceDemo1();
    StartActivityA();
    Trace.CorrelationManager.StopLogicalOperation();
    Thread.Sleep(3000);
    trace.TraceEvent(TraceEventType.Stop, 0, "Main stopped");
}
```

code snippet TracingDemo/Program.cs

The method `StartActivityA()` that is called from within the `Main()` method creates a new activity by setting the `ActivityId` of the `CorrelationManager` to a new GUID. Before the activity stops, the `ActivityId` of the `CorrelationManager` is reset to the previous value. This method invokes the `Foo()` method and creates a new task with the `Task.Factory.StartNew()` method. This task is created so that you can see how different threads are displayed in a trace viewer.

Tasks are explained in Chapter 20, "Threads, Tasks, and Synchronization."

```
private static void StartActivityA()
{
    Guid oldGuid = Trace.CorrelationManager.ActivityId;
    Guid newActivityId = Guid.NewGuid();
    Trace.CorrelationManager.ActivityId = newActivityId;

    Trace.CorrelationManager.StartLogicalOperation("StartActivityA");

    trace.TraceEvent(TraceEventType.Verbose, 0,
                     "starting Foo in StartNewActivity");
    Foo();

    trace.TraceEvent(TraceEventType.Verbose, 0,
                          "starting a new task");
        Task.Factory.StartNew(WorkForATask);

        Trace.CorrelationManager.StopLogicalOperation();
        Trace.CorrelationManager.ActivityId = oldGuid;
    }
```

The `Foo()` method that is started from within the `StartActivityA()` method starts a new logical operation. The logical operation `Foo` is started within the `StartActivityA` logical operation.

```
    private static void Foo()
    {
        Trace.CorrelationManager.StartLogicalOperation("Foo operation");

        trace.TraceEvent(TraceEventType.Verbose, 0, "running Foo");

        Trace.CorrelationManager.StopLogicalOperation();
    }
```

The task that is created from within the `StartActivityA()` method runs the method `WorkForATask()`. Here, just simple trace events with start and stop information, and verbose information, are written to the trace.

```
    private static void WorkForATask()
    {
        trace.TraceEvent(TraceEventType.Start, 0, "WorkForATask started");

        trace.TraceEvent(TraceEventType.Verbose, 0, "running WorkForATask");

        trace.TraceEvent(TraceEventType.Stop, 0, "WorkForATask completed");
    }
```

To analyze the trace information, the tool Service Trace Viewer, `svctraceviewer.exe`, can be started. This tool is mainly used to analyze WCF traces, but it can also be used to analyze any trace that is written with the `XmlWriterTraceListener`. Figure 19-3 shows the activities in the Activity screen, and each activity shows the events in the right screen. When you select an event you can set the display to show the complete message in XML or in a formatted view. In the formatted view, basic information, application data, the logical operation stack, and the call stack are nicely formatted.

EVENT LOGGING

The system administrator uses the Event Viewer to get critical messages on the health of the system and applications and also information messages. You should write error messages from your application to the event log so that the information can be read with the Event Viewer.

Trace messages can be written to the event log if you configure the `EventLogTraceListener` class. The `EventLogTraceListener` has an `EventLog` object associated with it to write the event log entries. You can also use the `EventLog` class directly to write and read event logs.

In this section, you explore the following:

- Event-logging architecture
- Classes for event logging from the `System.Diagnostics` namespace
- Adding event logging to services and to other application types
- Creating an event log listener with the `EnableRaisingEvents` property of the `EventLog` class
- Use a resource file to define messages

Figure 19-5 shows an example of a log entry from a failed access with Distributed COM.

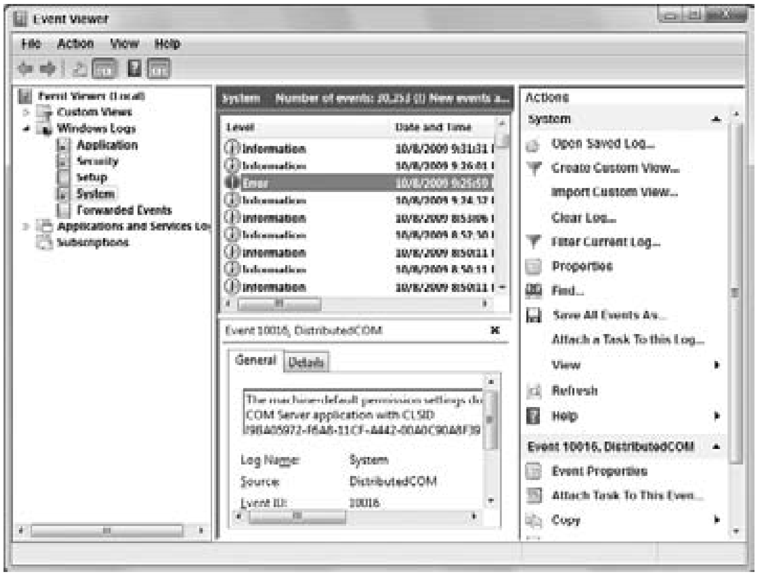
FIGURE 19-5

For custom event logging, you can use classes from the `System.Diagnostics` namespace.

Event-Logging Architecture

The event log information is stored in several log files. The most important ones are application, security, and system. Looking at the registry configuration of the event log service, you will notice several entries under `HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\Eventlog` with configurations pointing to the specific files. The system log file is used from the system and device drivers. Applications and services write to the application log. The security log is a read-only log for applications. The auditing feature of the operating system uses the security log. Every application can also create a custom category and log file to write event log entries there. For example, this is done by Media Center.

You can read these events by using the administrative tool Event Viewer. The Event Viewer can be started directly from the Server Explorer of Visual Studio by right-clicking the Event Logs item and selecting the Launch Event Viewer entry from the context menu. The Event Viewer is shown in Figure 19-6.



```

```

FIGURE 19-6

In the event log, you can see this information:

- **Type** — The type can be Information, Warning, or Error. Information is an infrequent successful operation; Warning is a problem that is not immediately significant; and Error is a major problem. Additional types are FailureAudit and SuccessAudit, but these types are used only for the security log.
- **Date** — Date and Time show the day and time that the event occurred.
- **Source** — The Source is the name of the software that logs the event. The source for the application log is configured in this registry key:

  ```
  HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\Eventlog\Application\
  [ApplicationName]
  ```

  Within this key, the value `EventMessageFile` is configured to point to a resource DLL that holds error messages.
- **Event ID** — The Event identifier specifies a particular event message.
- **Category** — A Category can be defined so that event logs can be filtered when using the Event Viewer. Categories can be defined by an event source.

Event-Logging Classes

For writing event logs, two different Windows APIs exist. One API that is available since Windows Vista is wrapped by classes in the namespace `System.Diagnostics.Eventing`, the other wrapper classes are in the `System.Diagnostics` namespace.

The `System.Diagnostics` namespace has the following classes for event logging, which are shown in the following table.

CLASS	DESCRIPTION
`EventLog`	With the `EventLog` class, you can read and write entries in the event log, and establish applications as event sources.
`EventLogEntry`	The `EventLogEntry` class represents a single entry in the event log. With the `EventLogEntryCollection`, you can iterate through `EventLogEntry` items.
`EventLogInstaller`	The `EventLogInstaller` class is the installer for an `EventLog` component. `EventLogInstaller` calls `EventLog.CreateEventSource()` to create an event source.
`EventLogTraceListener`	With the help of the `EventLogTraceListener`, traces can be written to the event log. This class implements the abstract class `TraceListener`.

The heart of event logging is in the `EventLog` class. The members of this class are explained in the following table.

EVENTLOG MEMBERS	DESCRIPTION
`Entries`	With the `Entries` property, you can read event logs. `Entries` returns an `EventLogEntryCollection` that contains `EventLogEntry` objects holding information about the events. There is no need to invoke a `Read()` method. The collection is filled as soon as you access this property.
`Log`	Specify the log for reading or writing event logs with the `Log` property.
`LogDisplayName`	`LogDisplayName` is a read-only property that returns the display name of the log.
`MachineName`	With the `MachineName`, you can specify the system on which to read or write log entries.

continues

(continued)

EVENTLOG MEMBERS	DESCRIPTION
`Source`	The `Source` property specifies the source of the event entries to write.
`CreateEventSource()`	The `CreateEventSource()` creates a new event source and a new log file, if a new log file is specified with this method.
`DeleteEventSource()`	To get rid of an event source, you can invoke `DeleteEventSource()`.
`SourceExists()`	Before creating an event source, you can verify if the source already exists by using this element.

`WriteEntry()`
`WriteEvent()`
	Write event log entries with either the `WriteEntry()` or `WriteEvent()` method. `WriteEntry()` is simpler, because you just need to pass a string. `WriteEvent()` is more flexible, because you can use message files that are independent of the application and that support localization.

`Clear()`	The `Clear()` method removes all entries from an event log.
`Delete()`	The `Delete()` method deletes a complete event log.

Creating an Event Source

Before writing events, you must create an event source. You can use either the `CreateEventSource()` method of the `EventLog` class or the class `EventLogInstaller`. Because you need administrative privileges when creating an event source, an installation program would be best for defining the new source.

Chapter 17, "Deployment," explains how to create installation programs.

The following sample verifies that an event log source named `EventLogDemoApp` already exists. If it doesn't exist, an object of type `EventSourceCreationData` is instantiated that defines the source name `EventLogDemoApp` and the log name `ProCSharpLog`. Here, all events of this source are written to the `ProCSharpLog` event log. The default is the application log.

```
string logName = "ProCSharpLog";
string sourceName = "EventLogDemoApp";

if (!EventLog.SourceExists(sourceName))
{
   var eventSourceData = new EventSourceCreationData(sourceName,
         logName);

   EventLog.CreateEventSource(eventSourceData);
}
```

code snippet EventLogDemo/Program.cs

The name of the event source is an identifier of the application that writes the events. For the system administrator reading the log, the information helps in identifying the event log entries to map them to application categories. Examples of names for event log sources are `LoadPerf` for the performance monitor, `MSSQLSERVER` for Microsoft SQL Server, `MsiInstaller` for the Windows Installer, `Winlogon`, `Tcpip`, `Time-Service`, and so on.

Setting the name Application for the event log writes event log entries to the application log. You can also create your own log by specifying a different application log name. Log files are located in the directory `<windows>\System32\WinEvt\Logs`.

With the `EventSourceCreationData`, you can also specify several more characteristics for the event log, as shown in the following table.

EVENTSOURCECREATIONDATA	DESCRIPTION
`Source`	The property `Source` gets or sets the name of the event source.
`LogName`	`LogName` defines the log where event log entries are written. The default is the application log.
`MachineName`	With `MachineName`, you can define the system to read or write log entries.
`CategoryResourceFile`	With the `CategoryResourceFile` property, you can define a resource file for categories. Categories can be used for an easier filtering of event log entries within a single source.
`CategoryCount`	The `CategoryCount` property defines the number of categories in the category resource file.
`MessageResourceFile`	Instead of specifying that the message should be written to the event log in the program that writes the events, messages can be defined in a resource file that is assigned to the `MessageResourceFile` property. Messages from the resource file are localizable.
`ParameterResourceFile`	Messages in a resource file can have parameters. The parameters can be replaced by strings defined in a resource file that is assigned to the `ParameterResourceFile` property.

Writing Event Logs

For writing event log entries, you can use the `WriteEntry()` or `WriteEvent()` methods of the `EventLog` class. The `EventLog` class has both a static and an instance method `WriteEntry()`. The static method `WriteEntry()` requires a parameter of the source. The source can also be set with the constructor of the `EventLog` class. Here in the constructor, the log name, the local machine, and the event source name are defined. Next, three event log entries are written with the message as the first parameter of the `WriteEntry()` method. `WriteEntry()` is overloaded. The second parameter you can assign is an enumeration of type `EventLogEntryType`. With `EventLogEntryType`, you can define the severity of the event log entry. Possible values are `Information`, `Warning`, and `Error`, and for auditing `SuccessAudit` and `FailureAudit`. Depending on the type, different icons are shown in the Event Viewer. With the third parameter, you can specify an application-specific event ID that can be used by the application itself. In addition to that, you can also pass application-specific binary data and a category.

```
using (var log = new EventLog(logName, ".", sourceName))
{
   log.WriteEntry("Message 1");
   log.WriteEntry("Message 2", EventLogEntryType.Warning);
   log.WriteEntry("Message 3", EventLogEntryType.Information, 33);
}
```

code snippet EventLogDemo/Program.cs

Resource Files

Instead of defining the messages for the event log in the C# code and passing it to the `WriteEntry()` method, you can create a *message resource file*, define messages in the resource file, and pass message identifiers to the `WriteEvent()` method. Resource files also support localization.

```
; // EventLogDemoMessages.mc

EventLogDemo.EXE
.
```

code snippet EventLogDemo/EventLogDemoMessages.mc

Use the Messages Compiler, `mc.exe`, to create a binary message file. The command `mc -s EventLogDemoMessages.mc` compiles the source file containing the messages to a messages file with the `.bin` extension and the file `Messages.rc`, which contains a reference to the binary message file:

```
mc -s EventLogDemoMessages.mc
```

Next, you must use the Resource Compiler, `rc.exe`. The command `rc EventLogDemoMessages.rc` creates the resource file `EventLogDemoMessages.RES`:

```
rc EventLogDemoMessages.rc
```

With the linker, you can bind the binary message file `EventLogDemoMessages.RES` to a native DLL:

```
link /DLL /SUBSYSTEM:WINDOWS /NOENTRY /MACHINE:x86 EventLogDemoMessages.RES
```

Now, you can register an event source that defines the resource files as shown in the following code. First, a check is done to see if the event source named `EventLogDemoApp` exists. If the event log must be created because it does not exist, the next check verifies that the resource file is available. Some samples in the MSDN documentation demonstrate writing the message file to the `<windows>\system32` directory, but you shouldn't do that. Copy the message DLL to a program-specific directory that you can get with the `SpecialFolder` enumeration value `ProgramFiles`. If you need to share the messages file among multiple applications, you can put it into `Environment.SpecialFolder.CommonProgramFiles`.

If the file exists, a new object of type `EventSourceCreationData` is instantiated. In the constructor, the name of the source and the name of the log are defined. You use the properties `CategoryResourceFile`, `MessageResourceFile`, and `ParameterResourceFile` to define a reference to the resource file. After the event source is created, you can find the information on the resource files in the registry with the event source. The method `CreateEventSource` registers the new event source and log file. Finally, the method `RegisterDisplayName()` from the `EventLog` class specifies the name of the log as it is displayed in the Event Viewer. The ID 5001 is taken from the message file.

```
string logName = "ProCSharpLog";
string sourceName = "EventLogDemoApp";
string resourceFile = Environment.GetFolderPath(
      Environment.SpecialFolder.ProgramFiles) +
      @"\procsharp\EventLogDemoMessages.dll";

if (!EventLog.SourceExists(sourceName))
{
   if (!File.Exists(resourceFile))
   {
      Console.WriteLine("Message resource file does not exist");
      return;
   }

   var eventSource = new EventSourceCreationData(sourceName, logName);

   eventSource.CategoryResourceFile = resourceFile;
   eventSource.CategoryCount = 4;
   eventSource.MessageResourceFile = resourceFile;
   eventSource.ParameterResourceFile = resourceFile;

   EventLog.CreateEventSource(eventSource);
}
else
{
   logName = EventLog.LogNameFromSourceName(sourceName, ".");
}
```

```
var evLog = new EventLog(logName, ".", sourceName);
evLog.RegisterDisplayName(resourceFile, 5001);
```

code snippet EventLogDemo/Program.cs

Now, you can use the `WriteEvent()` method instead of `WriteEntry()` to write the event log entry. `WriteEvent()` requires an object of type `EventInstance` as parameter. With the `EventInstance`, you can assign the message ID, the category, and the severity of type `EventLogEntryType`. In addition to the `EventInstance` parameter, `WriteEvent()` accepts parameters for messages that have parameters and binary data in the form of a byte array.

```
using (var log = new EventLog(logName, ".", sourceName))
{
    var info1 = new EventInstance(1000, 4,
        EventLogEntryType.Information);

    log.WriteEvent(info1);
    var info2 = new EventInstance(1001, 4,
        EventLogEntryType.Error);
    log.WriteEvent(info2, "avalon");

    var info3 = new EventInstance(1002, 3,
        EventLogEntryType.Error);
    byte[] addionalInfo = { 1, 2, 3 };
    log.WriteEvent(info3, addionalInfo);
}
```

For the message identifiers, it is useful to define a class with `const` *values that provide a more meaningful name for the identifiers in the application.*

You can read the event log entries with the Event Viewer.

PERFORMANCE MONITORING

Performance monitoring can be used to get information about the normal behavior of applications. Performance monitoring is a great tool that helps you understand the workload of the system and observe changes and trends, particularly in applications running on the server.

Microsoft Windows has many performance objects, such as `System`, `Memory`, `Objects`, `Process`, `Processor`, `Thread`, `Cache`, and so on. Each of these objects has many counts to monitor. For example, with the `Process` object, the user time, handle count, page faults, thread count, and so on can be monitored for all processes or for specific process instances. Some applications, such as SQL Server, also add application-specific objects.

Performance-Monitoring Classes

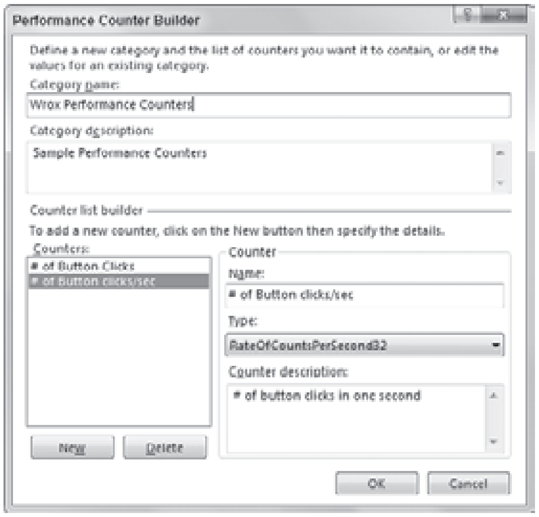
The `System.Diagnostics` namespace provides these classes for performance monitoring:

- `PerformanceCounter` can be used both to monitor counts and to write counts. New performance categories can also be created with this class.
- `PerformanceCounterCategory` enables you to step through all existing categories, as well as create new ones. You can programmatically get all the counters in a category.
- `PerformanceCounterInstaller` is used for the installation of performance counters. Its use is similar to that of the `EventLogInstaller` discussed previously.

Performance Counter Builder

The sample application PerformanceCounterDemo is a simple Windows application with just two buttons to demonstrate writing performance counts. With the handler of one button, a performance counter category is registered; with the handler of the other button, a performance counter value is written. In a similar way to the sample application, you can add performance counters to a Windows Service (see Chapter 25, "Windows Services"), to a network application (see Chapter 24, "Networking"), or to any other application from that you would like to receive live counts.

Using Visual Studio, you can create a new performance counter category by selecting the performance counters in the Server Explorer and by selecting the menu entry Create New Category on the context menu. This launches the Performance Counter Builder (see Figure 19-7).



Performance Counter Builder

Define a new category and the list of counters you want it to contain, or edit the values for an existing category.

Category name: Wrox Performance Counters

Category description: Sample Performance Counters

Counter list builder

To add a new counter, click on the New button then specify the details.

Counters:
- # of Button Clicks
- # of Button clicks/sec

Counter

Name: # of Button clicks/sec

Type: RateOfCountsPerSecond32

Counter description: # of button clicks in one second

FIGURE 19-7

To create a performance counter category with Visual Studio, Visual Studio must be started in elevated mode.

Set the name of the performance counter category to `Wrox Performance Counters`. The following table shows all performance counters of the quote service.

NAME	DESCRIPTION	TYPE
# of button clicks	Total # of button clicks	`NumberOfItems32`
# of button clicks/sec	# of button clicks in one second	`RateOfCountsPerSecond32`
# of mouse move events	Total # of mouse move events	`NumberOfItems32`
# of mouse move events/sec	# of mouse move events in one second	`RateOfCountsPerSecond32`

The Performance Counter Builder writes the configuration to the performance database. This can also be done dynamically by using the `Create()` method of the `PerformanceCounterCategory` class in the `System.Diagnostics` namespace. An installer for other systems can easily be added later using Visual Studio.

The following code snippet shows how a performance category can be added programmatically. With the tool from Visual Studio, you can only create a global performance category that doesn't have different values for different processes of running applications. Creating a performance category programmatically allows you to monitor performance counts from different applications, which is also done here.

First, a `const` for the category name is defined, as well as `SortedList<TKey, TValue>`, which contains the names of the performance counts:

```
private const string perfomanceCounterCategoryName = "Wrox Performance Counters";
private SortedList<string, Tuple<string, string>> perfCountNames;
```

code snippet PerformanceCounterDemo/MainWindow.xaml.cs

The list of the `perfCountNames` variable is filled in within the method `InitializePerformanceCountNames()`. The value of the sorted list is defined as `Tuple<string, string>` to define both the name and the description of the performance counter.

```
private void InitializePerfomanceCountNames()
{
    perfCountNames = new SortedList<string, Tuple<string, string>>();
    perfCountNames.Add("clickCount",
        Tuple.Create("# of button Clicks", "Total # of button clicks"));
    perfCountNames.Add("clickSec",
        Tuple.Create("# of button clicks/sec",
                     "# of mouse button clicks in one second"));
    perfCountNames.Add("mouseCount",
        Tuple.Create("# of mouse move events",
                     "Total # of mouse move events"));
    perfCountNames.Add("mouseSec",
        Tuple.Create("# of mouse move events/sec",
                     "# of mouse move events in one second"));
}
```

code snippet PerformanceCounterDemo/MainWindow.xaml.cs

The performance counter category is created next, in the method `OnRegisterCounts`. After a check to verify that the category does not already exist, an array of `CounterCreationData` is created that is filled with the types and names of the performance counts. Next, `PerformanceCounterCategory.Create()` creates the new category. `PerformanceCounterCategoryType.MultiInstance` defines that the counts are not global but that different values for different instances can exist.

```
private void OnRegisterCounts(object sender, RoutedEventArgs e)
{
    if (!PerformanceCounterCategory.Exists(
        perfomanceCounterCategoryName))
    {

        var counterCreationData = new CounterCreationData[4];
        counterCreationData[0] = new CounterCreationData
        {
            CounterName = perfCountNames["clickCount"].Item1,
            CounterType = PerformanceCounterType.NumberOfItems32,
            CounterHelp = perfCountNames["clickCount"].Item2
        };
        counterCreationData[1] = new CounterCreationData
        {
            CounterName = perfCountNames["clickSec"].Item1,
            CounterType = PerformanceCounterType.RateOfCountsPerSecond32,
            CounterHelp = perfCountNames["clickSec"].Item2,
        };
        counterCreationData[2] = new CounterCreationData
        {
            CounterName = perfCountNames["mouseCount"].Item1,
            CounterType = PerformanceCounterType.NumberOfItems32,
            CounterHelp = perfCountNames["mouseCount"].Item2,
        };
        counterCreationData[3] = new CounterCreationData
        {
            CounterName = perfCountNames["mouseSec"].Item1,
            CounterType = PerformanceCounterType.RateOfCountsPerSecond32,
            CounterHelp = perfCountNames["mouseSec"].Item2,
        };
```

```
            var counters =
                new CounterCreationDataCollection(counterCreationData);

            var category = PerformanceCounterCategory.Create(
                perfomanceCounterCategoryName,
                "Sample Counters for Professional C#",
                PerformanceCounterCategoryType.MultiInstance,
                counters);

            MessageBox.Show(String.Format(
                                "category {0} successfully created",
                                 category.CategoryName));
        }
```

code snippet PerformanceCounterDemo/MainWindow.xaml.cs

Adding PerformanceCounter Components

With Windows Forms or Windows Service applications, you can add `PerformanceCounter` components from the toolbox or from the Server Explorer with drag and drop to the designer surface.

With WPF applications that's not possible. However, it's not a lot of work to define the performance counters manually, as this is done with the method `InitializePerformanceCounts()`. Here, the `CategoryName` for all performance counts is set from the `const` string `performanceCounterCategoryName`; the `CounterName` is set from the sorted list. Because the application writes performance counts, the `ReadOnly` property must be set to `false`. When writing an application that just reads performance counts for display purposes, you can use the default value of the `ReadOnly` property, which is `true`. The `InstanceName` of the `PerformanceCounter` object is set to an application name. If the counters are configured to be global counts, the `InstanceName` may not be set.

```
        private PerformanceCounter performanceCounterButtonClicks;
        private PerformanceCounter performanceCounterButtonClicksPerSec;
        private PerformanceCounter performanceCounterMouseMoveEvents;
        private PerformanceCounter performanceCounterMouseMoveEventsPerSec;

        private void InitializePerformanceCounts()
        {
            performanceCounterButtonClicks = new PerformanceCounter
            {
                CategoryName = perfomanceCounterCategoryName,
                CounterName = perfCountNames["clickCount"].Item1,
                ReadOnly = false,
                MachineName = ".",
                InstanceLifetime = PerformanceCounterInstanceLifetime.Process,
                InstanceName = this.instanceName
            };
            performanceCounterButtonClicksPerSec = new PerformanceCounter
            {
                CategoryName = perfomanceCounterCategoryName,
                CounterName = perfCountNames["clickSec"].Item1,
                ReadOnly = false,
                MachineName = ".",
                InstanceLifetime = PerformanceCounterInstanceLifetime.Process,
                InstanceName = this.instanceName
            };
            performanceCounterMouseMoveEvents = new PerformanceCounter
            {
                CategoryName = perfomanceCounterCategoryName,
                CounterName =  perfCountNames["mouseCount"].Item1,
                ReadOnly = false,
                MachineName = ".",
                InstanceLifetime = PerformanceCounterInstanceLifetime.Process,
                InstanceName = this.instanceName
            };
            performanceCounterMouseMoveEventsPerSec = new PerformanceCounter
            {
                CategoryName = perfomanceCounterCategoryName,
                CounterName =  perfCountNames["mouseSec"].Item1,
                ReadOnly = false,
                MachineName = ".",
                InstanceLifetime = PerformanceCounterInstanceLifetime.Process,
                InstanceName = this.instanceName
            };
        }
```

code snippet PerformanceCounterDemo/MainWindow.xaml.cs

For the calculation of the performance values, you need to add the fields `clickCountPerSec` and `mouseMoveCountPerSec`:

```
    public partial class MainWindow : Window
    {
        // Performance monitoring counter values
        private int clickCountPerSec = 0;
        private int mouseMoveCountPerSec = 0;
```

Add an event handler to the `Click` event of the button and an event handler to the `MouseMove` event to the button, and add the following code to the handlers:

```
        private void OnButtonClick(object sender, RoutedEventArgs e)
        {
            this.performanceCounterButtonClicks.Increment();
            this.clickCountPerSec++;
        }

        private void OnMouseMove(object sender, MouseEventArgs e)
        {

            this.performanceCounterMouseMoveEvents.Increment();
            this.mouseMoveCountPerSec++;
        }
```

The `Increment()` method of the `PerformanceCounter` object increments the counter by one. If you need to increment the counter by more than one, for example, to add information about a byte count sent or received, you can use the `IncrementBy()` method. For the performance counts that show the value in seconds, just the two variables, `clickCountPerSec` and `mouseMovePerSec`, are incremented.

To show updated values every second, add a `DispatcherTimer` to the members of the `MainWindow`:

```
        private DispatcherTimer timer;
```

This timer is configured and started in the constructor. The `DispatcherTimer` class is a timer from the namespace `System.Windows.Threading`. For other than WPF applications, you can use other timers that are discussed in Chapter 20, "Threads, Tasks, and Synchronization." The code that is invoked by the timer is defined with an anonymous method.

```
        public MainWindow()
        {
            InitializeComponent();
            InitializePerfomanceCountNames();
            InitializePerformanceCounts();
            if (PerformanceCounterCategory.Exists(perfomanceCounterCategoryName))
            {
                buttonCount.IsEnabled = true;
                timer = new DispatcherTimer(TimeSpan.FromSeconds(1),
                    DispatcherPriority.Background,
                    delegate
                    {
                        this.performanceCounterButtonClicksPerSec.RawValue =
                            this.clickCountPerSec;
                        this.clickCountPerSec = 0;
                        this.performanceCounterMouseMoveEventsPerSec.RawValue =
                            this.mouseMoveCountPerSec;
                        this.mouseMoveCountPerSec = 0;
                    },
                    Dispatcher.CurrentDispatcher);
                timer.Start();
            }
        }
```

perfmon.exe

Now you can monitor the application. You can start the Performance Monitor from the Administrative Tools. Within the Performance Monitor, click the + button in the toolbar; there, you can add performance counts. Wrox Performance Counters shows up as a performance object. All the counters that have been configured appear in the counter list, as shown in Figure 19-8.

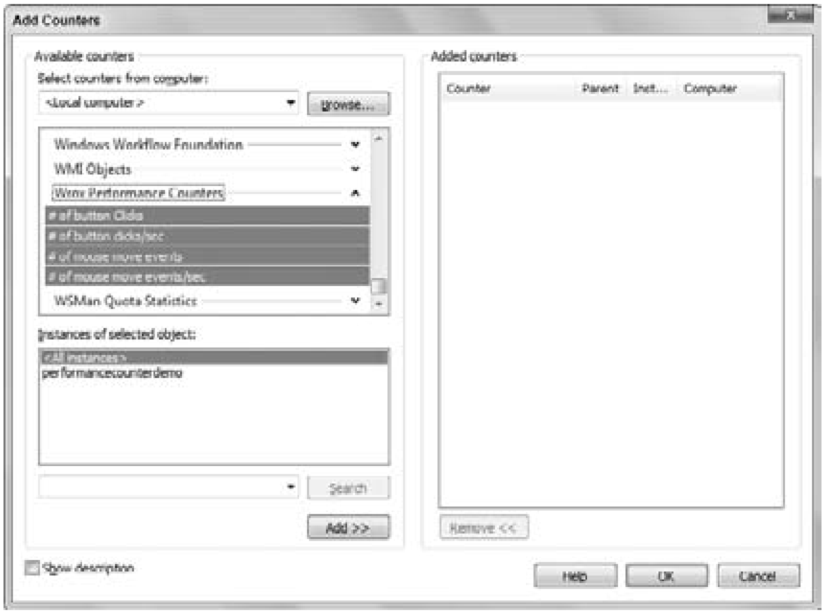


FIGURE 19-8

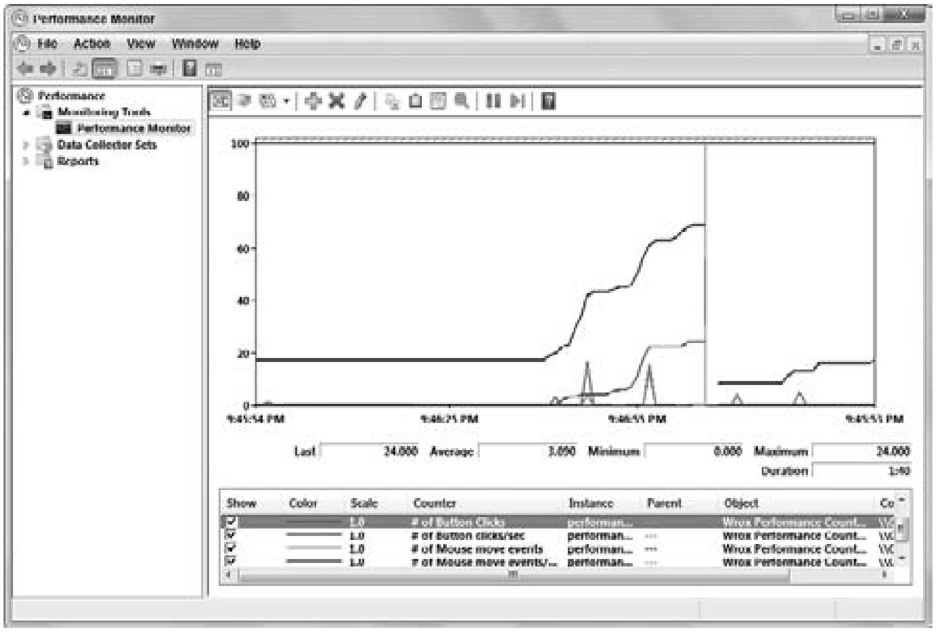
After you have added the counters to the performance monitor, you can see the actual values of the service over time (see Figure 19-9). Using this performance tool, you can also create log files to analyze the performance at a later time.



Last 24.000 Average 3.050 Minimum 0.000 Maximum 24.000
Duration 1:40

Show	Color	Scale	Counter	Instance	Parent	Object	Co

FIGURE 19-9

SUMMARY

In this chapter, you have seen tracing and logging facilities that can help you find intermediate problems in your applications. You should plan early, building these features into your applications. This will help you avoid many troubleshooting problems later.

With tracing, you can write debugging messages to an application that can also be used for the final product delivered. If there are problems, you can turn tracing on by changing configuration values, and find the issues.

Event logging provides information to the system administrator to help find some of the critical issues with the application. Performance monitoring helps in analyzing the load from applications and in planning in advance for resources that might be required.

In the next chapter you learn all about writing multithreaded applications.

20 Threads, Tasks, and Synchronization

WHAT'S IN THIS CHAPTER?

- ➤ An overview of threading
- ➤ Lightweight threading using delegates
- ➤ `Thread` class and thread pools
- ➤ Tasks
- ➤ `Parallel` class
- ➤ Cancellation framework
- ➤ Threading issues
- ➤ Synchronization techniques
- ➤ Timers
- ➤ Event-based asynchronous pattern

There are several reasons for using threading. Suppose that you are making a network call from an application that might take some time. You don't want to stall the user interface and just let the user wait until the response is returned from the server. The user could perform some other actions in the meantime or even cancel the request that was sent to the server. Using threads can help.

For all activities that require a wait — for example, because of file, database, or network access — a new thread can be started to fulfill other tasks at the same time. Even if you have only processing-intensive tasks to do, threading can help. Multiple threads of a single process can run on different CPUs, or, nowadays, on different cores of a multiple-core CPU, at the same time.

You must be aware of some issues when running multiple threads, however. Because they can run during the same time, you can easily get into problems if the threads access the same data. You must implement synchronization mechanisms.

This chapter provides the foundation you will need when programming applications with multiple threads.

OVERVIEW

A thread is an independent stream of instructions in a program. All your C# programs up to this point have one entry point — the `Main()` method. Execution starts with the first statement in the `Main()` method and continues until that method returns.

This program structure is all very well for programs in which there is one identifiable sequence of tasks, but often a program needs to do more than one thing at the same time. Threads are important both for client-side and for server-side applications. While you type C# code in the Visual Studio editor, the code is analyzed to underline missing semicolons or other syntax errors. This is done by a background thread. The same thing is done by the spell checker in Microsoft Word. One thread is waiting for input from the user, while the other does some background research. A third thread can store the written data in an interim file, while another one downloads some additional data from the Internet.

In an application that is running on the server, one thread, the listener thread, waits for a request from a client. As soon as the request comes in, the request is forwarded to a separate worker thread, which continues the communication with the client. The listener thread immediately comes back to get the next request from the next client.

A process contains resources, such as Window handles, handles to the file system, or other kernel objects. Every process has virtual memory allocated. A process contains at least one thread. The operating system schedules threads. A thread has a priority, a program counter for the program location where it is actually processing, and a stack in which to store its local variables. Every thread has its own stack, but the memory for the program code and the heap are shared among all threads of a single process. This makes communication among threads of one process fast — the same virtual memory is addressed by all threads of a process. However, this also makes things difficult because multiple threads can change the same memory location.

A process manages resources, which include virtual memory and Window handles, and contains at least one thread. A thread is required to run the program.

ASYNCHRONOUS DELEGATES

A simple way to create a thread is by defining a delegate and invoking the delegate asynchronously. In Chapter 8, "Delegates, Lambdas, and Events," you saw delegates as type-safe references to methods. The `Delegate` class also supports invoking the methods asynchronously. Behind the scenes, the `Delegate` class creates a thread that fulfills the task.

The delegate uses a thread pool for asynchronous tasks. Thread pools are discussed later in this chapter.

To demonstrate the asynchronous features of delegates, start with a method that takes a while to complete. The method `TakesAWhile()` needs at least the number of milliseconds passed with the second argument to finish because of the `Thread.Sleep()` method:

```
 static int TakesAWhile(int data, int ms)
{
    Console.WriteLine("TakesAWhile started");
    Thread.Sleep(ms);
    Console.WriteLine("TakesAWhile completed");
    return ++data;
}
```

code snippet AsyncDelegate/Program.cs

To invoke this method from a delegate, a delegate with the same parameter and return types must be defined, as shown by the delegate `TakesAWhileDelegate`:

```
        public delegate int TakesAWhileDelegate(int data, int ms);
```

Now you can use different techniques, invoking the delegate asynchronously and having the result returned.

Polling

One technique is to poll and check if the delegate has already finished its work. The created `delegate` class provides the method `BeginInvoke()`, where you can pass the input parameters defined with the delegate type. `BeginInvoke()` always has two additional parameters of type `AsyncCallback` and `object`, which are discussed later. What's important now is the return type, `BeginInvoke()`: `IAsyncResult`. With `IAsyncResult`, you can get information about the delegate, and also verify if the delegate has already finished its work, as is done with the `IsCompleted` property. The main thread of the program continues the `while` loop as long as the delegate hasn't completed its work.

```
static void Main()
{
   // synchronous method call
   // TakesAWhile(1, 3000);

   // asynchronous by using a delegate
   TakesAWhileDelegate d1 = TakesAWhile;

   IAsyncResult ar = d1.BeginInvoke(1, 3000, null, null);
   while (!ar.IsCompleted)
   {
      // doing something else in the main thread
      Console.Write(".");
      Thread.Sleep(50);
   }
   int result = d1.EndInvoke(ar);
   Console.WriteLine("result: {0}", result);
}
```

code snippet Async Delegate/Program.cs

When you run the application, you can see the main thread and the thread of the delegate running concurrently, and the main thread stops looping after the delegate thread completes:

```
.TakesAWhile started
..TakesAWhile completed
result: 2
```

Instead of examining if the delegate is completed, you can just invoke the `EndInvoke()` method of the delegate type after you are finished with the work that can be done by the main thread. `EndInvoke()` itself waits until the delegate has completed its work.

Wait Handle

Another way to wait for the result from the asynchronous delegate is by using the wait handle that is associated with `IAsyncResult`. You can access the wait handle with the `AsyncWaitHandle` property. This property returns an object of type `WaitHandle`, where you can wait for the delegate thread to finish its work. The method `WaitOne()` accepts a timeout with the optional first parameter, where you can define the maximum time you want to wait; here, it is set to 50 milliseconds. If a timeout occurs, `WaitOne()` returns `false` and the `while` loop continues. If the wait is successful, the `while` loop is exited with a break, and the result is received with the delegate `EndInvoke()` method. From the UI standpoint the result is similar to the previous sample; just the wait is done in a different manner.

```
static void Main()
{
    TakesAWhileDelegate d1 = TakesAWhile;

    IAsyncResult ar = d1.BeginInvoke(1, 3000, null, null);
    while (true)
    {
        Console.Write(".");
        if (ar.AsyncWaitHandle.WaitOne(50, false))
        {
            Console.WriteLine("Can get the result now");
            break;
        }
    }
    int result = d1.EndInvoke(ar);
    Console.WriteLine("result: {0}", result);
}
```

Asynchronous Callback

The third version of waiting for the result from the delegate uses an asynchronous callback. With the third parameter of `BeginInvoke()`, you can pass a method that fulfills the requirements of the `AsyncCallback` delegate. The `AsyncCallback` delegate defines a parameter of `IAsnycResult` and a `void` return type. Here, the address of the method `TakesAWhileCompleted` is assigned to the third parameter, which fulfills the requirements of the `AsyncCallback` delegate. For the last parameter, you can pass any object for accessing it from the callback method. It is useful to pass the delegate instance itself, so the callback method can use it to get the result of the asynchronous method.

The method `TakesAWhileCompleted()` is invoked as soon as the delegate `TakesAWhileDelegate` has completed its work. There is no need to wait for a result inside the main thread. However, you may not end the main thread before the work of the delegate threads is finished, unless you don't have a problem with delegate threads stopping when the main thread ends.

```
static void Main()
{
    TakesAWhileDelegate d1 = TakesAWhile;

    d1.BeginInvoke(1, 3000, TakesAWhileCompleted, d1);
    for (int i = 0; i < 100; i++)
    {
        Console.Write(".");
        Thread.Sleep(50);
    }
}
```

code snippet Async Delegate/Program.cs

The method `TakesAWhileCompleted()` is defined with the parameter and return type specified by the `AsyncCallback` delegate. The last parameter passed with the `BeginInvoke()` method can be read here by using `ar.AsyncState`. With the `TakesAWhileDelegate`, you can invoke the `EndInvoke` method to get the result.

```
static void TakesAWhileCompleted(IAsyncResult ar)
{
    if (ar == null) throw new ArgumentNullException("ar");

    TakesAWhileDelegate d1 = ar.AsyncState as TakesAWhileDelegate;
    Trace.Assert(d1 != null, "Invalid object type");

    int result = d1.EndInvoke(ar);
    Console.WriteLine("result: {0}", result);
}
```

With a callback method, you need to pay attention to the fact that this method is invoked from the thread of the delegate and not from the main thread.

Instead of defining a separate method and passing it to the `BeginInvoke()` method, Lambda expressions can be used. The parameter `ar` is of type `IAsyncResult`. With the implementation, there is no need to assign a value to the last parameter of the `BeginInvoke()` method because the Lambda expression can directly access variable `d1` that is in the outer scope. However, the implementation block of the Lambda expression is still invoked from the thread of the delegate, which might not be clear immediately when defining the method this way.

```
static void Main()
{
    TakesAWhileDelegate d1 = TakesAWhile;
    d1.BeginInvoke(1, 3000,
        ar =>
        {
            int result = d1.EndInvoke(ar);
            Console.WriteLine("result: {0}", result);
        },
        null);
    for (int i = 0; i < 100; i++)
    {
        Console.Write(".");
        Thread.Sleep(50);
    }
}
```

The programming model and all of these options with asynchronous delegates — polling, wait handles, and asynchronous callbacks — are not only available with delegates. The same programming model — this is the asynchronous pattern — can be found in various places in the .NET Framework. For example, you can send an HTTP Web request asynchronously with the `BeginGetResponse()` method of the `HttpWebRequest` class. You can send an asynchronous request to the database with the `BeginExecuteReader()` of the `SqlCommand` class. The parameters are similar to those of the `BeginInvoke()` class of the delegate, and you can use the same mechanisms to get the result.

`HttpWebRequest` *is covered in Chapter 24, "Networking," and* `SqlCommand` *is discussed in Chapter 30, "Core ADO.NET."*

Instead of using the delegate for creating threads, you can create threads with the `Thread` class, which is covered in the next section.

THE THREAD CLASS

With the `Thread` class, you can create and control threads. The code here is a very simple example of creating and starting a new thread. The constructor of the `Thread` class is overloaded to accept a delegate parameter of type `ThreadStart` or `ParameterizedThreadStart`. The `ThreadStart` delegate defines a method with a void return type and without arguments. After the `Thread` object is created, you can start the thread with the `Start()` method:

```
using System;
using System.Threading;

namespace Wrox.ProCSharp.Threading
{
   class Program
   {
      static void Main()
      {
         var t1 = new Thread(ThreadMain);
         t1.Start();
         Console.WriteLine("This is the main thread.");
      }

      static void ThreadMain()
      {
         Console.WriteLine("Running in a thread.");
      }
   }
}
```

code snippet ThreadSamples/Program.cs

When you run the application, you get the output of the two threads:

```
This is the main thread.
Running in a thread.
```

There is no guarantee as to what output comes first. Threads are scheduled by the operating system; which thread comes first can be different each time.

You have seen how a Lambda expression can be used with an asynchronous delegate. You can use it with the `Thread` class as well by passing the implementation of the thread method to the argument of the `Thread` constructor:

```
using System;
using System.Threading;

namespace Wrox.ProCSharp.Threading
{
   class Program
   {
      static void Main()
      {
         var t1 = new Thread(() => Console.WriteLine("running in a thread, id: {0}",
                                      Thread.CurrentThread.ManagedThreadId));
         t1.Start();
         Console.WriteLine("This is the main thread, id: {0}",
                           Thread.CurrentThread.ManagedThreadId);
      }
   }
}
```

With the output of the application, now you can also see the thread name and ID:

```
This is the main thread, id: 1
Running in a thread, id: 3.
```

Passing Data to Threads

There are two ways to pass some data to a thread. You can either use the `Thread` constructor with the `ParameterizedThreadStart` delegate, or you can create a custom class and define the method of the thread as an instance method so that you can initialize data of the instance before starting the thread.

For passing data to a thread, a class or struct that holds the data is needed. Here, the struct `Data` containing a string is defined, but you can pass any object you want:

```
public struct Data
{
   public string Message;
}
```

code snippet ThreadSamples/Program.cs

If the `ParameterizedThreadStart` delegate is used, the entry point of the thread must have a parameter of type object and a void return type. The object can be cast to what it is, and here the message is written to the console:

```
static void ThreadMainWithParameters(object o)
{
   Data d = (Data)o;
   Console.WriteLine("Running in a thread, received {0}", d.Message);
}
```

With the constructor of the `Thread` class, you can assign the new entry point `ThreadMainWithParameters` and invoke the `Start()` method, passing the variable `d`:

```
static void Main()
{
   var d = new Data { Message = "Info" };
   var t2 = new Thread(ThreadMainWithParameters);
   t2.Start(d);
}
```

Another way to pass data to the new thread is to define a class (see the class `MyThread`), where you define the fields that are needed as well as the main method of the thread as an instance method of the class:

```
public class MyThread
{
   private string data;

   public MyThread(string data)
   {
      this.data = data;
   }

   public void ThreadMain()
   {
      Console.WriteLine("Running in a thread, data: {0}", data);
   }
}
```

This way, you can create an object of `MyThread` and pass the object and the method `ThreadMain()` to the constructor of the `Thread` class. The thread can access the data.

```
var obj = new MyThread("info");
var t3 = new Thread(obj.ThreadMain);
t3.Start();
```

Background Threads

The process of the application keeps running as long as at least one foreground thread is running. If more than one foreground thread is running and the `Main()` method ends, the process of the application remains active until all foreground threads finish their work.

A thread you create with the `Thread` class, by default, is a foreground thread. Thread pool threads are always background threads.

When you create a thread with the `Thread` class, you can define whether it should be a foreground or background thread by setting the property `IsBackground`. The `Main()` method sets the `IsBackground` property of the thread `t1` to `false` (which is the default). After starting the new thread, the main thread just writes an end message to the console. The new thread writes a start and an end message, and in between it sleeps for 3 seconds. The 3 seconds provide a good chance for the main thread to finish before the new thread completes its work.

```
class Program
 {
    static void Main()
    {
       var t1 = new Thread(ThreadMain)
           { Name = "MyNewThread", IsBackground = false };
       t1.Start();
       Console.WriteLine("Main thread ending now.");
    }

    static void ThreadMain()
    {
       Console.WriteLine("Thread {0} started", Thread.CurrentThread.Name);
       Thread.Sleep(3000);
       Console.WriteLine("Thread {0} completed", Thread.CurrentThread.Name);
    }
 }
```

code snippet ThreadSamples/Program.cs

When you start the application, you will still see the completion message written to the console, although the main thread completed its work earlier. The reason is that the new thread is a foreground thread as well.

```
Main thread ending now.
Thread MyNewThread1 started
Thread MyNewThread1 completed
```

If you change the `IsBackground` property used to start the new thread to `true`, the result shown at the console is different. You can have the same result as shown here — the start message of the new thread is shown but never the end message. You might not see the start message either, if the thread was prematurely ended before it had a chance to kick off.

```
Main thread ending now.
Thread MyNewThread1 started
```

Background threads are very useful for background tasks. For example, when you close the Word application, it doesn't make sense for the spell checker to keep its process running. The spell checker thread can be killed when the application is closed. However, the thread organizing the Outlook message store should remain active until it is finished, even if Outlook is closed.

Thread Priority

You have learned that the operating system schedules threads. You have had a chance to influence the scheduling by assigning a priority to the thread.

Before changing the priority, you must understand the thread scheduler. The operating system schedules threads based on a priority, and the thread with the highest priority is scheduled to run in the CPU. A thread stops running and gives up the CPU if it waits for a resource. There are several reasons why a thread must wait; for example, in response to a sleep instruction, while waiting for disk I/O to complete, while waiting for a network packet to arrive, and so on. If the thread does not give up the CPU on its own, it is preempted by the thread scheduler. If a thread does have a *time quantum,* it can use the CPU continuously. If there are multiple threads running with the same priority waiting to get the CPU, the thread scheduler uses a *round-robin* scheduling principle to give the CPU to one thread after another. If a thread is preempted, it goes last to the queue.

The time quantum and round-robin principles are used only if multiple threads are running at the same priority. The priority is dynamic. If a thread is CPU-intensive (requires the CPU continuously without waiting for resources), the priority is lowered to the level of the base priority that is defined with the thread. If a thread is waiting for a resource, the thread gets a priority boost and the priority is increased. Because of the boost, there is a good chance that the thread gets the CPU the next time that the wait ends.

With the `Thread` class, you can influence the base priority of the thread by setting the `Priority` property. The `Priority` property requires a value that is defined by the `ThreadPriority` enumeration. The levels defined are `Highest`, `AboveNormal`, `Normal`, `BelowNormal`, and `Lowest`.

Be careful when giving a thread a higher priority, because this may decrease the chance for other threads to run. You can change the priority for a short time if necessary.

Controlling Threads

The thread is created by invoking the `Start()` method of a `Thread` object. However, after invoking the `Start()` method, the new thread is still not in the `Running` state, but in the `Unstarted` state. The thread changes to the `Running` state as soon as the operating system thread scheduler selects the thread to run. You can read the current state of a thread by reading the property `Thread.ThreadState`.

With the `Thread.Sleep()` method, a thread goes into the `WaitSleepJoin` state and waits until it is woken up again after the time span defined with the `Sleep()` method has elapsed.

To stop another thread, you can invoke the method `Thread.Abort()`. When this method is called, an exception of type `ThreadAbortException` is thrown in the thread that receives the abort. With a handler to catch this exception, the thread can do some cleanup before it ends. The thread also has a chance to continue running after receiving the `ThreadAbortException` as a result of invoking `Thread.ResetAbort()`. The state of the thread receiving the abort request changes from `AbortRequested` to the `Aborted` state if the thread does not reset the abort.

If you need to wait for a thread to end, you can invoke the `Thread.Join()` method. `Thread.Join()` blocks the current thread and sets it to the `WaitSleepJoin` state until the thread that is joined is completed.

THREAD POOLS

Creating threads takes time. When you have different short tasks to do, you can create a number of threads in advance and send requests as they should be done. It would be nice if this number increased as more threads were needed and decreased as needed to release resources.

There is no need to create such a list on your own. The list is managed by the `ThreadPool` class. This class increases and decreases the number of threads in the pool as they are needed, up to the maximum number of threads. The maximum number of threads in a pool is configurable. With a dual-core CPU, the default number is set to 1,023 worker threads and 1,000 I/O threads. You can specify the minimum number of threads that should be started immediately when the pool is created and the maximum number of threads that are available in the pool. If there are more jobs to process, and the maximum number of threads in the pool has already been reached, the newest jobs are queued and must wait for a thread to complete its work.

The following sample application first reads the maximum number of worker and I/O threads and writes this information to the console. Then, in a `for` loop, the method `JobForAThread()` is assigned to a thread from the thread pool by invoking the method `ThreadPool.QueueUserWorkItem()` and passing a delegate of type `WaitCallback`. The thread pool receives this request and selects one of the threads from the pool to invoke the method. If the pool is not already running, the pool is created and the first thread is started. If the pool is already running and one thread is free to do the task, the job is forwarded to that thread.

```
using System;
using System.Threading;

namespace Wrox.ProCSharp.Threading
{
   class Program
   {
      static void Main()
      {
         int nWorkerThreads;
         int nCompletionPortThreads;
         ThreadPool.GetMaxThreads(out nWorkerThreads, out nCompletionPortThreads);
         Console.WriteLine("Max worker threads: {0}, " +
                           "I/O completion threads: {1}",
                           nWorkerThreads, nCompletionPortThreads);

         for (int i = 0; i < 5; i++)
         {
            ThreadPool.QueueUserWorkItem(JobForAThread);
         }
         Thread.Sleep(3000);
      }

      static void JobForAThread(object state)
      {
         for (int i = 0; i < 3; i++)
         {
            Console.WriteLine("loop {0}, running inside pooled thread {1}",
               i, Thread.CurrentThread.ManagedThreadId);
            Thread.Sleep(50);
         }
      }
   }
}
```

code snippet ThreadPoolSamples/Program.cs

When you run the application, you can see that 50 worker threads are possible with the current settings. The five jobs are processed by just two pooled threads. Your experience may be different, and you can also change the sleep time with the job and the number of jobs to process to get very different results.

```
Max worker threads: 1023, I/O completion threads: 1000
loop 0, running inside pooled thread 4
loop 0, running inside pooled thread 3
loop 1, running inside pooled thread 4
loop 1, running inside pooled thread 3
loop 2, running inside pooled thread 4
loop 2, running inside pooled thread 3
loop 0, running inside pooled thread 4
loop 0, running inside pooled thread 3
loop 1, running inside pooled thread 4
loop 1, running inside pooled thread 3
loop 2, running inside pooled thread 4
loop 2, running inside pooled thread 3
loop 0, running inside pooled thread 4
loop 1, running inside pooled thread 4
loop 2, running inside pooled thread 4
```

Thread pools are very easy to use. However, there are some restrictions:

- ➤ All thread pool threads are background threads. If all foreground threads of a process are finished, all background threads are stopped. You cannot change a pooled thread to a foreground thread.
- ➤ You cannot set the priority or name of a pooled thread.

- For COM objects, all pooled threads are multithreaded apartment (MTA) threads. Many COM objects require a single-threaded apartment (STA) thread.
- Use pooled threads only for a short task. If a thread should run all the time (for example, the spell-checker thread of Word), create a thread with the Thread class.

TASKS

.NET 4 includes the new namespace System.Threading.Tasks, which contains classes to abstract threading functionality. Behind the scenes, ThreadPool is used. A *task* represents some unit of work that should be done. This unit of work can run in a separate thread; and it is also possible to start a task in a synchronized manner, which results in a wait for the calling thread. With tasks, you have an abstraction layer but also a lot of control over the underlying threads.

Tasks allow much more flexibility in organizing the work you need to do. For example, you can define continuation work — what should be done after a task is complete. This can be differentiated whether the task was successful or not. Also, you can organize tasks in a hierarchy. For example, a parent task can create new children tasks. This can create a dependency, so that canceling a parent task also cancels its child tasks.

Starting Tasks

To start a task, you can use either the TaskFactory or the constructor of the Task and the Start() method. The Task constructor just gives you more flexibility in creating the task.

When starting a task, an instance of the Task class can be created and the code that should run can be assigned, with an Action or Action<object> delegate, with either no parameters or one object parameter. This is similar to what you saw with the Thread class. Here, a method is defined without a parameter. In the implementation, the ID of the task is written to the console.

```
static void TaskMethod()
{
    Console.WriteLine("running in a task");
    Console.WriteLine("Task id: {0}", Task.CurrentId);
}
```

code snippet TaskSamples/Program.cs

In the previous code, you can see different ways to start a new task. The first way is with an instantiated TaskFactory, where the method TaskMethod is passed to the StartNew() method, and the task is immediately started. The second approach uses the constructor of the Task class. When the Task object is instantiated, the task does not run immediately. Instead, it is given the status Created. The task is then started by calling the Start() method of the Task class. With the Task class, instead of invoking the Start() method, you can invoke the RunSynchronously() method. This way, the task is started as well, but it is running in the current thread of the caller, and the caller needs to wait until the task finishes. By default, the task runs asynchronously.

```
// using task factory
TaskFactory tf = new TaskFactory();
Task t1 = tf.StartNew(TaskMethod);

// using the task factory via a task
Task t2 = Task.Factory.StartNew(TaskMethod);

// using Task constructor
Task t3 = new Task(TaskMethod);
t3.Start();
```

With both the Task constructor and the StartNew() method of the TaskFactory, you can pass values from the enumeration TaskCreationOptions. Setting the option LongRunning, you can inform the task scheduler that the task takes a long time, so the scheduler will more likely use a new thread. If the task should be attached to the parent task and, thus, should be canceled if the parent were canceled, set the option `AttachToParent`. The value `PreferFairness` means that the scheduler should take first tasks that are already waiting. That's not the default case if a task is created within another task. If tasks create additional work using child tasks, child tasks are preferred to other tasks. They are not waiting last in the thread pool queue for the work to be done. If these tasks should be handled in a fair manner to all other tasks, set the option to `PreferFairness`.

```
Task t4 = new Task(TaskMethod, TaskCreationOptions.PreferFairness);
t4.Start();
```

Continuation Tasks

With tasks, you can specify that after a task is finished another specific task should start to run, for example, a new task that uses a result from the previous one or that should do some cleanup if the previous task failed.

Whereas the task handler has either no parameter or one object parameter, the continuation handler has a parameter of type `Task`. Here, you can access information about the originating task.

```
static void DoOnFirst()
{
    Console.WriteLine("doing some task {0}", Task.CurrentId);
    Thread.Sleep(3000);
}

static void DoOnSecond(Task t)
{
    Console.WriteLine("task {0} finished", t.Id);
    Console.WriteLine("this task id {0}", Task.CurrentId);
    Console.WriteLine("do some cleanup");
    Thread.Sleep(3000);
}
```

code snippet TaskSamples/Program.cs

A continuation task is defined by invoking the `ContinueWith` method on a task. You could also use the `TaskFactory` for this. `t1.OnContinueWith(DoOnSecond)` means that a new task invoking the method `DoOnSecond()` should be started as soon as the task *t1* is finished. You can start multiple tasks when one task is finished, and a continuation task can also have another continuation task, as this example demonstrates.

```
Task t1 = new Task(DoOnFirst);
Task t2 = t1.ContinueWith(DoOnSecond);
Task t3 = t1.ContinueWith(DoOnSecond);
Task t4 = t2.ContinueWith(DoOnSecond);
```

The continuation tasks so far were always started when the previous task was finished, no matter how the previous task was finished. With values from `TaskContinuationOptions`, you can define that a continuation task should only start if the originating task was successful (or faulted). Some of the possible values are `OnlyOnFaulted`, `NotOnFaulted`, `OnlyOnCanceled`, `NotOnCanceled`, and `OnlyOnRanToCompletion`.

```
Task t5 = t1.ContinueWith(DoOnError,
                          TaskContinuationOptions.OnlyOnFaulted);
```

Task Hierarchies

With task continuations, one task is started after another. Tasks can also form a hierarchy. When a task itself starts a new task, a parent/child hierarchy is started.

In the code snippet that follows, within the task of the parent, a new task is created. The code to create a child task is the same as creating a parent task. The only difference is that the task is created from within another task.

```
static void ParentAndChild()
{
    var parent = new Task(ParentTask);
    parent.Start();
    Thread.Sleep(2000);
    Console.WriteLine(parent.Status);
    Thread.Sleep(4000);
    Console.WriteLine(parent.Status);

}
static void ParentTask()
{
    Console.WriteLine("task id {0}", Task.CurrentId);
    var child = new Task(ChildTask);
    child.Start();
    Thread.Sleep(1000);
    Console.WriteLine("parent started child");
}
static void ChildTask()
{
    Console.WriteLine("child");
    Thread.Sleep(5000);
    Console.WriteLine("child finished");
}
```

code snippet TaskSamples/Program.cs

If the parent task is finished before the child task, the status of the parent task is shown as `WaitingForChildrenToComplete`. The parent task is completed with the status `RanToCompletion` as soon as all children are completed as well. Of course, this is not valid if the parent creates a task with the `TaskCreationOption` `DetachedFromParent`.

Canceling a parent task also cancels the children. The cancellation framework is discussed later in this chapter.

Results from Tasks

When a task is finished, it can write some stateful information to a shared object. Such a shared object must be thread-safe. Another option is to use a task that returns a result. With the generic version of the `Task` class, it is possible to define the type that is returned with a task that returns a result.

A method that is invoked by a task to return a result can be declared with any return type. The example method `TaskWithResult` returns two `int` values with the help of a `Tuple`. The input of the method can be void or of type `object`, as shown here.

```
static Tuple<int, int> TaskWithResult(object division)
{
    Tuple<int, int> div = (Tuple<int, int>)division;
    int result = div.Item1 / div.Item2;
    int reminder = div.Item1 % div.Item2;
    Console.WriteLine("task creates a result...");

    return Tuple.Create<int, int>(result, reminder);
}
```

code snippet TaskSamples/Program.cs

Tuples are explained in Chapter 6, "Arrays and Tuples."

When defining a task to invoke the method `TaskWithResult`, the generic class `Task<TResult>` is used. The generic parameter defines the return type. With the constructor, the method is passed to the `Func` delegate, and the second parameter defines the input value. Because this task needs two input values in the `object` parameter, a tuple is created as well. Next, the task is started. The `Result` property of the `Task` instance `t1` blocks and waits until the task is completed. Upon task completion, the `Result` property contains the result from the task.

```
var t1 = new Task<Tuple<int,int>>(TaskWithResult,
                                  Tuple.Create<int, int>(8, 3));
t1.Start();
Console.WriteLine(t1.Result);
t1.Wait();
Console.WriteLine("result from task: {0} {1}", t1.Result.Item1,
                  t1.Result.Item2);
```

PARALLEL CLASS

Another abstraction of threads that is new with .NET 4 is the `Parallel` class. This class defines static methods for a parallel `for` and `foreach`. With the language defined for `for` and `foreach`, the loop is run from one thread. The `Parallel` class uses multiple tasks and, thus, multiple threads for this job.

While the `Parallel.For()` and `Parallel.ForEach()` methods invoke the same method several times, `Parallel.Invoke()` allows invoking different methods concurrently.

Looping with the Parallel.For Method

The `Parallel.For()` method is similar to the C# `for` loop statement to do a task a number of times. With the `Parallel.For()`, the iterations run in parallel. The order of iteration is not defined.

With the `For()` method, the first two parameters define the start and end of the loop. The sample has the iterations from 0 to 9. The third parameter is an `Action<int>` delegate. The integer parameter is the iteration of the loop that is passed to the method referenced by the delegate. The return type of `Parallel.For()` is the struct `ParallelLoopResult`, which provides information if the loop is completed.

```
ParallelLoopResult result =
    Parallel.For(0, 10, i =>
        {
            Console.WriteLine("{0}, task: {1}, thread: {2}", i,
               Task.CurrentId, Thread.CurrentThread.ManagedThreadId);
            Thread.Sleep(10);
        });
Console.WriteLine(result.IsCompleted);
```

code snippet ParallelSamples/Program.cs

In the body of the `Parallel.For()`, the index, task identifier, and thread identifier are written to the console. As you can see from this output, the order is not guaranteed. This run of the program had the order 0-5-1-6-2… with three tasks and three threads.

```
0, task: 1, thread: 1
5, task: 2, thread: 3
1, task: 3, thread: 4
6, task: 2, thread: 3
2, task: 1, thread: 1
4, task: 3, thread: 4
7, task: 2, thread: 3
3, task: 1, thread: 1
```

```
8, task: 3, thread: 4
9, task: 3, thread: 4
True
```

You can also break the `Parallel.For()` early. A method overload of the `For()` method accepts a third parameter of type `Action<int, ParallelLoopState>`. By defining a method with these parameters, you can influence the outcome of the loop by invoking the `Break()` or `Stop()` methods of the `ParallelLoopState`.

Remember, the order of iterations is not defined.

```
            ParallelLoopResult result =
                Parallel.For(10, 40, (int i, ParallelLoopState pls) =>
                    {
                        Console.WriteLine("i: {0} task {1}", i, Task.CurrentId);
                        Thread.Sleep(10);
                        if (i > 15)
                            pls.Break();
                    });
            Console.WriteLine(result.IsCompleted);
            Console.WriteLine("lowest break iteration: {0}",
                             result.LowestBreakIteration);
```

This run of the application demonstrates that the iteration breaks up with a value higher than 15, but other tasks can simultaneously run and tasks with other values can run. With the help of the `LowestBreakIteration` property, you can decide to ignore results from other tasks.

```
10 task 1
25 task 2
11 task 1
13 task 3
12 task 1
14 task 3
16 task 1
15 task 3
False
lowest break iteration: 16
```

`Parallel.For()` might use several threads to do the loops. If you need an initialization that should be done with every thread, you can use the `Parallel.For<TLocal>()` method. The generic version of the `For` method accepts — besides the `from` and `to` values — three delegate parameters. The first parameter is of type `Func<TLocal>`. Because the example here uses a string for `TLocal`, the method needs to be defined as `Func<string>`, a method returning a `string`. This method is invoked only once for each thread that is used to do the iterations.

The second delegate parameter defines the delegate for the body. In the example, the parameter is of type `Func<int, ParallelLoopState, string, string>`. The first parameter is the loop iteration; the second parameter, `ParallelLoopState`, allows for stopping the loop, as you saw earlier. With the third parameter, the body method receives the value that is returned from the `init` method. The body method also needs to return a value of the type that was defined with the generic `For` parameter.

The last parameter of the `For()` method specifies a delegate, `Action<TLocal>`; in the example, a string is received. This method again is called only once for each thread; this is a thread exit method.

```
            Parallel.For<string>(0, 20,
                () =>
                {
                    // invoked once for each thread
                    Console.WriteLine("init thread {0}, task {1}",
                        Thread.CurrentThread.ManagedThreadId, Task.CurrentId);
                    return String.Format("t{0}",
                        Thread.CurrentThread.ManagedThreadId);
                },
                (i, pls, str1) =>
```

```
                    {
                        // invoked for each member
                        Console.WriteLine("body i {0} str1 {1} thread {2} task {3}", i, str1,
                            Thread.CurrentThread.ManagedThreadId,
                            Task.CurrentId);
                        Thread.Sleep(10);
                        return String.Format("i {0}", i);

                    },
                    (str1) =>
                    {
                        // final action on each thread
                        Console.WriteLine("finally {0}", str1);
                    });
```

The result of one time running this program is shown here:

```
init thread 1, task 1
body i 0 str1 t1 thread 1 task 1
body i 1 str1 i 0 thread 1 task 1
init thread 3, task 2
body i 10 str1 t3 thread 3 task 2
init thread 4, task 3
body i 3 str1 t4 thread 4 task 3
body i 2 str1 i 1 thread 1 task 1
body i 11 str1 i 10 thread 3 task 2
body i 4 str1 i 3 thread 4 task 3
body i 6 str1 i 2 thread 1 task 1
body i 12 str1 i 11 thread 3 task 2
body i 5 str1 i 4 thread 4 task 3
body i 7 str1 i 6 thread 1 task 1
body i 13 str1 i 12 thread 3 task 2
body i 17 str1 i 5 thread 4 task 3
body i 8 str1 i 7 thread 1 task 1
body i 14 str1 i 13 thread 3 task 2
body i 9 str1 i 8 thread 1 task 1
body i 18 str1 i 17 thread 4 task 3
body i 15 str1 i 14 thread 3 task 2
body i 19 str1 i 18 thread 4 task 3
finally i 9
body i 16 str1 i 15 thread 3 task 2
finally i 19
finally i 16
```

Looping with the Parallel.ForEach Method

`Parallel.ForEach` iterates through a collection implementing `IEnumerable` in a way similar to the `foreach` statement, but in an asynchronous manner. Again, the order is not guaranteed.

```
            string[] data = {"zero", "one", "two", "three", "four",
                             "five", "six", "seven", "eight", "nine",
                             "ten", "eleven", "twelve"};

            ParallelLoopResult result =
                Parallel.ForEach<string>(data, s =>
                    {
                        Console.WriteLine(s);
                    });
```

code snippet ParallelSamples/Program.cs

If you need to break up the loop, you can use an overload of the `ForEach()` method with a `ParallelLoopState` parameter. You can do this in the same way as with the `For()` method you saw earlier. An overload of the `ForEach()` method can also be used to access an indexer to get the iteration number as shown.

```
        Parallel.ForEach<string>(data,
            (s, pls, l) =>
            {
                Console.WriteLine("{0} {1}", s, l);

            });
```

Invoking Multiple Methods with the Parallel.Invoke Method

If multiple tasks should run in parallel, you can use the `Parallel.Invoke()` method. `Parallel.Invoke()` allows the passing of an array of `Action` delegates, where you can assign methods that should run. The sample code passes the `Foo` and `Bar` methods to be invoked in parallel.

```
static void ParallelInvoke()
{
    Parallel.Invoke(Foo, Bar);
}

static void Foo()
{
    Console.WriteLine("foo");
}

static void Bar()
{
    Console.WriteLine("bar");
}
```

code snippet ParallelSamples/Program.cs

CANCELLATION FRAMEWORK

.NET 4 includes a new cancellation framework to allow the canceling of long-running tasks in a standard manner. Every blocking call should support this mechanism. As of today, of course, not every blocking call implements this new technology, but more and more are doing so. Among the technologies that offer this mechanism already are tasks, concurrent collection classes, and Parallel LINQ, as well as several synchronization mechanisms.

The cancellation framework is based on cooperative behavior; it is not forceful. A long-running task checks if it is canceled and returns control.

A method that supports cancellation accepts a `CancellationToken` parameter. This class defines the property `IsCancellationRequested`, where a long operation can check if it should abort. Other ways for a long operation to check for cancellation are to use a `WaitHandle` property that is signaled when the token is canceled, or to use the `Register()` method. The `Register()` method accepts parameters of type `Action` and `ICancelableOperation`. The method that is referenced by the `Action` delegate is invoked when the token is canceled. This is similar to the `ICancelableOperation`, where the `Cancel()` method of an object implementing this interface is invoked when the cancellation is done.

Cancellation of Parallel.For

Let's start with a simple example using the `Parallel.For()` method. The `Parallel` class provides overloads for the `For()` method, where you can pass parameter of type `ParallelOptions`. With the `ParallelOptions`, you can pass a `CancellationToken`. The `CancellationToken` is generated by creating a `CancellationTokenSource`. `CancellationTokenSource` implements the interface `ICancelableOperation` and, thus, can be registered with the `CancellationToken` and allows cancellation with the `Cancel()` method. To cancel the parallel loop, a new task is created to invoke the `Cancel()` method of the `CancellationTokenSource` after 500 milliseconds.

Within the implementation of the `For()` loop, the `Parallel` class verifies the outcome of the `CancellationToken` and cancels the operation. Upon cancellation, the `For()` method throws an exception of type `OperationCanceledException`, which is caught in the example. With the `CancellationToken`, it is possible to register for information when the cancellation is done. This is accomplished by calling the `Register()` method and passing a delegate that is invoked on cancellation.

```
var cts = new CancellationTokenSource();
cts.Token.Register(() =>
    Console.WriteLine("*** token canceled"));

// start a task that sends a cancel after 500 ms
new Task(() =>
   {
       Thread.Sleep(500);
       cts.Cancel(false);
   }).Start();

try
{
    ParallelLoopResult result =
       Parallel.For(0, 100,
           new ParallelOptions()
           {
               CancellationToken = cts.Token,
           },
           x =>
           {
               Console.WriteLine("loop {0} started", x);
               int sum = 0;
               for (int i = 0; i < 100; i++)
               {
                   Thread.Sleep(2);
                   sum += i;
               }
               Console.WriteLine("loop {0} finished", x);
           });
}
catch (OperationCanceledException ex)
{
    Console.WriteLine(ex.Message);
}
```

code snippet CancellationSamples/Program.cs

When running the application, you will get output similar to the following. Iteration 0, 1, 25, 26, 50, 51, 75, and 76 were all started. This is on a system with a quad-core CPU. With the cancellation, all other iterations were canceled before starting. The iterations that were started are allowed to finish because cancellation is always done in a cooperative way so as to avoid the risk of resource leaks when iterations are canceled somewhere in between.

```
loop 0 started
loop 50 started
loop 25 started
loop 75 started
loop 50 finished
loop 25 finished
loop 0 finished
loop 1 started
loop 26 started
loop 51 started
loop 75 finished
loop 76 started
** token canceled
loop 1 finished
loop 51 finished
loop 26 finished
loop 76 finished
The operation was canceled.
```

Cancellation of Tasks

The same cancellation pattern is used with tasks. First, a new `CancellationTokenSource` is created. If you need just one cancellation token, you can use a default one by accessing `Task.Factory.CancellationToken`. Then, similar to the previous code, a new task is created that sends a cancel request to this `cancellationSource` by invoking the `Cancel()` method after 500 milliseconds. The task doing the major work within a loop receives the cancellation token via the `TaskFactory` object. The cancellation token is assigned to the `TaskFactory` by setting it in the constructor. This cancellation token is used by the task to check if cancellation is requested by checking the `IsCancellationRequested` property of the `CancellationToken`.

```
var cts = new CancellationTokenSource();
cts.Token.Register(() =>
    Console.WriteLine("*** task canceled"));

// start a task that sends a cancel to the
// cts after 500 ms
Task.Factory.StartNew(() =>
{
    Thread.Sleep(500);
    cts.Cancel();
});

var factory = new TaskFactory(cancellationSource.Token);
Task t1 = factory.StartNew(new Action<object>(f =>
    {
        Console.WriteLine("in task");
        for (int i = 0; i < 20; i++)
        {
            Thread.Sleep(100);
            CancellationToken ct = (f as TaskFactory).CancellationToken;
            if (ct.IsCancellationRequested)
            {
                Console.WriteLine("canceling was requested, " +
                    "canceling from within the task");
                ct.ThrowIfCancellationRequested();
                break;
            }
            Console.WriteLine("in loop");
        }
        Console.WriteLine("task finished without cancellation");
    }), factory, cts.Token);

try
{
        t1.Wait();
    }
    catch (Exception ex)
    {
        Console.WriteLine("exception: {0}, {1}", ex.GetType().Name,
            ex.Message);
        if (ex.InnerException != null)
            Console.WriteLine("inner exception: {0}, {1}",
                              ex.InnerException.GetType().Name,
                              ex.InnerException.Message);
    }
    Console.WriteLine("status of the task: {0}", t1.Status);
```

code snippet CancellationSamples/Program.cs

When running the application, you can see that the task starts, runs for a few loops, and gets the cancellation request. The task is canceled and throws a `TaskCanceledException`, which is initiated from the method call `ThrowIfCancellationRequested()`. With the caller waiting for the task, you can see that the exception `AggregateException` is caught and contains the inner exception `TaskCanceledException`. This is used for a hierarchy of cancellations, for example, if you run a `Parallel.For` within a task that is canceled as well. The final status of the task is `Canceled`.

```
in task
in loop
in loop
in loop
in loop
*** task canceled
canceling was requested, canceling from within the task
exception AggregateException, One or more errors occurred.
inner exception TaskCanceledException, A task was canceled.
status of the task: Canceled
```

THREADING ISSUES

Programming with multiple threads is not easy. When starting multiple threads that access the same data, you can get intermittent problems that are hard to find. This is the same if you use tasks, Parallel LINQ, or the `Parallel` class. To avoid getting into trouble, you must pay attention to synchronization issues and the problems that can happen with multiple threads. We discuss two in particular next: race conditions and deadlocks.

Race Condition

A race condition can occur if two or more threads access the same objects and access to the shared state is not synchronized.

To demonstrate a race condition, the class `StateObject`, with an `int` field and the method `ChangeState`, is defined. In the implementation of `ChangeState`, the state variable is verified to see if it contains 5; if it does, the value is incremented. `Trace.Assert` is the next statement, which immediately verifies that state now contains the value 6.

After incrementing by 1 a variable that contains the value 5, you might expect that the variable now has the value 6. But this is not necessarily the case. For example, if one thread has just completed the `if (state == 5)` statement, it might be preempted and the scheduler run another thread. The second thread now goes into the `if` body and, because the state still has the value 5, the state is incremented by 1 to 6. The first thread is now scheduled again, and in the next statement the state is incremented to 7. This is when the race condition occurs and the assert message is shown.

```
public class StateObject
{
   private int state = 5;

   public void ChangeState(int loop)
   {
      if (state == 5)
      {
         state++;
         Trace.Assert(state == 6, "Race condition occurred after " +
               loop + " loops");
      }
      state = 5;
   }
}
```

code snippet ThreadingIssues/SampleTask.cs

Let's verify this by defining a method for a task. The method `RaceCondition()` of the class `SampleTask` gets a `StateObject` as a parameter. Inside an endless `while` loop, the `ChangeState()` method is invoked. The variable `i` is used just to show the loop number in the assert message:

```
public class SampleTask
{
   public void RaceCondition(object o)
   {
      Trace.Assert(o is StateObject, "o must be of type StateObject");
      StateObject state = o as StateObject;

      int i = 0;
      while (true)
      {
         state.ChangeState(i++);
      }
   }
}
```

code snippet ThreadingIssues/SampleTask.cs

In the `Main()` method of the program, a new `StateObject` is created that is shared among all the tasks. `Task` objects are created by passing the address of `RaceCondition` with an object of type `SampleThread` in the constructor of the `Task` class. The task is then started with the `Start()` method, passing the `state` object. The main thread then sleeps for 10 seconds, assuming in that time that the race condition will occur.

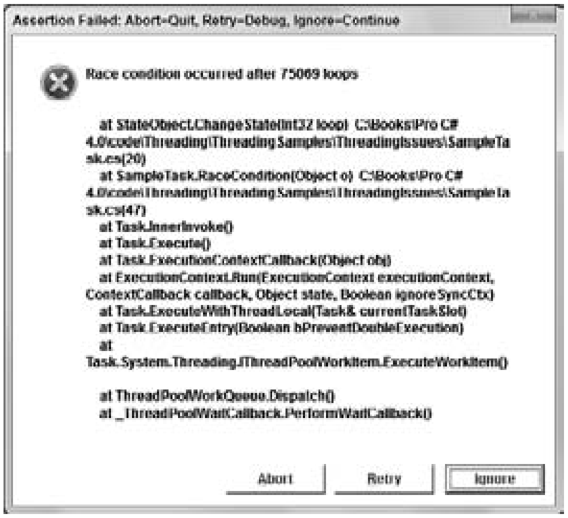
```
   static void Main()
   {
      var state = new StateObject();
      for (int i = 0; i < 20; i++)
      {
         new Task(new SampleTask().RaceCondition, state).Start();
      }
      Thread.Sleep(10000);
   }
```

code snippet ThreadingIssues/SampleTask.cs

When you start the program, you will get race conditions. How long it takes until the first race condition happens depends on your system and whether you build the program as a release or debug build. With a release build, the problem will happen more often because the code is optimized. If you have multiple CPUs in your system or dual/quad-core CPUs, where multiple threads can run concurrently, the problem will also occur more often than with a single-core CPU. The problem will occur with a single-core CPU because thread scheduling is preemptive, but not that often.

Figure 20-1 shows an assertion of the program, where the race condition occurred after 75,069 loops. You can start the application multiple times, and you will always get different results.

You can avoid the problem by locking the shared object. You can do this inside the thread by locking the variable state, which is shared among the threads, with the `lock` statement as shown. Only one thread can be inside the lock block for the state object. Because this object is shared among all threads, a thread must wait at the lock if another thread has the lock for state. As soon as the lock is accepted, the thread owns the lock and gives it up with the end of the lock block. If every thread changing the object referenced with the state variable is using a lock, the race condition no longer occurs.



```
Assertion Failed: Abort=Quit, Retry=Debug, Ignore=Continue

Race condition occurred after 75069 loops

FIGURE 20-1

```
public class SampleTask
{
   public void RaceCondition(object o)
   {
      Trace.Assert(o is StateObject, "o must be of type StateObject");
      StateObject state = o as StateObject;

      int i = 0;
      while (true)
      {
         lock (state)  // no race condition with this lock
         {
            state.ChangeState(i++);
         }
      }
   }
}
```

code snippet ThreadingIssues/SampleTask.cs

Instead of performing the lock when using the shared object, you can make the shared object thread-safe. Here, the `ChangeState()` method contains a `lock` statement. Because you cannot lock the `state` variable itself (only reference types can be used for a lock), the variable `sync` of type `object` is defined and used with the `lock` statement. If a lock is done using the same synchronization object every time the value state is changed, race conditions no longer happen.

```
public class StateObject
{
   private int state = 5;
   private object sync = new object();

   public void ChangeState(int loop)
   {
      lock (sync)
      {
         if (state == 5)
         {
                state++;
                Trace.Assert(state == 6, "Race condition occurred after " +
                      loop + " loops");
             }
             state = 5;
          }
       }
    }
```

code snippet ThreadingIssues/SampleTask.cs

Deadlock

Too much locking can get you in trouble as well. In a deadlock, at least two threads halt and wait for each other to release a lock. As both threads wait for each other, a deadlock occurs and the threads wait endlessly.

To demonstrate deadlocks, two objects of type `StateObject` are instantiated and passed with the constructor of the `SampleTask` class. Two tasks are created: one task running the method `Deadlock1()` and the other task running the method `Deadlock2()`:

```
          var state1 = new StateObject();
          var state2 = new StateObject();
          new Task(new SampleTask(state1, state2).Deadlock1).Start();
          new Task(new SampleTask(state1, state2).Deadlock2).Start();
```

code snippet ThreadingIssues/Program.cs

The methods `Deadlock1()` and `Deadlock2()` now change the state of two objects: `s1` and `s2`. That's why two locks are generated. The method `Deadlock1()` first does a lock for `s1` and next for `s2`. The method `Deadlock2()` first does a lock for `s2` and then for `s1`. Now, it may happen from time to time that the lock for `s1` in `Deadlock1()` is resolved. Next, a thread switch occurs, and `Deadlock2()` starts to run and gets the lock for `s2`. The second thread now waits for the lock of `s1`. Because it needs to wait, the thread scheduler schedules the first thread again, which now waits for `s2`. Both threads now wait and don't release the lock as long as the lock block is not ended. This is a typical deadlock.

```
    public class SampleThread
    {
       public SampleThread(StateObject s1, StateObject s2)
       {
          this.s1 = s1;
          this.s2 = s2;
       }

       private StateObject s1;
       private StateObject s2;

       public void Deadlock1()
       {
          int i = 0;
          while (true)
          {
             lock (s1)
             {
                lock (s2)
                {
                   s1.ChangeState(i);
                   s2.ChangeState(i++);
                   Console.WriteLine("still running, {0}", i);
                }
             }
          }
```

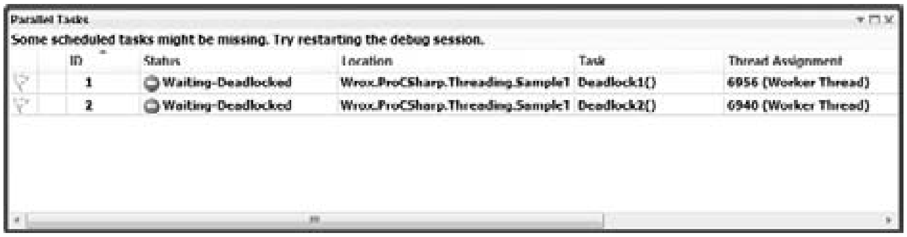
```
        }

        public void Deadlock2()
        {
           int i = 0;
           while (true)
           {
              lock (s2)
              {
                 lock (s1)
                 {
                    s1.ChangeState(i);
                    s2.ChangeState(i++);
                    Console.WriteLine("still running, {0}", i);
                 }
              }
           }
        }
     }
```

code snippet ThreadingIssues/SampleTask.cs

As a result, the program will run a number of loops and will soon be unresponsive. The message still running is just written a few times to the console. Again, how soon the problem happens depends on your system configuration, and the result will differ from time to time.

With Visual Studio 2010, you can run the program in debug mode, click the Break All button, and open the Parallel Tasks window (see Figure 20-2). Here, you can see that the threads are in the status Waiting-Deadlocked.



Parallel Tasks

Some scheduled tasks might be missing. Try restarting the debug session.

ID	Status	Location	Task	Thread Assignment
1	Waiting-Deadlocked	Wrox.ProCSharp.Threading.Sample1	Deadlock1()	6956 (Worker Thread)
2	Waiting-Deadlocked	Wrox.ProCSharp.Threading.Sample1	Deadlock2()	6940 (Worker Thread)

FIGURE 20-2

The problem of deadlocks is not always as obvious as it is here. One thread locks `s1` and then `s2`; the other thread locks `s2` and then `s1`. You just need to change the order so that both threads perform the locks in the same order. However, the locks might be hidden deeply inside a method. You can prevent this problem by designing a good lock order from the beginning in the architecture of the application, and also by defining timeouts for the locks, which we show in the next section.

SYNCHRONIZATION

It is best to avoid synchronization issues by not sharing data between threads. Of course, this is not always possible. If data sharing is necessary, you must use synchronization techniques so that only one thread at a time accesses and changes shared state. Remember the synchronization issues with race conditions and deadlocks. If you don't pay attention to these issues, the reason for problems in applications is hard to find because threading issues occur only from time to time.

This section discusses synchronization technologies that you can use with multiple threads:

- `lock` statement
- `Interlocked` class

- `Monitor` class
- `SpinLock struct`
- `WaitHandle` class
- `Mutex` class
- `Semaphore` class
- Events classes
- `Barrier` class
- `ReaderWriterLockSlim` class

`lock`, `Interlocked`, and `Monitor` can be used for synchronization within a process. The classes `Mutex`, `Event`, `SemaphoreSlim`, and `ReaderWriterLockSlim` also offer synchronization among threads of multiple processes.

lock Statement and Thread Safety

C# has its own keyword for the synchronization of multiple threads: the `lock` statement. The `lock` statement is an easy way to hold for a lock and release it.

Before adding `lock` statements, let's go into another race condition. The class `SharedState` demonstrates using shared state between threads and keeps an integer value:

```
public class SharedState
{
   public int State { get; set; }
}
```

code snippet SynchronizationSamples/SharedState.cs

The class `Job` contains the method `DoTheJob()`, which is the entry point for a new task. With the implementation, the `State` of `SharedState` is incremented 50,000 times. The variable `sharedState` is initialized in the constructor of this class.

```
public class Job
{
   SharedState sharedState;
   public Job(SharedState sharedState)
   {
      this.sharedState = sharedState;
   }
   public void DoTheJob()
   {
      for (int i = 0; i < 50000; i++)
      {
         sharedState.State += 1;
      }
   }
}
```

code snippet SynchronizationSamples/Job.cs

In the `Main()` method, a `SharedState` object is created and passed to the constructor of 20 `Task` objects. All tasks are started. After starting the tasks, the `Main()` method does another loop to wait until every one of the 20 tasks is completed. After the tasks are completed, the summarized value of the shared state is written to the console. Having 50,000 loops and 20 tasks, a value of 1,000,000 could be expected. Often, however, this is not the case.

```
      class Program
      {
         static void Main()
         {
            int numTasks = 20;
            var state = new SharedState();
            var tasks = new Task[numTasks];

            for (int i = 0; i < numTasks; i++)
            {
               tasks[i] = new Task(new Job(state).DoTheJob);
               tasks[i].Start();
            }

            for (int i = 0; i < numTasks; i++)
            {
               tasks[i].Wait();
            }
            Console.WriteLine("summarized {0}", state.State);
         }
      }
   }
```

code snippet SynchronizationSamples/Program.cs

Results received from multiple runs of the application are as shown here:

```
summarized 785895
summarized 776131
summarized 774400
summarized 871286
```

The behavior is different every time, but none of the results are correct. You get big differences between debug and release builds, and according to the types of CPUs that you are using. If you change the loop count for smaller values, you will get correct values many times — but not every time. The application is small enough to see the problem easily; the reason for such a problem can be hard to find in a large application.

You must add synchronization to this program. This can be done with the `lock` keyword.

The object's being defined with the `lock` statement means that you wait to get the lock for the specified object. You can pass only a reference type. Locking a value type would just lock a copy, and this wouldn't make any sense. Anyway, the C# compiler provides an error if value types are used with the `lock` statement. As soon as the lock is granted — only one thread gets the lock — the block of the `lock` statement can run. At the end of the `lock` statement block, the lock for the object is released, and another thread waiting for the lock can be granted access to it.

```
lock (obj)
{
   // synchronized region
}
```

To lock static members, you can place the lock on the type object:

```
lock (typeof(StaticClass))
{
}
```

You can make the instance members of a class thread-safe by using the `lock` keyword. This way, only one thread at a time can access the methods `DoThis()` and `DoThat()` for the same instance.

```
public class Demo
{
   public void DoThis()
   {
      lock (this)
      {
         // only one thread at a time can access the DoThis and DoThat methods
      }
   }
   public void DoThat()
   {
      lock (this)
      {
      }
   }
}
```

However, because the object of the instance can also be used for synchronized access from the outside, and you can't control this from the class itself, you can apply the SyncRoot pattern. With the SyncRoot pattern, a private object named `syncRoot` is created, and this object is used with the `lock` statements:

```
public class Demo
{
   private object syncRoot = new object();

   public void DoThis()
   {
      lock (syncRoot)
      {
         // only one thread at a time can access the DoThis and DoThat methods
      }
   }
   public void DoThat()
   {
      lock (syncRoot)
      {
      }
   }
}
```

Using locks costs time and is not always needed. You can create two versions of a class: a synchronized and a nonsynchronized version. This is demonstrated here by changing the class `Demo`. The class `Demo` itself is not synchronized, as you can see in the implementation of the `DoThis()` and `DoThat()` methods. The class also defines the `IsSynchronized` property, where the client can get information about the synchronization option of the class. To make a synchronized variant of the class, the static method `Synchronized()` can be used to pass a nonsynchronized object, and this method returns an object of type `SynchronizedDemo`. `SynchronizedDemo` is implemented as an inner class that is derived from the base class `Demo` and overrides the virtual members of the base class. The overridden members make use of the SyncRoot pattern.

```
public class Demo
{
   private class SynchronizedDemo: Demo
   {
      private object syncRoot = new object();
      private Demo d;

      public SynchronizedDemo(Demo d)
      {
         this.d = d;
      }

      public override bool IsSynchronized
      {
         get { return true; }
      }
```

```
         public override void DoThis()
         {
            lock (syncRoot)
            {
               d.DoThis();
            }
         }

         public override void DoThat()
         {
            lock (syncRoot)
            {
               d.DoThat();
            }
         }
      }

      public virtual bool IsSynchronized
      {
         get { return false; }
      }

      public static Demo Synchronized(Demo d)
      {
         if (!d.IsSynchronized)
         {
            return new SynchronizedDemo(d);
         }
         return d;
      }

      public virtual void DoThis()
      {
      }

      public virtual void DoThat()
      {
      }
   }
```

You must bear in mind that, when using the `SynchronizedDemo` class, only methods are synchronized. There is no synchronization for invoking two members of this class.

Let's change the `SharedState` class that was not synchronized at first to use the SyncRoot pattern now. If you try to make the `SharedState` class thread-safe by locking access to the properties with the SyncRoot pattern, you still get the race condition shown earlier in the "Race Condition" section.

```
      public class SharedState
      {
         private int state = 0;
         private object syncRoot = new object();

         public int State // there's still a race condition,
                          // don't do this!
         {
            get { lock (syncRoot) {return state; }}
            set { lock (syncRoot) {state = value; }}
         }
      }
```

code snippet SynchronizationSamples/SharedState.cs

The thread invoking the `DoTheJob()` method is accessing the `get` accessor of the `SharedState` class to get the current value of the state, and then the `get` accessor sets the new value for the state. In between calling the `get` and the `set` accessor, the object is not locked, and another thread can be the interim value.

```
public void DoTheJob()
{
   for (int i = 0; i < 50000; i++)
   {
      sharedState.State += 1;
   }
}
```

code snippet SynchronizationSamples/Job.cs

So, it is better to leave the `SharedState` class as it was earlier without thread safety:

```
public class SharedState
{
   public int State { get; set; }
}
```

code snippet SynchronizationSamples/SharedState.cs

And to add the `lock` statement where it belongs, inside the method `DoTheJob()`:

```
public void DoTheJob()
{
   for (int i = 0; i < 50000; i++)
   {
      lock (sharedState)
      {
         sharedState.State += 1;
      }
   }
}
```

code snippet SynchronizationSamples/Job.cs

This way, the results of the application are always as expected:

```
summarized 1000000
```

Using the `lock` statement in one place does not mean that all other threads accessing the object are waiting. You have to explicitly use synchronization with every thread accessing the shared state.

Of course, you can also change the design of the `SharedState` class and offer incrementing as an atomic operation. This is a design question — what should be an atomic functionality of the class?

```
public class SharedState
{
   private int state = 0;
   private object syncRoot = new object();

   public int State
   {
      get { return state; }
   }

   public int IncrementState()
   {
```

```
            lock (syncRoot)
            {
               return ++state;
            }
         }
      }
```

code snippet SynchronizationSamples/SharedState.cs

There is, however, a faster way to lock the increment of the state, as shown next.

Interlocked

The `Interlocked` class is used to make simple statements for variables atomic. `i++` is not thread-safe. `i++` consists of getting a value from the memory, incrementing the value by `1`, and storing the value back in memory. These operations can be interrupted by the thread scheduler. The `Interlocked` class provides methods for incrementing, decrementing, exchanging, and reading values in a thread-safe manner.

Using the `Interlocked` class is much faster than other synchronization techniques. However, you can use it only for simple synchronization issues.

For example, instead of using the `lock` statement to lock access to the variable `someState` when setting it to a new value, in case it is null, you can use the `Interlocked` class, which is faster:

```
lock (this)
{
   if (someState == null)
   {
      someState = newState;
   }
}
```

code snippet SynchronizationSamples/SharedState.cs

The faster version with the same functionality uses the `Interlocked.CompareExchange()` method:

```
Interlocked.CompareExchange<SomeState>(ref someState,
        newState, null);
```

And instead of performing incrementing inside a `lock` statement:

```
public int State
{
   get
   {
      lock (this)
      {
         return ++state;
      }
   }
}
```

You can use `Interlocked.Increment()`, which is faster:

```
public int State
{
   get
   {
      return Interlocked.Increment(ref state);
   }
}
```

Monitor

The C# compiler resolves the `lock` statement to use the `Monitor` class. The following `lock` statement:

```
lock (obj)
{
   // synchronized region for obj
}
```

is resolved to invoking the `Enter()` method, which waits until the thread gets the lock of the object. Only one thread at a time may be the owner of the object lock. As soon as the lock is resolved, the thread can enter the synchronized section. The `Exit()` method of the `Monitor` class releases the lock. The compiler puts the `Exit()` method into a `finally` handler of a `try` block so that the lock is also released if an exception is thrown.

`try`/`finally` *is covered in Chapter 15, "Errors and Exceptions."*

```
Monitor.Enter(obj);
try
{
   // synchronized region for obj
}
finally
{
   Monitor.Exit(obj);
}
```

code snippet SynchronizationSamples/Program.cs

The `Monitor` class has a big advantage compared to the `lock` statement of C#: you can add a timeout value for waiting to get the lock. So instead of endlessly waiting to get the lock, you can use the `TryEnter()` method, where you can pass a timeout value that defines the maximum amount of time to wait to get the lock. If the lock for `obj` is acquired, `TryEnter()` sets the Boolean ref parameter to `true` and performs synchronized access to the state guarded by the object `obj`. If `obj` is locked for more than 500 milliseconds by another thread, `TryEnter()` sets the variable `lockTaken` to `false`, and the thread does not wait any longer but is used to do something else. Maybe at a later time, the thread can try to acquire the lock once more.

```
bool lockTaken = false;
Monitor.TryEnter(obj, 500, ref lockTaken);
if (lockTaken)
{
   try
   {
      // acquired the lock
      // synchronized region for obj
   }
   finally
   {
      Monitor.Exit(obj);
   }

}
else
{
   // didn't get the lock, do something else
}
```

SpinLock

The SpinLock struct is new with .NET 4. If the overhead on object-based lock objects (Monitor) would be too high because of garbage collection, SpinLock can be used. SpinLock is useful if you have a high number of locks (for example, for every node in a list) and hold times are always extremely short. You should avoid holding more than one SpinLock and don't call anything that might block.

Other than the architectural differences, SpinLock is very similar in usage to the Monitor class. Acquiring the lock is done with Enter() or TryEnter() and releasing the lock with Exit(). SpinLock also offers properties to provide information if it is currently locked: IsHeld and IsHeldByCurrentThread.

Be careful when passing SpinLock *instances around. Because* SpinLock *is defined as a* struct, *assigning one variable to another creates a copy. Always pass* SpinLock *instances by reference.*

WaitHandle

WaitHandle is an abstract base class that you can use to wait for a signal to be set. There are different things you can wait for, because WaitHandle is a base class and some classes are derived from it.

When describing asynchronous delegates earlier in this chapter, the WaitHandle was already in use. The method BeginInvoke() of the asynchronous delegate returns an object that implements the interface IAsyncResult. Using IAsyncResult, you can access a WaitHandle with the property AsyncWaitHandle. When you invoke the method WaitOne(), the thread waits until a signal is received that is associated with the wait handle.

```
static void Main()
{
   TakesAWhileDelegate d1 = TakesAWhile;

   IAsyncResult ar = d1.BeginInvoke(1, 3000, null, null);
   while (true)
   {
      Console.Write(".");
      if (ar.AsyncWaitHandle.WaitOne(50, false))
      {
         Console.WriteLine("Can get the result now");
         break;
      }
   }
   int result = d1.EndInvoke(ar);
   Console.WriteLine("result: {0}", result);
}
```

code snippet AsyncDelegate/Program.cs

With WaitHandle, you can wait for one signal to occur (WaitOne()), multiple objects that all must be signaled (WaitAll()), or one of multiple objects (WaitAny()). WaitAll and WaitAny are static members of the WaitHandle class and accept an array of WaitHandle parameter.

WaitHandle has a SafeWaitHandle property, where you can assign a native handle to an operating system resource and wait for that handle. For example, you can assign a SafeFileHandle to wait for a file I/O operation to complete, or a custom SafeTransactionHandle as shown in Chapter 23, "System.Transactions."

The classes `Mutex`, `EventWaitHandle`, and `Semaphore` are derived from the base class `WaitHandle`, so you can use all of these with waits.

Mutex

`Mutex` (mutual exclusion) is one of the classes of the .NET Framework that offers synchronization across multiple processes. It is very similar to the `Monitor` class in that there is just one owner. Just one thread can get a lock on the mutex and access the synchronized code regions that are secured by the mutex.

With the constructor of the `Mutex` class, you can define if the mutex should initially be owned by the calling thread, define a name for the mutex, and get the information if the mutex already exists. In the sample code, the third parameter is defined as an `out` parameter to receive a Boolean value if the mutex was newly created. If the value returned is `false`, the mutex was already defined. The mutex might be defined in a different process, because a mutex with a name is known to the operating system and is shared among different processes. If there is no name assigned to the mutex, the mutex is unnamed and not shared among different processes.

```
bool createdNew;
Mutex mutex = new Mutex(false, "ProCSharpMutex", out createdNew);
```

To open an existing mutex, you can also use the method `Mutex.OpenExisting()`, which doesn't require the same .NET privileges as creating the mutex with the constructor.

Because the `Mutex` class derives from the base class `WaitHandle`, you can do a `WaitOne()` to acquire the mutex lock and be the owner of the mutex during that time. The mutex is released by invoking the `ReleaseMutex()` method.

```
if (mutex.WaitOne())
{
   try
   {
      // synchronized region
   }
   finally
   {
      mutex.ReleaseMutex();
   }
}
else
{
   // some problem happened while waiting
}
```

Because a named mutex is known system-wide, you can use it to keep an application from being started twice. In the following Windows Forms application, the constructor of the `Mutex` object is invoked. Then, it is verified if the mutex with the name `SingletonWinAppMutex` exists already. If it does, the application exits.

```
static class Program
{
   [STAThread]
   static void Main()
   {
      bool createdNew;
      Mutex mutex = new Mutex(false, "SingletonWinAppMutex",
                              out createdNew);
      if (!createdNew)
      {
         MessageBox.Show("You can only start one instance " +
                         "of the application");
         Application.Exit();
         return;
```

```
            }

            Application.EnableVisualStyles();
            Application.SetCompatibleTextRenderingDefault(false);
            Application.Run(new Form1());
         }
      }
```

Semaphore

A semaphore is very similar to a mutex, but, in contrast, the semaphore can be used by multiple threads at once. A semaphore is a counting mutex, meaning that with a semaphore you can define the number of threads that are allowed to access the resource guarded by the semaphore simultaneously. This can be used if you have several of the resources available and can allow only a specific number of threads access to the resource. For example, say that you want to access physical I/O ports on the system and there are three ports available. So, three threads can access the I/O ports simultaneously, but the fourth thread needs to wait until the resource is released by one of the other threads.

.NET 4 gives you two classes with semaphore functionality: `Semaphore` and `SemaphoreSlim`. `Semaphore` can be named, use system-wide resources, and allow synchronization between different processes. `SemaphoreSlim` is lightweight version that is optimized for shorter wait times.

In the sample application, in the `Main()` method six threads are created and one semaphore with a count of 4. In the constructor of the `Semaphore` class, you can define the count for the number of locks that can be acquired with the semaphore (the second parameter) and the number of locks that are free initially (the first parameter). If the first parameter has a lower value than the second parameter, the difference between the values defines the already allocated semaphore count. As with the mutex, you can also assign a name to the semaphore to share it among different processes. Here, no name is defined with the semaphore, so it is used only within this process. After the `SemaphoreSlim` object is created, six threads are started, and they all get the same semaphore.

```
using System;
using System.Threading;
using System.Diagnostics;

namespace Wrox.ProCSharp.Threading
{
   class Program
   {
      static void Main()
      {
         int threadCount = 6;
         int semaphoreCount = 4;
         var semaphore = new SemaphoreSlim(semaphoreCount, semaphoreCount);
         var threads = new Thread[threadCount];

         for (int i = 0; i < threadCount; i++)
         {
            threads[i] = new Thread(ThreadMain);
            threads[i].Start(semaphore);
         }

         for (int i = 0; i < threadCount; i++)
         {
            threads[i].Join();
         }
         Console.WriteLine("All threads finished");
      }
```

code snippet Semaphore/Program.cs

In the thread's main method, `ThreadMain()`, the thread does a `WaitOne()` to lock the semaphore. Remember, the semaphore has a count of 4, so four threads can acquire the lock. Thread 5 must wait and, here, the timeout of 600 milliseconds is defined as the maximum wait time. If the lock cannot be acquired after the wait time, the thread writes a message to the console and repeats the wait in a loop. As soon as the lock is made, the thread writes a message to the console, sleeps for some time, and releases the lock. Again, with the release of the lock it is important that the resource be released in all cases. That's why the `Release()` method of the `Semaphore` class is invoked in a `finally` handler.

```
      static void ThreadMain(object o)
      {
         SemaphoreSlim semaphore = o as SemaphoreSlim;
         Trace.Assert(semaphore != null, "o must be a Semaphore type");
         bool isCompleted = false;
         while (!isCompleted)
         {
            if (semaphore.Wait(600))
            {
               try
               {
                  Console.WriteLine("Thread {0} locks the semaphore",
                        Thread.CurrentThread.ManagedThreadId);
                  Thread.Sleep(2000);
               }
               finally
               {
                  semaphore.Release();
                  Console.WriteLine("Thread {0} releases the semaphore",
                     Thread.CurrentThread.ManagedThreadId);
                  isCompleted = true;
               }
            }
            else
            {
               Console.WriteLine("Timeout for thread {0}; wait again",
                  Thread.CurrentThread.ManagedThreadId);
            }
         }
      }
   }
}
```

When you run the application, you can indeed see that, with four threads, the lock is made immediately. The threads with IDs 7 and 8 must wait. The wait continues in the loop until one of the other threads releases the semaphore.

```
Thread 3 locks the semaphore
Thread 4 locks the semaphore
Thread 5 locks the semaphore
Thread 6 locks the semaphore
Timeout for thread 8; wait again
Timeout for thread 7; wait again
Timeout for thread 8; wait again
Timeout for thread 7; wait again
Timeout for thread 7; wait again
Timeout for thread 8; wait again
Thread 3 releases the semaphore
Thread 8 locks the semaphore
Thread 4 releases the semaphore
Thread 7 locks the semaphore
Thread 5 releases the semaphore
Thread 6 releases the semaphore
Thread 8 releases the semaphore
Thread 7 releases the semaphore
All threads finished
```

Events

Events are the next of the system-wide synchronization resources. For using system events from managed code, the .NET Framework offers the classes `ManualResetEvent`, `AutoResetEvent`, `ManualResetEventSlim`, and `CountdownEvent` in the namespace `System.Threading`. `ManualResetEventSlim` and `CountdownEvent` are new with .NET 4.

You can use events to inform other tasks that some data is present, something is completed, and so on. An event can be signaled or not signaled. A task can wait for the event to be in a signaled state with the help of the `WaitHandle` class, which was already discussed.

A `ManualResetEventSlim` is signaled by invoking the `Set()` method and turned back to a nonsignaled state with the `Reset()` method. If multiple threads are waiting for an event to be signaled, and the `Set()` method is invoked, then all threads waiting are released. Also, if a thread just invokes the `WaitOne()` method, but the event is already signaled, the waiting thread can continue immediately.

An `AutoResetEvent` is also signaled by invoking the `Set()` method. It is also possible to set it back to a nonsignaled state with the `Reset()` method. However, if a thread is waiting for an auto-reset event to be signaled, the event is automatically changed into a nonsignaled state when the wait state of the first thread is finished. This way, if multiple threads are waiting for the event to be set, only one thread is released from its wait state. It is not the thread that has been waiting the longest for the event to be signaled, but the thread waiting with the highest priority.

To demonstrate events with the `ManualResetEventSlim` class, the class `Calculator` defines the method `Calculation()`, which is the entry point for a task. With this method, the task receives input data for calculation and writes the result to the variable result that can be accessed from the `Result` property. As soon as the result is completed (after a random amount of time), the event is signaled by invoking the `Set()` method of the `ManualResetEventSlim`.

```
public class Calculator
{
   private ManualResetEventSlim mEvent;

   public int Result { get; private set; }

   public Calculator(ManualResetEventSlim ev)
   {
      this.mEvent = ev;
   }

   public void Calculation(object obj)
   {
      Tuple<int, int> data = (Tuple<int, int>)obj;
      Console.WriteLine("Task {0} starts calculation", Task.Current.Id);
      Thread.Sleep(new Random().Next(3000));
      Result = data.Item1 + data.Item2;

      // signal the event-completed!
      Console.WriteLine("Task {0} is ready", Task.Current.Id);
      mEvent.Set();
   }
}
```

code snippet EventSample/Program.cs

The Main() method of the program defines arrays of four ManualResetEventSlim objects and four Calculator objects. Every Calculator is initialized in the constructor with a ManualResetEventSlim object, so that every task gets its own event object to signal when it is completed. Now the TaskFactory class is used to have different tasks running the calculation.

```
class Program
{
   static void Main()
   {
      const int taskCount = 4;

      var mEvents = new ManualResetEventSlim[taskCount];
      var waitHandles = new WaitHandle[taskCount];
      var calcs = new Calculator[taskCount];

      TaskFactory taskFactory = new TaskFactory();
      for (int i = 0; i < taskCount; i++)
      {
         mEvents[i] = new ManualResetEventSlim(false);
         waitHandles[i] = mEvents[i].WaitHandle;
         calcs[i] = new Calculator(mEvents[i]);

         taskFactory.StartNew(calcs[i].Calculation, Tuple.Create(i + 1, i + 3));
      }
      //...
```

The WaitHandle class is now used to wait for any one of the events in the array. WaitAny() waits until any one of the events is signaled. In contrast to ManualResetEvent, ManualResetEventSlim does not derive from WaitHandle. That's why a separate collection of WaitHandle objects is kept that is filled from the WaitHandle property of the ManualResetEventSlim class. WaitAny() returns an index value that provides information about the event that was signaled. The returned value matches the index of the event array that is passed to WaitAny(). Using this index the information from the signaled event can be read:

```
      for (int i = 0; i < taskCount; i++)
      {
         int index = WaitHandle.WaitAny(mEvents);
         if (index == WaitHandle.WaitTimeout)
         {
            Console.WriteLine("Timeout!!");
         }
         else
         {
            mEvents[index].Reset();
            Console.WriteLine("finished task for {0}, result: {1}",
                              index, calcs[index].Result);
         }
      }
   }
}
```

code snippet EventSample/Program.cs

When starting the application, you can see the threads doing the calculation and setting the event to inform the main thread that it can read the result. At random times, depending on whether the build is a debug or release build and on your hardware, you might see different orders and also a different number of threads from the pool performing tasks. Here, thread 4 was reused from the pool for doing two tasks because it was fast enough to finish the calculation first:

```
Task 1 starts calculation
Task 2 starts calculation
Task 2 is ready
Task 3 starts calculation
```

```
finished task for 0, result: 4
Task 4 starts calculation
Task 3 is ready
finished task for 2, result: 8
Task 1 is ready
finished task for 1, result: 6
Thread 4 is ready
finished task for 3, result: 10
```

In a scenario like this, to fork some work into multiple tasks and later join the result, the new `CountdownEvent` class can be very useful. Instead of creating a separate event object for every task, you need to create just one. `CountdownEvent` defines an initial number for all the tasks that set the event, and after the count is reached, the `CountdownEvent` is signaled.

The `Calculator` class is modified to use the `CountdownEvent` instead of the `ManualResetEvent`. Instead of setting the signal with the `Set()` method, `CountdownEvent` defines the `Signal()` method.

```
public class Calculator
{
    private CountdownEvent cEvent;

    public int Result { get; private set; }

    public Calculator(CountdownEvent ev)
    {
        this.cEvent = ev;
    }

    public void Calculation(object obj)
    {
        Tuple<int, int> data = (Tuple<int, int>)obj;
        Console.WriteLine("Task {0} starts calculation", Task.Current.Id);
        Thread.Sleep(new Random().Next(3000));
        Result = data.Item1 + data.Item2;

        // signal the event-completed!
        Console.WriteLine("Task {0} is ready", Task.Current.Id);
        cEvent.Signal();
    }
}
```

code snippet EventSample/Calculator.cs

The `Main()` method can now be simplified so that it's just necessary to wait for the single event. If you don't deal with the results separately as it was done before, this new edition might be all that's needed.

```
const int taskCount = 4;
var cEvent = new CountdownEvent(taskCount);
var calcs = new Calculator[taskCount];

var taskFactory = new TaskFactory();
for (int i = 0; i < taskCount; i++)
{
    calcs[i] = new Calculator(cEvent);

    taskFactory.StartNew(calcs[i].Calculation,
                         Tuple.Create(i + 1, i + 3));
}

cEvent.Wait();
Console.WriteLine("all finished");
```

```
    for (int i = 0; i < taskCount; i++)
    {
        Console.WriteLine("task for {0}, result: {1}", i, calcs[i].Result);
    }
```

code snippet EventSample/Program.cs

Barrier

For synchronization, .NET 4 offers the new `Barrier` class. `Barrier` is great for a scenario where work is forked into multiple tasks, and the work needs to be joined afterward. `Barrier` is used for participants need to be synchronized. While the job is active, additional participants can be added dynamically, for example, child tasks that are created from a parent task. Participants can wait until the work is done by all the other participants before continuing.

The sample application uses a collection containing 2,000,000 strings. Multiple tasks are used to iterate through the collection and count the number of strings starting with a, b, c, and so on.

The method `FillData()` creates a collection and fills it with random strings.

```
public static IEnumerable<string> FillData(int size)
{
    List<string> data = new List<string>(size);
    Random r = new Random();
    for (int i = 0; i < size; i++)
    {
        data.Add(GetString(r));
    }
    return data;
}
private static string GetString(Random r)
{
    StringBuilder sb = new StringBuilder(6);
    for (int i = 0; i < 6; i++)
    {
        sb.Append((char)(r.Next(26) + 97));
    }
    return sb.ToString();
}
```

code snippet BarrierSample/Program.cs

The `CalculationInTask()` method defines the job that's done by a task. With the parameter, a tuple containing four items is received. The third parameter is a reference to the `Barrier` instance. When the job is done by the task, the task removes itself from the barrier with the `RemoveParticipant()` method.

```
static int[] CalculationInTask(object p)
{
    var p1 = p as Tuple<int, int, Barrier, List<string>>;
    Barrier barrier = p1.Item3;
    List<string> data = p1.Item4;

    int start = p1.Item1 * p1.Item2;
    int end = start + p1.Item2;
    Console.WriteLine("Task {0}: partition from {1} to {2}",
            Task.Current.Id, start, end);
    int[] charCount = new int[26];
    for (int j = start; j < end; j++)
    {
        char c = data[j][0];
        charCount[c - 97]++;
```

```
            }
            Console.WriteLine("Calculation completed from task {0}. {1} " +
                    "times a, {2} times z", Task.Current.Id, charCount[0],
                    charCount[25]);

            barrier.RemoveParticipant();
            Console.WriteLine("Task {0} removed from barrier, " +
                    "remaining participants {1}", Task.Current.Id,
                    barrier.ParticipantsRemaining);
            return charCount;
        }
```

With the `Main()` method, a `Barrier` instance is created. In the constructor, you can specify the number of participants. In the sample, this number is 3 because there are two created tasks, and the `Main()` method itself is a participant as well. Using a `TaskFactory`, two tasks are created to fork the iteration through the collection into two parts. After starting the tasks, using `SignalAndWait()`, the main method signals its completion and waits until all remaining participants either signal the completion or remove themselves as participants from the barrier. As soon as all participants are ready, the results from the tasks are taken and zipped together with the `Zip()` extension method.

```
        static void Main()
        {
            const int numberTasks = 2;
            const int partitionSize = 1000000;
            var data = new List<string>(FillData(partitionSize * numberTasks));

            var barrier = new Barrier(numberTasks + 1);

            var taskFactory = new TaskFactory();
            var tasks = new Task<int[]>[numberTasks];
            for (int i = 0; i < participants; i++)
            {
                tasks[i] = taskFactory.StartNew<int[]>(CalculationInTask,
                    Tuple.Create(i, partitionSize, barrier, data));
            }

            barrier.SignalAndWait();
            var resultCollection = tasks[0].Result.Zip(tasks[1].Result, (c1, c2) =
                {
                    return c1 + c2;
                });

            char ch = 'a';
            int sum = 0;
            foreach (var x in resultCollection)
            {
                Console.WriteLine("{0}, count: {1}", ch++, x);
                sum += x;
            }

            Console.WriteLine("main finished {0}", sum);
            Console.WriteLine("remaining {0}", barrier.ParticipantsRemaining);

        }
```

ReaderWriterLockSlim

For a locking mechanism to allow multiple readers, but just one writer, for a resource, the class `ReaderWriterLockSlim` can be used. This class offers a locking functionality in which multiple readers can access the resource if no writer locked it, and only a single writer can lock the resource.

The ReaderWriterLockSlim class has properties to acquire a read lock that are blocking and nonblocking, such as EnterReadLock() and TryEnterReadLock(), and to acquire a write lock with EnterWriteLock() and TryEnterWriteLock(). If a task reads first and writes afterward, it can acquire an upgradable read lock with EnterUpgradableReadLock() or TryEnterUpgradableReadLock(). With this lock, the write lock can be acquired without releasing the read lock.

Several properties of this class offer information about the held locks, for example, CurrentReadCount, WaitingReadCount, WaitingUpgradableReadCount, and WaitingWriteCount.

The sample program creates a collection containing six items and a ReaderWriterLockSlim object. The method ReaderMethod() acquires a read lock to read all items of the list and write them to the console. The method WriterMethod() tries to acquire a write lock to change all values of the collection. In the Main() method, six threads are started that invoke either the method ReaderMethod() or the method WriterMethod().

```
using System;
using System.Collections.Generic;
using System.Threading;
using System.Threading.Tasks;

namespace Wrox.ProCSharp.Threading
{
   class Program
   {
      private static List<int> items = new List<int>() { 0, 1, 2, 3, 4, 5};
      private static ReaderWriterLockSlim rwl =
            new ReaderWriterLockSlim(LockRecursionPolicy.SupportsRecursion);

      static void ReaderMethod(object reader)
      {
         try
         {
            rwl.EnterReadLock();

            for (int i = 0; i < items.Count; i++)
            {
               Console.WriteLine("reader {0}, loop: {1}, item: {2}",
                     reader, i, items[i]);
               Thread.Sleep(40);
            }
         }
         finally
         {
            rwl.ExitReadLock();
         }
      }

      static void WriterMethod(object writer)
      {
         try
         {
            while (!rwl.TryEnterWriteLock(50))
            {
               Console.WriteLine("Writer {0} waiting for the write lock",
                     writer);
               Console.WriteLine("current reader count: {0}",
                     rwl.CurrentReadCount);
            }
            Console.WriteLine("Writer {0} acquired the lock", writer);
            for (int i = 0; i < items.Count; i++)
            {
                items[i]++;
                Thread.Sleep(50);
              }
              Console.WriteLine("Writer {0} finished", writer);
            }
            finally
            {
              rwl.ExitWriteLock();
            }
          }

          static void Main()
          {
            var taskFactory = new TaskFactory(TaskCreationOptions.LongRunning,
                TaskContinuationOptions.None);
            var tasks = new Task[6];
            tasks[0] = taskFactory.StartNew(WriterMethod, 1);
            tasks[1] = taskFactory.StartNew(ReaderMethod, 1);
            tasks[2] = taskFactory.StartNew(ReaderMethod, 2);
            tasks[3] = taskFactory.StartNew(WriterMethod, 2);
            tasks[4] = taskFactory.StartNew(ReaderMethod, 3);
            tasks[5] = taskFactory.StartNew(ReaderMethod, 4);

            for (int i = 0; i < 6; i++)
            {
              tasks[i].Wait();
            }
          }
        }
      }
```

code snippet ReaderWriterSample/Program.cs

With a run of the application here, the first writer gets the lock first. The second writer and all readers need to wait. Next, the readers can work concurrently, while the second writer still waits for the resource.

```
Writer 1 acquired the lock
Writer 2 waiting for the write lock
current reader count: 0
Writer 2 waiting for the write lock
current reader count: 0
Writer 2 waiting for the write lock
current reader count: 0
Writer 2 waiting for the write lock
current reader count: 0
Writer 1 finished
reader 4, loop: 0, item: 1
reader 1, loop: 0, item: 1
Writer 2 waiting for the write lock
current reader count: 4
reader 2, loop: 0, item: 1
reader 3, loop: 0, item: 1
reader 4, loop: 1, item: 2
reader 1, loop: 1, item: 2
reader 3, loop: 1, item: 2
reader 2, loop: 1, item: 2
Writer 2 waiting for the write lock
current reader count: 4
reader 4, loop: 2, item: 3
reader 1, loop: 2, item: 3
reader 2, loop: 2, item: 3
reader 3, loop: 2, item: 3
```

```
Writer 2 waiting for the write lock
current reader count: 4
reader 4, loop: 3, item: 4
reader 1, loop: 3, item: 4
reader 2, loop: 3, item: 4
reader 3, loop: 3, item: 4
reader 4, loop: 4, item: 5
reader 1, loop: 4, item: 5
Writer 2 waiting for the write lock
current reader count: 4
reader 2, loop: 4, item: 5
reader 3, loop: 4, item: 5
reader 4, loop: 5, item: 6
reader 1, loop: 5, item: 6
reader 2, loop: 5, item: 6
reader 3, loop: 5, item: 6
Writer 2 waiting for the write lock
current reader count: 4
Writer 2 acquired the lock
Writer 2 finished
```

TIMERS

The .NET Framework offers several `Timer` classes that can be used to invoke a method after some time interval. The following table lists the `Timer` classes and their namespaces, as well as their functionality.

NAMESPACE	DESCRIPTION
`System.Threading`	The `Timer` class from the `System.Threading` namespace offers core functionality. In the constructor, you can pass a delegate that should be invoked at the time interval specified.
`System.Timers`	The `Timer` class from the `System.Timers` namespace is a component, because it derives from the `Component` base class. So, you can drag and drop it from the toolbox to the design surface of a server application such as a Windows service. This `Timer` class uses `System.Threading.Timer` but provides an event-based mechanism instead of a delegate.
`System.Windows.Forms`	With the `Timer` classes from the namespaces `System.Threading` and `System.Timers`, the callback or event methods are invoked from a different thread than the calling thread. Windows Forms controls are bound to the creator thread. Calling back into this thread is done by the `Timer` class from the `System.Windows.Forms` namespace.
`System.Web.UI`	The `Timer` from the `System.Web.UI` namespace is an AJAX Extension that can be used with web pages.
`System.Windows.Threading`	The `DispatcherTimer` class from the `System.Windows.Threading` namespace is used by WPF applications. `DispatcherTimer` runs on the UI thread.

Using the `System.Threading.Timer` class, you can pass the method to be invoked as the first parameter in the constructor. This method must fulfill the requirements of the `TimerCallback` delegate, which defines a void return type and an `object` parameter. With the second parameter, you can pass any object, which is then received with the object argument in the callback method. For example, you can pass an `Event` object to signal the caller. The third parameter specifies the time span during which the callback should be invoked the first time. With the last parameter, you specify the repeating interval for the callback. If the timer should fire only once, set the fourth parameter to the value –1.

If the time interval should be changed after creating the `Timer` object, you can pass new values with the `Change()` method.

```
private static void ThreadingTimer()
{
   var t1 = new System.Threading.Timer(
      TimeAction, null, TimeSpan.FromSeconds(2),
      TimeSpan.FromSeconds(3));

   Thread.Sleep(15000);

   t1.Dispose();
}

static void TimeAction(object o)
{
   Console.WriteLine("System.Threading.Timer {0:T}", DateTime.Now);
}
```

code snippet TimerSample/Program.cs

The constructor of the `Timer` class from the `System.Timers` namespace requires just a time interval. The method that should be invoked after the interval is specified by the `Elapsed` event. This event requires a delegate of type `ElapsedEventHandler`, which requires object and `ElapsedEventArgs` parameters, as you can see with the `TimeAction` method. The `AutoReset` property specifies whether the timer should be fired repeatedly. If you set this property to `false`, the event is fired only once. Calling the `Start` method enables the timer to fire the events. Instead of calling the `Start` method, you can set the `Enabled` property to `true`. Behind the scenes `Start()` does nothing else. The `Stop()` method sets the `Enabled` property to `false` to stop the timer.

```
private static void TimersTimer()
{
   var t1 = new System.Timers.Timer(1000);
   t1.AutoReset = true;
   t1.Elapsed += TimeAction;
   t1.Start();
   Thread.Sleep(10000);
   t1.Stop();

   t1.Dispose();
}

static void TimeAction(object sender, System.Timers.ElapsedEventArgs e)
{
   Console.WriteLine("System.Timers.Timer {0:T}", e.SignalTime );
}
```

EVENT-BASED ASYNCHRONOUS PATTERN

Earlier in this chapter, you saw the asynchronous pattern based on the `IAsyncResult` interface. With an asynchronous callback, the callback thread is different from the calling thread. Using Windows Forms or WPF, this is a problem, because Windows Forms and WPF controls are bound to a single thread. With every control, you can invoke methods only from the thread that created the control. This also means that if you have a background thread, you cannot directly access the UI controls from this thread.

The only methods with Windows Forms controls that you can invoke from a different thread than the creator thread are `Invoke()`, `BeginInvoke()`, `EndInvoke()`, and the property `InvokeRequired`. `BeginInvoke()` and `EndInvoke()` are asynchronous variants of `Invoke()`. These methods switch to the creator thread to invoke the method that is assigned to a delegate parameter that you can pass to these methods. Using these methods is not that easy, which is why beginning with .NET 2.0 a new component, together with a new asynchronous pattern, was added: the event-based asynchronous pattern.

With the event-based asynchronous pattern, the asynchronous component offers a method with the suffix `Async`; for example, the synchronous method `DoATask()` has the name `DoATaskAsync()` in the asynchronous version. To get the result information, the component also needs to define an event that has the suffix `Completed`, for example, `DoATaskCompleted`. While the action happening in the `DoATaskAsync()` method is running in a background thread, the event `DoATaskCompleted` is fired in the same thread as the caller.

With the event-based asynchronous pattern, the asynchronous component optionally can support cancellation and information about progress. For cancellation, the method should have the name `CancelAsync()`, and for progress information, an event with the suffix `ProgressChanged`, for example, `DoATaskProgressChanged`, is provided.

BackgroundWorker

The `BackgroundWorker` class is one implementation of the asynchronous event pattern. The method `RunWorkerAsync()` starts the method that is associated with the `DoWork` event asynchronously. As soon as the work is done, the event `RunWorkerCompleted` is fired. The names used here are in complete conformance with the event-based asynchronous pattern naming explained earlier.

The `BackgroundWorker` might also support cancellation if the property `WorkerSupportsCancellation` is set to `true`. In that case, the work can be canceled by invoking the `CancelAsync` method. However, the job that is done needs to check for the `CancellationPending` property to verify if it should stop its work. Similar to the new cancellation framework, the `BackgroundWorker` supports cooperative cancellation.

Displaying progress information, the `BackgroundWorker` also does a useful job. The property `WorkerReportsProgress` provides information if the task at work returns progress information. If that's the case, the `ProgressChanged` event can be assigned to receive information about progress changes. The job that does the work needs to report progress by calling the method `ReportProgress()` with the percentage of completed information.

Another class that implements the asynchronous event pattern is the component `WebClient` *in the* `System.Net` *namespace. This class uses the* `WebRequest` *and* `WebResponse` *classes but provides an easier-to-use interface. The* `WebRequest` *and* `WebResponse` *classes also offer asynchronous programming, but here it is based on the asynchronous pattern with the* `IAsyncResult` *interface.*

The sample application demonstrates the use of the `BackgroundWorker` control in a WPF application by doing a task that takes some time. Create a new WPF application, and add three `Label` controls, three `TextBox` controls, two `Button` controls, and one `ProgressBar` to the window, as you can see for the running application in Figure 20-3.

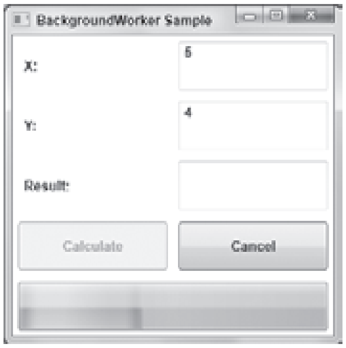


FIGURE 20-3

Configure the properties of the controls as listed in the following table.

CONTROL	PROPERTY AND EVENTS	VALUE
Label	Content	X:
TextBox	x:Name	textX
Label	Content	Y:
TextBox	x:Name	textY

continues

(continued)

CONTROL	PROPERTY AND EVENTS	VALUE
Label	Content	Result:
TextBox	x:Name	textResult
Button	x:Name	buttonCalculate
	Text	Calculate
	Click	OnCalculate
Button	x:Name	buttonCancel
	Text	Cancel
	IsEnabled	False
	Click	OnCancel
ProgressBar	x:Name	progressBar

Within the code-behind, add a `BackgroundWorker` object to the `BackgroundWorkerWindow` and assign the event `DoWork` to the `OnDoWork()` method. For the `BackgroundWorker` class, you need to import the namespace `System.ComponentModel`.

```
public partial class BackgroundWorkerWindow : Window
{
    private BackgroundWorker backgroundWorker;

    public BackgroundWorkerWindow()
    {
        InitializeComponent();
        backgroundWorker = new BackgroundWorker();
        backgroundWorker.DoWork += OnDoWork;
```

code snippet BackgroundWorkersSample/Window1.xaml.cs

The method `OnCalculate()` is the event handler for the `Click` event from the `Button` control named `buttonCalculate`. In the implementation, `buttonCalculate` is disabled, so the user cannot click the button again until the calculation is completed. To start the `BackgroundWorker`, invoke the method `RunWorkerAsync()`. The `BackgroundWorker` uses a thread pool thread to do the calculation. `RunWorkerAsync()` requires the input parameters, which are passed to the handler that is assigned to the `DoWork` event.

```
private void OnCalculate(object sender, RoutedEventArgs e)
{
   this.buttonCalculate.IsEnabled = false;
   this.textResult.Text = String.Empty;
   this.buttonCancel.IsEnabled = true;
   this.progressBar.Value = 0;

   backgroundWorker.RunWorkerAsync(Tuple.Create<int.Parse(textX.Text),
         int.Parse(textY.Text)));
}
```

The method `OnDoWork()` is connected to the `DoWork` event of the `BackgroundWorker` control. With the `DoWorkEventArgs`, the input parameters are received with the property `Argument`. The implementation simulates functionality that takes some time with a sleep time of 5 seconds. After sleeping, the result of the calculation is written to the `Result` property of `DoEventArgs`. If you add the calculation and sleep time to the `OnCalculate()` method instead, the Windows application is blocked from user input while this is active. However, here a separate thread is used, and the user interface is still active.

```
private void OnDoWork(object sender, DoWorkEventArgs e)
{
   var t = e.Argument as Tuple<int, int>;

   Thread.Sleep(5000);
   e.Result = t.Item1 + t.Item2;
}
```

After OnDoWork is completed, the background worker fires the RunWorkerCompleted event. The method OnWorkCompleted() is associated with this event. Here, the result is received from the Result property of the RunWorkerCompletedEventArgs parameter, and this result is written to the result TextBox control. When firing the event, the BackgroundWorker control changes control to the creator thread, so there is no need to use the Invoke methods of the WPF controls, and you can invoke properties and methods of UI controls directly.

```
private void OnWorkCompleted(object sender,
                              RunWorkerCompletedEventArgs e)
{
   this.textResult.Text = e.Result.ToString();

   this.buttonCalculate.IsEnabled = true;
   this.buttonCancel.IsEnabled = false;
}
```

Now, you can test the application and see that the calculation runs independently of the UI thread, the UI is still active, and the window can be moved around. However, the cancel and progress bar functionality still needs implementation.

Enable Cancel

To enable the cancel functionality to stop the thread's progress while it is running, you must set the BackgroundWorker property WorkerSupportsCancellation to true. Next, you have to implement the OnCancel handler that is connected to the Click event of the control buttonCancel. The BackgroundWorker control has the CancelAsync() method to cancel an asynchronous task that is going on.

```
private void OnCancel(object sender, RoutedEventArgs e)
{
   backgroundWorker.CancelAsync();
}
```

code snippet BackgroundWorkersSample/Window1.xaml.cs

The asynchronous task is not canceled automatically. In the OnDoWork() handler that does the asynchronous task, you must change the implementation to examine the CancellationPending property of the BackgroundWorker control. This property is set as soon as CancelAsync() is invoked. If a cancellation is pending, set the Cancel property of DoWorkEventArgs to true and exit the handler.

```
private void OnDoWork(object sender, DoWorkEventArgs e)
{
   var t = e.Argument as Tuple<int, int>;

   for (int i = 0; i < 10; i++)
   {
      Thread.Sleep(500);

      if (backgroundWorker.CancellationPending)
      {
         e.Cancel = true;
         return;
      }
   }

   e.Result = t.Item1 + t.Item2;
}
```

The completion handler `OnWorkCompleted()` is invoked if the asynchronous method has completed successfully or if it was canceled. If it was canceled, you cannot access the `Result` property, because this throws an `InvalidOperationException` with the information that the operation has been canceled. So, you have to check the `Cancelled` property of `RunWorkerCompletedEventArgs` and behave accordingly.

```
private void OnWorkCompleted(object sender,
                             RunWorkerCompletedEventArgs e)
{
   if (e.Cancelled)
   {
      this.textResult.Text = "Cancelled";
   }
   else
   {
      this.textResult.Text = e.Result.ToString();
   }
   this.buttonCalculate.IsEnabled = true;
   this.buttonCancel.IsEnabled = false;
}
```

Running the application once more, you can cancel the asynchronous progress from the user interface.

Enable Progress

To get progress information to the user interface, you must set the `BackgroundWorker` property `WorkerReportsProgress` to `true`.

With the `OnDoWork` method, you can report the progress to the `BackgroundWorker` control with the `ReportProgress()` method:

```
private void OnDoWork(object sender, DoWorkEventArgs e)
{
   var t = e.Argument as Tuple<int, int>;

   for (int i = 0; i < 10; i++)
   {
      Thread.Sleep(500);
      backgroundWorker.ReportProgress(i * 10);
      if (backgroundWorker.CancellationPending)
      {
         e.Cancel = true;
         return;
      }
   }

   e.Result = t.Item1 + t.Item2;
}
```

code snippet BackgroundWorkersSample/Window1.xaml.cs

The method `ReportProgress()` fires the `ProgressChanged` event of the `BackgroundWorker` control. This event changes the control to the UI thread.

Add the method `OnProgressChanged()` to the `ProgressChanged` event, and in the implementation set a new value to the progress bar control that is received from the property `ProgressPercentage` of `ProgressChangedEventArgs`:

```
private void OnProgressChanged(object sender, ProgressChangedEventArgs e)
{
   this.progressBar.Value = e.ProgressPercentage;
}
```

In the `OnWorkCompleted()` event handler, the progress bar finally is set to the 100% value:

```
        private void OnWorkCompleted(object sender, RunWorkerCompletedEventArgs e)
        {
           if (e.Cancelled)
           {
              this.textBoxResult.Text = "Canceled";
           }
           else
           {
              this.textBoxResult.Text = e.Result.ToString();
           }
           this.buttonCalculate.Enabled = true;
           this.buttonCancel.Enabled = false;
           this.progressBar.Value = 100;
        }
```

Creating an Event-Based Asynchronous Component

To create a custom component that supports the event-based asynchronous pattern, more work needs to be done. To demonstrate this with a simple scenario, the class `AsyncComponent` just returns a converted input string after a time span, as you can see with the synchronous method `LongTask()`. To offer asynchronous support, the public interface provides the asynchronous method `LongTaskAsync()` and the event `LongTaskCompleted`. This event is of type `EventHandler<LongTaskCompletedEventArgs>`, `which` defines the parameter types `object` and `LongTaskCompletedEventArgs`. `LongTaskCompletedEventArgs` is a type created later where the caller can read the result of the asynchronous operation.

In addition, some helper methods such as `DoLongTask` and `CompletionMethod` are needed; these are discussed next.

```
using System;
using System.Collections.Generic;
using System.ComponentModel;
using System.Threading;

namespace Wrox.ProCSharp.Threading
{
   public delegate void LongTaskCompletedEventHandler(object sender,
         LongTaskCompletedEventArgs e);

   public partial class AsyncComponent: Component
   {
      private Dictionary<object, AsyncOperation> userStateDictionary =
            new Dictionary<object, AsyncOperation>();
      private SendOrPostCallback onCompletedDelegate;

      public event EventHandler<LongTaskCompletedEventArgs> LongTaskCompleted;

      public AsyncComponent()
      {
         InitializeComponent();
         InitializeDelegates();
      }

      public AsyncComponent(IContainer container)
      {
         container.Add(this);

         InitializeComponent();
         InitializeDelegates();
      }

      private void InitializeDelegates()
```

```
            {
               onCompletedDelegate = LongTaskCompletion;
            }

            public string LongTask(string input)
            {
               Console.WriteLine("LongTask started");
               Thread.Sleep(5000);
               Console.WriteLine("LongTask finished");
               return input.ToUpper();
            }

            public void LongTaskAsync(string input, object taskId)
            {
               //.
            }

            private void LongTaskCompletion(object operationState)
            {
               //.
            }

            protected void OnLongTaskCompleted(LongTaskCompletedEventArgs e)
            {
               //.
            }

            // running in a background thread
            private void DoLongTask(string input, AsyncOperation asyncOp)
            {
               //.
            }

            private void CompletionMethod(string output, Exception ex,
                  bool cancelled, AsyncOperation asyncOp)
            {
               //.
            }
         }

         public class LongTaskCompletedEventArgs: AsyncCompletedEventArgs
         {
            //.
         }
      }
```

code snippet AsyncComponent/AsyncComponent.cs

The method `LongTaskAsync` needs to start the synchronous operation asynchronously. If the component allows starting the asynchronous task several times concurrently, the client needs to have an option to map the different results to the tasks started. This is why the second parameter of `LongTaskAsync` requires a `taskId` that can be used by the client to map the results. Of course, inside the component itself the task ID needs to be remembered to map the results. .NET provides the class `AsyncOperationManager` to create `AsyncOperationObjects` to help keep track of the state of operations. The class `AsyncOperationManager` has one method, `CreateOperation()`, where a task identifier can be passed, and an `AsyncOperation` object is returned. This operation is kept as an item in the dictionary `userStateDictionary` that was created earlier.

Then, a delegate of type `Action<string, AsyncOperation>` is created, and the method `DoLongTask` is assigned to that delegate instance. `BeginInvoke()` is the method of the delegate used to start the method `DoLongTask()` asynchronously, using a thread from the thread pool. The parameters needed with this delegate are all input parameters from the caller plus the AsyncOperation parameter for getting the status and mapping the result of the operation.

```
public void LongTaskAsync(string input, object taskId)
{
   AsyncOperation asyncOp = AsyncOperationManager.CreateOperation(taskId);

   lock (userStateDictionary)
   {
      if (userStateDictionary.ContainsKey(taskId))
         throw new ArgumentException("taskId must be unique", "taskId");

      userStateDictionary[taskId] = asyncOp;
   }

   Action<string, Asyncoperation> longTaskDelegate = DoLongTask;
   longTaskDelegate.BeginInvoke(input, asyncOp, null, null);
}
```

The method DoLongTask() is now called asynchronously by using the delegate. The synchronous method LongTask() can now be invoked to get the output value.

Because an exception that might happen inside the synchronous method should not just blow up the background thread, any exception is caught and remembered with the variable e of type Exception. Finally, the CompletionMethod() is invoked to inform the caller about the result.

```
// running in a background thread
private void DoLongTask(string input, AsyncOperation asyncOp)
{
   Exception e = null;
   string output = null;
   try
   {
      output = LongTask(input);
   }
   catch (Exception ex)
   {
      e = ex;
   }

   this.CompletionMethod(output, e, false, asyncOp);
}
```

With the implementation of the CompletionMethod, the userStateDictionary is cleaned up as the operation is removed. The PostOperationCompleted() method of the AsyncOperation object ends the lifetime of the asynchronous operation and informs the caller, using the onCompletedDelegate method. This method ensures that the delegate is invoked on the thread as needed for the application type. To get information to the caller, an object of type LongTaskCompletedEventArgs is created and passed to the method PostOperationCompleted().

```
   private void CompletionMethod(string output, Exception ex,
         bool cancelled, AsyncOperation asyncOp)
   {
      lock (userStateDictionary)
      {
         userStateDictionary.Remove(asyncOp.UserSuppliedState);
      }

      // results of the operation
      asyncOp.PostOperationCompleted(onCompletedDelegate,
         new LongTaskCompletedEventArgs(output, ex, cancelled,
               asyncOp.UserSuppliedState));
   }
}
```

For passing information to the caller, the class LongTaskCompletedEventArgs derives from the base class AsyncCompletedEventArgs and adds a property containing output information. In the constructor, the base constructor is invoked to pass exception, cancellation, and user state information.

```
public class LongTaskCompletedEventArgs: AsyncCompletedEventArgs
{
   public LongTaskCompletedEventArgs(string output, Exception e,
                                     bool cancelled, object state)
       : base(e, cancelled, state)
   {
      this.output = output;
   }

   private string output;

   public string Output
   {
      get
      {
         RaiseExceptionIfNecessary();
         return output;
      }
   }
}
```

The method asyncOp.PostOperationCompleted() uses the onCompletedDelegate. This delegate was initialized to reference the method LongTaskCompletion. LongTaskCompletion needs to fulfill the parameter requirements of the SendOrPostCallbackDelegate. The implementation just casts the parameter to LongTaskCompletedEventArgs, which was the type of the object that was passed to the PostOperationCompleted method, and calls the method OnLongTaskCompleted.

```
private void LongTaskCompletion(object operationState)
{
   var e = operationState as LongTaskCompletedEventArgs;

   OnLongTaskCompleted(e);
}
```

OnLongTaskCompleted then just fires the event LongTaskCompleted to return the LongTaskCompletedEventArgs to the caller.

```
protected void OnLongTaskCompleted(LongTaskCompletedEventArgs e)
{
   if (LongTaskCompleted != null)
   {
      LongTaskCompleted(this, e);
   }
}
```

After creating the component, it is really easy to use it. The event LongTaskCompleted is assigned to the method Comp_LongTaskCompleted, and the method LongTaskAsync() is invoked. With a simple console application, you will see that the event handler Comp_LongTaskCompleted is called from a thread different from the main thread. (This is different from Windows Forms applications, as you will see in the code that follows.)

```
static void Main()
{
   Console.WriteLine("Main thread: {0}",
         Thread.CurrentThread.ManagedThreadId);

   AsyncComponent comp = new AsyncComponent();
   comp.LongTaskCompleted += Comp_LongTaskCompleted;
```

```
        comp.LongTaskAsync("input", 33);

        Console.ReadLine();
    }

    static void Comp_LongTaskCompleted(object sender,
          LongTaskCompletedEventArgs e)
    {
        Console.WriteLine("completed, result: {0}, thread: {1}", e.Output,
              Thread.CurrentThread.ManagedThreadId);
    }
```

code snippet AsyncComponent/Program.cs

With a Windows Forms application the `SynchronizationContext` is set to `WindowsFormsSynchronizationContext` — that's why the event handler code is invoked in the same thread:

```
WindowsFormsSynchronizationContext syncContext =
      new WindowsFormsSynchronizationContext();
SynchronizationContext.SetSynchronizationContext(syncContext);
```

SUMMARY

This chapter explored how to code applications that use multiple threads using the `System.Threading` namespace and multiple tasks using the `System.Threading.Tasks` namespace. Using multithreading in your applications takes careful planning. Too many threads can cause resource issues, and not enough threads can cause your application to seem sluggish and to perform poorly. With tasks, you get an abstraction to threads. This abstraction helps you not to create too many threads because threads are reused from a pool.

You've seen various ways to create multiple threads such as using the delegate, timers, a `ThreadPool`, and the `Thread` class. Various synchronization techniques have been explored, such as a simple `lock` statement, as well as the `Monitor`, `Semaphore`, and `Event` classes. You've seen how to program the asynchronous pattern with the `IAsyncResult` interface and the event-based asynchronous pattern.

The `System.Threading` namespace in the .NET Framework gives you multiple ways to manipulate threads; however, this does not mean that the .NET Framework handles all the difficult tasks of multithreading for you. You need to consider thread priority and synchronization issues. This chapter discussed these issues and how to code for them in your C# applications. It also looked at the problems associated with deadlocks and race conditions.

Just remember that if you are going to use multithreading in your C# applications, careful planning needs to be a major part of your efforts.

Here are some final guidelines regarding threading:

- Try to keep synchronization requirements to a minimum. Synchronization is complex and blocks threads. You can avoid it if you try to avoid sharing state. Of course, this is not always possible.
- Static members of a class should be thread-safe. Usually, this is the case with classes in the .NET Framework.
- Instance state does not need to be thread-safe. For best performance, synchronization is better used outside of the class where it is needed, and not with every member of the class. Instance members of .NET Framework classes usually are not thread-safe. In the MSDN library, you can find this information documented for every class of the Framework in the Thread Safety section.

The next chapter gives information on another core .NET topic: security.

21 Security

WHAT'S IN THIS CHAPTER?

- ➤ Authentication and authorization
- ➤ Cryptography
- ➤ Access control to resources
- ➤ Code access security

Security has several key elements that you need to consider in making your applications secure. One is the user of the application. Is it really the user, or someone posing as the user, who is accessing the application? How can this user be trusted? As you will see in this chapter, the user first needs to be authenticated, and then authorization occurs to verify if the user is allowed to use the requested resources.

What about data that is stored or sent across the network? Is it possible that someone accesses this data, for example, by using a network sniffer? Encryption of data is important here. Some technologies, such as Windows Communication Foundation (WCF) provide encryption capabilities by simple configuration, so you can see what's done behind the scenes.

Yet another aspect is the application itself. What if the application is hosted by a web provider? How is the application restricted from doing harm to the server?

This chapter explores the features available in .NET to help you manage security, and shows you how .NET protects you from malicious code, how to administer security policies, and how to access the security subsystem programmatically.

AUTHENTICATION AND AUTHORIZATION

Two fundamental pillars of security are authentication and authorization. *Authentication* is the process of identifying the user, and *authorization* occurs afterward to verify if the identified user is allowed to access a specific resource.

Identity and Principal

You can identify the user running the application by using an *identity*. The `WindowsIdentity` class represents a Windows user. If you don't identify the user with a Windows account, you can use other classes that implement the interface `IIdentity`. With this interface you have access to the name of the user, information about whether the user is authenticated, and the authentication type.

A *principal* is an object that contains the identity of the user and the roles that the user belongs to. The interface `IPrincipal` defines the property `Identity`, which returns an `IIdentity` object, and the method `IsInRole` with which you can verify that the user is a member of a specific role. A *role* is a collection of users who have the same security permissions, and it is the unit of administration for users. Roles can be Windows groups or just a collection of strings that you define.

The principal classes available with .NET are `WindowsPrincipal` and `GenericPrincipal`. You can also create a custom principal class that implements the interface `IPrincipal`.

In the following example, you create a console application that provides access to the principal in an application that, in turn, enables you to access the underlying Windows account. You need to import the `System.Security.Principal` and `System.Threading` namespaces. First, you must specify that .NET should automatically hook up the principal with the underlying Windows account. This must be done because .NET does not automatically populate the thread's `CurrentPrincipal` property for security reasons. You can do it like this:

```
using System;
using System.Security.Principal;
using System.Threading;

namespace Wrox.ProCSharp.Security
{
   class Program
   {
      static void Main()
      {
AppDomain.CurrentDomain.SetPrincipalPolicy(PrincipalPolicy.WindowsPrincipal);
```

code snippet WindowsPrincipal/Program.cs

It is possible to use `WindowsIdentity.GetCurrent()` to access the Windows account details; however, that method is best used when you are going to look at the principal only once. If you want to access the principal a number of times, it is more efficient to set the policy so that the current thread provides access to the principal for you. If you use the `SetPrincipalPolicy` method, it is specified that the principal in the current thread should hold a `WindowsIdentity` object. All identity classes, such as `WindowsIdentity`, implement the `IIdentity` interface. The interface contains three properties (`AuthenticationType`, `IsAuthenticated`, and `Name`) for all derived identity classes to implement.

Add code to access the principal's properties from the `Thread` object:

```
         WindowsPrincipal principal =
            (WindowsPrincipal)Thread.CurrentPrincipal;
         WindowsIdentity identity = (WindowsIdentity)principal.Identity;
         Console.WriteLine("IdentityType: " + identity.ToString());
         Console.WriteLine("Name: {0}", identity.Name);
         Console.WriteLine("'Users'?: {0} ",
                           principal.IsInRole(WindowsBuiltInRole.User));
         Console.WriteLine("'Administrators'? {0}",
               principal.IsInRole(WindowsBuiltInRole.Administrator));
         Console.WriteLine("Authenticated: {0}", identity.IsAuthenticated);
         Console.WriteLine("AuthType: {0}", identity.AuthenticationType);
         Console.WriteLine("Anonymous? {0}", identity.IsAnonymous);
         Console.WriteLine("Token: {0}", identity.Token);
      }
   }
}
```

The output from this console application looks similar to the following lines; it will vary according to your machine's configuration and the roles associated with the account under which you are signed in:

```
IdentityType:System.Security.Principal.WindowsIdentity
Name: farabove\christian
'Users'? True
'Administrators'? False
Authenticated: True
AuthType: NTLM
Anonymous? False
Token: 416
```

It is enormously beneficial to be able to easily access details about the current users and their roles. With this information, you can make decisions about what actions should be permitted or denied. The ability to make use of roles and Windows user groups provides the added benefit that administration can be done by using standard user administration tools, and you can usually avoid altering the code when user roles change. The following section looks at roles in more detail.

Roles

Role-based security is especially useful in situations in which access to resources is an issue. A primary example is the finance industry, in which employees' roles define what information they can access and what actions they can perform.

Role-based security is also ideal for use in conjunction with Windows accounts, or a custom user directory to manage access to web-based resources. For example, a web site could restrict access to its content until a user registers with the site, and then additionally provide access to special content only, if the user is a paying subscriber. In many ways, ASP.NET makes role-based security easier because much of the code is based on the server.

For example, to implement a Web service that requires authentication, you could use the account subsystem of Windows and write the web method in such a way that it ensures the user is a member of a specific Windows user group before allowing access to the method's functionality.

Imagine a scenario with an intranet application that relies on Windows accounts. The system has a group called `Manager` and one called `Assistant`; users are assigned to these groups according to their role within the organization. Say that the application contains a feature that displays information about employees that should be accessed only by users in the `Managers` group. You can easily use code that checks whether the current user is a member of the `Managers` group and whether he is permitted or denied access.

However, if you decide later to rearrange the account groups and to introduce a group called `Personnel` that also has access to employee details, you will have a problem. You will need to go through all the code and update it to include rules for this new group.

A better solution would be to create a permission called something like `ReadEmployeeDetails` and assign it to groups where necessary. If the code applies a check for the `ReadEmployeeDetails` permission, updating the application to allow those in the `Personnel` group access to employee details is simply a matter of creating the group, placing the users in it, and assigning the `ReadEmployeeDetails` permission.

Declarative Role-Based Security

Just as with code access security, you can implement role-based security requests ("the user must be in the Administrators group") using imperative requests by calling the `IsInRole()` method from the `IPrincipal` class, or using attributes. You can state permission requirements declaratively at the class or method level using the `[PrincipalPermission]` attribute:

```
using System;
using System.Security;
using System.Security.Principal;
using System.Security.Permissions;
```

```
namespace Wrox.ProCSharp.Security
{
   class Program
   {
      static void Main()
      {
         AppDomain.CurrentDomain.SetPrincipalPolicy(
            PrincipalPolicy.WindowsPrincipal);
         try
         {
            ShowMessage();
         }
         catch (SecurityException exception)
         {
            Console.WriteLine("Security exception caught ({0})", exception.Message);
            Console.WriteLine("The current principal must be in the local"
                              + "Users group");
         }
      }

      [PrincipalPermission(SecurityAction.Demand, Role = "BUILTIN\\Users")]
      static void ShowMessage()
      {
         Console.WriteLine("The current principal is logged in locally ");
         Console.WriteLine("(member of the local Users group)");
      }
   }
}
```

code snippet RoleBasedSecurity/Program.cs

The `ShowMessage()` method will throw an exception unless you execute the application in the context of a user in the Windows local Users group. For a web application, the account under which the ASP.NET code is running must be in the group, although in a "real-world" example you would certainly avoid adding this account to the administrators group!

If you run the preceding code using an account in the local Users group, the output will look like this:

```
The current principal is logged in locally
(member of the local Users group)
```

Client Application Services

Visual Studio makes it easy to use authentication services that previously have been built for ASP.NET web applications. With this service, it is possible to use the same authentication mechanism with both Windows and web applications. This is a provider model that is primarily based on the classes `Membership` and `Roles` in the namespace `System.Web.Security`. With the `Membership` class you can validate, create, delete, and find users; change the password; and do other things related to users. With the `Roles` class you can add and delete roles, get the roles for a user, and change roles for a user. Where the roles and users are stored depends on the provider. The `ActiveDirectoryMembershipProvider` accesses users and roles in the Active Directory; the `SqlMembershipProvider` uses a SQL Server database. With .NET 4 these providers exist for client application services `ClientFormsAuthenticationMembershipProvider` and `ClientWindowsAuthenticationMembershipProvider`.

Next, you use client application services with Forms authentication. To do this, first you need to start an application server, and then you can use this service from Windows Forms or Windows Presentation Foundation (WPF).

Application Services

For using client application services, you can create an ASP.NET Web service project that offers application services.

With the project a membership provider is needed. You can use an existing one, but you can also easily create a custom provider. The sample code here defines the class `SampleMembershipProvider`, which is derived from the base class `MembershipProvider`. `MembershipProvider` is defined in the namespace `System.Web.Security` in the assembly `System.Web.ApplicationServices`. You must override all abstract methods from the base class. For login, the only implementation needed is the method `ValidateUser`. All other methods can throw a `NotSupportedException`, as shown with the property `ApplicationName`. The sample code here uses a `Dictionary<string, string>` that contains usernames and passwords. Of course, you can change it to your own implementation, for example, to read username and password from the database.

```
using System;
using System.Collections.Generic;
using System.Collections.Specialized;
using System.Web.Security;

namespace Wrox.ProCSharp.Security
{
   public class SampleMembershipProvider: MembershipProvider
   {
      private Dictionary<string, string> users = new Dictionary<string, string>();
      internal static string ManagerUserName = "Manager".ToLowerInvariant();
      internal static string EmployeeUserName = "Employee".ToLowerInvariant();

      public override void Initialize(string name, NameValueCollection config)
      {
         users = new Dictionary<string, string>();
         users.Add(ManagerUserName, "secret@Pa$$w0rd");
         users.Add(EmployeeUserName, "s0me@Secret");

         base.Initialize(name, config);
      }

      public override string ApplicationName
      {
         get
         {
            throw new NotImplementedException();
         }
         set
         {
            throw new NotImplementedException();
         }
      }

      // override abstract Membership members
      // ...

      public override bool ValidateUser(string username, string password)
      {
         if (users.ContainsKey(username.ToLowerInvariant()))
         {
            return password.Equals(users[username.ToLowerInvariant()]);
         }
         return false;
      }
   }
}
```

code snippet AppServices/SampleMembershipProvider.cs

For using roles, you also need to implement a role provider. The class `SampleRoleProvider` derives from the base class `RoleProvider` and implements the methods `GetRolesForUser()` and `IsUserInRole()`:

```
using System;
using System.Collections.Specialized;
using System.Web.Security;

namespace Wrox.ProCSharp.Security
{
   public class SampleRoleProvider: RoleProvider
   {
      internal static string ManagerRoleName = "Manager".ToLowerInvariant();
      internal static string EmployeeRoleName = "Employee".ToLowerInvariant();

      public override void Initialize(string name, NameValueCollection config)
      {
         base.Initialize(name, config);
      }

      public override void AddUsersToRoles(string[] usernames,
            string[] roleNames)
      {
         throw new NotImplementedException();
      }

      // override abstract RoleProvider members
      // ...

      public override string[] GetRolesForUser(string username)
      {
         if (string.Compare(username,
             SampleMembershipProvider.ManagerUserName, true) == 0)
         {
            return new string[] { ManagerRoleName };
         }
         else if (string.Compare(username,
                  SampleMembershipProvider.EmployeeUserName, true) == 0)
         {
            return new string[] { EmployeeRoleName };
         }
         else
         {
            return new string[0];
         }
      }

      public override bool IsUserInRole(string username, string roleName)
      {
         string[] roles = GetRolesForUser(username);
         foreach (var role in roles)
         {
            if (string.Compare(role, roleName, true) == 0)
            {
               return true;
            }
         }
         return false;
      }
   }
}
```

code snippet AppServices/SampleRoleProvider.cs

Authentication services must be configured in the `Web.config` file. On the production system, it would be useful from a security standpoint to configure SSL with the server hosting application services.

```
<system.web.extensions>
  <scripting>
    <webServices>
      <authenticationService enabled="true" requireSSL="false"/>
      <roleService enabled="true"/>
    </webServices>
  </scripting>
</system.web.extensions>
```

code snippet AppServices/web.config

Within the `<system.web>` section, the `membership` and `roleManager` elements must be configured to reference the classes that implement the membership and role provider:

```
<system.web>
  <membership defaultProvider="SampleMembershipProvider">
    <providers>
      <add name="SampleMembershipProvider"
            type="Wrox.ProCSharp.Security.SampleMembershipProvider"/>
    </providers>
  </membership>
  <roleManager enabled="true" defaultProvider="SampleRoleProvider">
    <providers>
      <add name="SampleRoleProvider"
          type="Wrox.ProCSharp.Security.SampleRoleProvider"/>
    </providers>
  </roleManager>
```

For debugging, you can assign a port number and virtual path with the Web tab of project properties. The sample application uses the port 55555 and the virtual path `/AppServices`. If you use different values, you need to change the configuration of the client application accordingly.

Now the application service can be used from a client application.

Client Application

With the client application, WPF is used. Visual Studio has a project setting named Services that allows the use of client application services. Here, you can set Forms authentication and the location of the authentication and roles service to the address defined previously: `http://localhost:55555/AppServices`. All that's done from this project configuration is to reference the assemblies `System.Web` and `System.Web.Extensions`, and change the application's configuration file to configure membership and role providers that use the classes `ClientAuthenticationMembershipProvider` and `ClientRoleProvider` and the address of the Web service that is used by these providers.

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <system.web>
    <membership defaultProvider="ClientAuthenticationMembershipProvider">
      <providers>
        <add name="ClientAuthenticationMembershipProvider"
            type="System.Web.ClientServices.Providers.
            ClientFormsAuthenticationMembershipProvider,
            System.Web.Extensions, Version=4.0.0.0, Culture=neutral,
            PublicKeyToken=31bf3856ad364e35" serviceUri=
"http://localhost:55555/AppServices/Authentication_JSON_AppService.axd" />
      </providers>
    </membership>
    <roleManager defaultProvider="ClientRoleProvider" enabled="true">
      <providers>

```

code snippet AuthenticationServices/app.config

The Windows application just uses `Label`, `TextBox`, `PasswordBox`, and `Button` controls, as shown in Figure 21-1. The `Label` with the content User Validated shows up only when the logon is successful.

The handler of the `Button.Click` event invokes the `ValidateUser()` method of the `Membership` class. Because of the configured provider `ClientAuthenticationMembershipProvider`, the provider in turn invokes the Web service and calls the method `ValidateUser()` of the `SampleMembershipProvider` class to verify a successful logon. With success, the Label `labelValidatedInfo` is made visible; otherwise, a message box pops up:

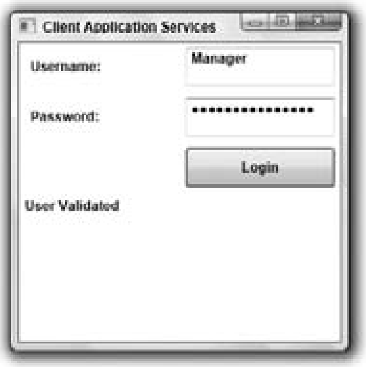

FIGURE 21-1

```
private void OnLogin(object sender, RoutedEventArgs e)
{
   try
   {
      if (Membership.ValidateUser(textUsername.Text,
            textPassword.Password))
      {
         // user validated!
         labelValidatedInfo.Visibility = Visibility.Visible;
      }
      else
      {
         MessageBox.Show("Username or password not valid",
               "Client Authentication Services", MessageBoxButton.OK,
               MessageBoxImage.Warning);
      }
   }
   catch (WebException ex)
   {
      MessageBox.Show(ex.Message, "Client Application Services",
            MessageBoxButton.OK, MessageBoxImage.Error);
   }
}
```

code snippet AuthenticationServices/MainWindow.xaml.cs

ENCRYPTION

Confidential data should be secured so that it cannot be read by unprivileged users. This is valid both for data that is sent across the network, or stored data. You can encrypt such data with symmetric or asymmetric encryption keys.

With a symmetric key, the same key can be used for encryption and decryption. With asymmetric encryption, different keys are used for encryption and decryption: a public and a private key. Something encrypted using a public key can be decrypted with the corresponding private key. This also works the other way around: something encrypted using a private key can be decrypted by using the corresponding public key, but not the private key.

Public and private keys are always created as a pair. The public key can be made available to everybody, and it can even be put on a web site, but the private key must be safely locked away. Following are some examples where these public and private keys are used to explain encryption.

If Alice sends a message to Bob (see Figure 21-2), and Alice wants to make sure that no one else but Bob can read the message, she uses Bob's public key. The message is encrypted using Bob's public key. Bob opens the message and can decrypt it using his secretly stored private key. This key exchange guarantees that no one but Bob can read Alice's message.

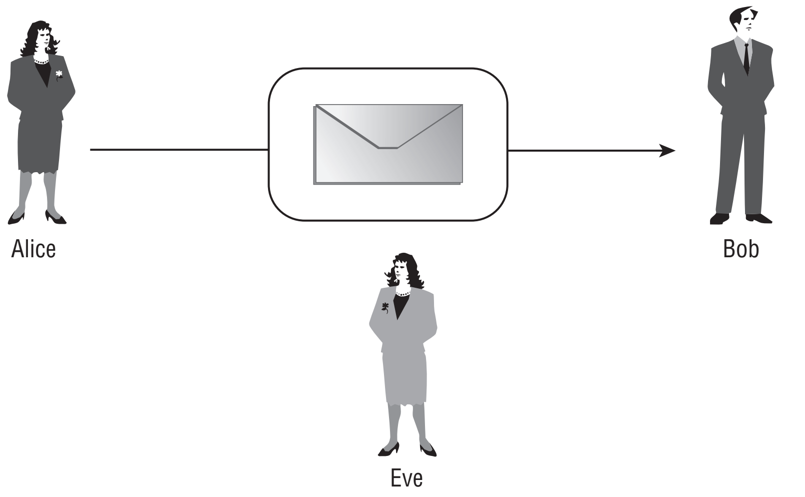

FIGURE 21-2

There is one problem left: Bob can't be sure that the mail comes from Alice. Eve can use Bob's public key to encrypt messages sent to Bob and pretend to be Alice. We can extend this principle using public/private keys. Let's start again with Alice sending a message to Bob. Before Alice encrypts the message using Bob's public key, she adds her signature and encrypts the signature using her own private key. Then she encrypts the mail using Bob's public key. Therefore, it is guaranteed that no one else but Bob can read the mail. When Bob decrypts the message, he detects an encrypted signature. The signature can be decrypted using Alice's public key. For Bob, it is not a problem to access Alice's public key because the key is public. After decrypting the signature, Bob can be sure that it was Alice who sent the message.

The encryption and decryption algorithms using symmetric keys are a lot faster than those using asymmetric keys. The problem with symmetric keys is that the keys must be exchanged in a safe manner. With network communication, one way to do this is by using asymmetric keys first for the key exchange and then symmetric keys for encryption of the data that is sent across the wire.

With the .NET Framework, you find classes for encryption in the namespace `System.Security.Cryptography`. Several symmetric and asymmetric algorithms are implemented. You can find algorithm classes for many different purposes. Some of the classes added in .NET 3.5 have a `Cng` prefix or suffix. Cng is short for *Cryptography Next Generation,* which can be used since Windows Vista and Windows Server 2008. This API makes it possible to write a program independently of the algorithm by using a provider-based model. If you are targeting Windows Server 2003 as well, you need to pay attention to what encryption classes to use.

The following table lists encryption classes from the namespace `System.Security.Cryptography` and their purposes. The classes without a `Cng`, `Managed`, or `CryptoServiceProvider` suffix are abstract base classes, such as `MD5`. The `Managed` suffix means that this algorithm is implemented with managed code; other classes might wrap native Windows API calls. The suffix `CryptoServiceProvider` is used with classes that implement the abstract base class. The `Cng` suffix is used with classes that make use of the new Cryptography CNG API.

CATEGORY	CLASSES	DESCRIPTION

Hash	`MD5`, `MD5Cng`
	`SHA1`, `SHA1Managed`,
	`SHA1Cng`
	`SHA256`, `SHA256Managed`, `SHA256Cng`
	`SHA384`, `SHA384Managed`, `SHA384Cng`
	`SHA512`, `SHA512Managed`, `SHA512Cng`
		The purpose of hash algorithms is to create a fixed-length hash value from binary strings of arbitrary length. These algorithms are used with digital signatures and for data integrity. If the same binary string is hashed again, the same hash result is returned. MD5 (Message Digest Algorithm 5) was developed at RSA Laboratories and is faster than SHA1. SHA1 is stronger against brute force attacks. The SHA algorithms were designed by the National Security Agency (NSA). MD5 uses a 128-bit hash size; SHA1 uses 160 bits. The other SHA algorithms contain the hash size in the name. SHA512 is the strongest of these algorithms; with a hash size of 512 bits; it is also the slowest.

Symmetric	`DES`, `DESCryptoServiceProvider`
	`TripleDES`,
	`TripleDESCryptoServiceProvider`
	`Aes`, `AesCryptoServiceProvider`, `AesManaged`
	`RC2`, `RC2CryptoServiceProvider`
	`Rijandel`, `RijandelManaged`
		Symmetric key algorithms use the same key for encryption and decryption of data. DES (Data Encryption Standard) is now considered insecure because it uses just 56 bits for the key size and can be broken in less than 24 hours. Triple-DES is the successor to DES and has a key length of 168 bits, but the effective security it provides is only 112 bit. AES (Advanced Encryption Standard) has a key size of 128, 192, or 256 bits. Rijandel is very similar to AES; it just has more options with the key size. AES is an encryption standard adopted by the U.S. government.

Asymmetric	`DSA, DSACryptoServiceProvider`
	`ECDsa`, `ECDsaCng`
	`ECDiffieHellman`, `ECDiffieHellmanCng`
	`RSA`, `RSACryptoServiceProvider`
		Asymmetric algorithms use different keys for encryption and decryption. RSA (Rivest, Shamir, Adleman) was the first algorithm used for signing as well as encryption. This algorithm is widely used in e-commerce protocols. DSA (Digital Signature Algorithm) is a United States Federal Government standard for digital signatures. ECDSA (Elliptic Curve DSA) and ECDiffieHellman use algorithms based on elliptic curve groups. These algorithms are more secure with shorter key sizes. For example, having a key size of 1024 bits for DSA is similar in security to 160 bits for ECDSA. As a result, ECDSA is much faster. ECDiffieHellman is an algorithm used to exchange private keys in a secure way over a public channel.

Let's get into examples of how these algorithms can be used programmatically.

Signature

The first example demonstrates a signature using the ECDSA algorithm for signing. Alice creates a signature that is encrypted with her private key and can be accessed using her public key. This way, it is guaranteed that the signature is from Alice.

First, take a look at the major steps in the `Main()` method: Alice's keys are created, and the string `"Alice"` is signed and finally verified if the signature is really from Alice by using the public key. The message that is signed is converted to a byte array by using the `Encoding` class. To write the encrypted signature to the console, the byte array that contains the signature is converted to a string with the method `Convert.ToBase64String()`.

Never convert encrypted data to a string using the `Encoding` *class. The* `Encoding` *class verifies and converts invalid values that are not allowed with Unicode, and thus converting the string back to a byte array yields a different result.*

```
using System;
using System.Security.Cryptography;
using System.Text;

namespace Wrox.ProCSharp.Security
{
   class Program
   {
      internal static CngKey aliceKeySignature;
      internal static byte[] alicePubKeyBlob;

      static void Main()
      {
         CreateKeys();

         byte[] aliceData = Encoding.UTF8.GetBytes("Alice");
         byte[] aliceSignature = CreateSignature(aliceData, aliceKeySignature);
         Console.WriteLine("Alice created signature: {0}",
               Convert.ToBase64String(aliceSignature));

         if (VerifySignature(aliceData, aliceSignature, alicePubKeyBlob))
         {
            Console.WriteLine("Alice signature verified successfully");
         }
      }
```

Code snippet SigningDemo/Program.cs

`CreateKeys()` is the method that creates a new key pair for Alice. This key pair is stored in a static field, so it can be accessed from the other methods. The `Create()` method of `CngKey` gets the algorithm as an argument to define a key pair for the algorithm. With the `Export()` method, the public key of the key pair is exported. This public key can be given to Bob for the verification of the signature. Alice keeps the private key. Instead of creating a key pair with the `CngKey` class, you can open existing keys that are stored in the key store. Usually Alice would have a certificate containing a key pair in her private store, and the store could be accessed with `CngKey.Open()`.

```
      static void CreateKeys()
      {
         aliceKeySignature = CngKey.Create(CngAlgorithm.ECDsaP256);
         alicePubKeyBlob = aliceKeySignature.Export(CngKeyBlobFormat.GenericPublicBlob);
      }
```

With the key pair, Alice can create the signature using the `ECDsaCng` class. The constructor of this class receives the `CngKey` from Alice that contains both the public and private key. The private key is used, signing the data with the `SignData()` method.

```
      static byte[] CreateSignature(byte[] data, CngKey key)
      {
         var signingAlg = new ECDsaCng(key);
```

```
            byte[] signature = signingAlg.SignData(data);
            signingAlg.Clear();

            return signature;
         }
```

For verification if the signature was really from Alice, Bob checks the signature by using the public key from Alice. The byte array containing the public key blob can be imported to a `CngKey` object with the static `Import()` method. The `ECDsaCng` class is then used to verify the signature by invoking `VerifyData()`.

```
         static bool VerifySignature(byte[] data, byte[] signature, byte[] pubKey)
         {
            bool retValue = false;
            using (CngKey key = CngKey.Import(pubKey, CngKeyBlobFormat.GenericPublicBlob))
            {
               var signingAlg = new ECDsaCng(key);
               retValue = signingAlg.VerifyData(data, signature);
               signingAlg.Clear();
            }
            return retValue;
         }
      }
   }
```

Key Exchange and Secure Transfer

Let's get into a more complex example to exchange a symmetric key for a secure transfer by using the Diffie Hellman algorithm. In the `Main()` method, you can see the main functionality. Alice creates an encrypted message and sends the encrypted message to Bob. Before that, key pairs are created for Alice and Bob. Bob gets access only to Alice's public key, and Alice gets access only to Bob's public key.

```
   using System;
   using System.IO;
   using System.Security.Cryptography;
   using System.Text;

   namespace Wrox.ProCSharp.Security
   {
      class Program
      {
         static CngKey aliceKey;
         static CngKey bobKey;
         static byte[] alicePubKeyBlob;
         static byte[] bobPubKeyBlob;

         static void Main()
         {
            CreateKeys();
            byte[] encrytpedData = AliceSendsData("secret message");
            BobReceivesData(encrytpedData);

         }
```

code snippet SecureTransfer/Program.cs

In the implementation of the `CreateKeys()` method, keys are created to be used with the EC Diffie Hellman 256 algorithm.

```
         private static void CreateKeys()
         {
            aliceKey = CngKey.Create(CngAlgorithm.ECDiffieHellmanP256);
            bobKey = CngKey.Create(CngAlgorithm.ECDiffieHellmanP256);
```

```
        alicePubKeyBlob = aliceKey.Export(CngKeyBlobFormat.EccPublicBlob);
        bobPubKeyBlob = bobKey.Export(CngKeyBlobFormat.EccPublicBlob);
    }
```

In the method `AliceSendsData()`, the string that contains text characters is converted to a byte array by using the `Encoding` class. An `ECDiffieHellmanCng` object is created and initialized with the key pair from Alice. Alice creates a symmetric key by using her key pair and the public key from Bob calling the method `DeriveKeyMaterial()`. The returned symmetric key is used with the symmetric algorithm AES to encrypt the data. `AesCryptoServiceProvider` requires the key and an initialization vector (IV). The IV is generated dynamically from the method `GenerateIV()`. The symmetric key is exchanged with the help of the EC Diffie Hellman algorithm, but the IV must also be exchanged. From the security standpoint, it is okay to transfer the IV unencrypted across the network — just the key exchange must be secured. The IV is stored first as content in the memory stream, followed by the encrypted data where the `CryptoStream` class uses the `encryptor` created by the `AesCryptoServiceProvider` class. Before the encrypted data is accessed from the memory stream, the crypto stream must be closed. Otherwise, end bits would be missing from the encrypted data.

```
    private static byte[] AliceSendsData(string message)
    {
        Console.WriteLine("Alice sends message: {0}", message);
        byte[] rawData = Encoding.UTF8.GetBytes(message);
        byte[] encryptedData = null;

        using (var aliceAlgorithm = new ECDiffieHellmanCng(aliceKey))
        using (CngKey bobPubKey = CngKey.Import(bobPubKeyBlob,
              CngKeyBlobFormat.EccPublicBlob))
        {
            byte[] symmKey = aliceAlgorithm.DeriveKeyMaterial(bobPubKey);
            Console.WriteLine("Alice creates this symmetric key with " +
                  "Bobs public key information: {0}",
                  Convert.ToBase64String(symmKey));

            var aes = new AesCryptoServiceProvider();
            aes.Key = symmKey;
            aes.GenerateIV();
            using (ICryptoTransform encryptor = aes.CreateEncryptor())
            using (MemoryStream ms = new MemoryStream())
            {
                // create CryptoStream and encrypt data to send
                var cs = new CryptoStream(ms, encryptor, CryptoStreamMode.Write);

                // write initialization vector not encrypted
                ms.Write(aes.IV, 0, aes.IV.Length);
                cs.Write(rawData, 0, rawData.Length);
                cs.Close();
                encryptedData = ms.ToArray();
            }
            aes.Clear();
        }
        Console.WriteLine("Alice: message is encrypted: {0}",
              Convert.ToBase64String(encryptedData));;
        Console.WriteLine();
        return encryptedData;
    }
```

Bob receives encrypted data in the argument of the method `BobReceivesData()`. First, the unencrypted initialization vector must be read. The `BlockSize` property of the class `AesCryptoServiceProvider` returns the number of bits for a block. The number of bytes can be calculated by doing a divide by 8, and the fastest way to do this is by doing a bit shift of 3 bits. Shifting by 1 bit is a division by 2, 2 bits by 4, and 3 bits by 8. With the `for` loop, the first bytes of the raw bytes that contain the IV unencrypted are written to the array `iv`. Next, an `ECDiffieHellmanCng` object is instantiated with the key pair from Bob. Using the public key from Alice, the symmetric key is returned from the method `DeriveKeyMaterial()`.

Comparing the symmetric keys created from Alice and Bob shows that the same key value gets created. Using this symmetric key and the initialization vector, the message from Alice can be decrypted with the `AesCryptoServiceProvider` class.

```
private static void BobReceivesData(byte[] encryptedData)
{
   Console.WriteLine("Bob receives encrypted data");
   byte[] rawData = null;

   var aes = new AesCryptoServiceProvider();

   int nBytes = aes.BlockSize  3;
   byte[] iv = new byte[nBytes];
   for (int i = 0; i < iv.Length; i++)
      iv[i] = encryptedData[i];

   using (var bobAlgorithm = new ECDiffieHellmanCng(bobKey))
   using (CngKey alicePubKey = CngKey.Import(alicePubKeyBlob,
         CngKeyBlobFormat.EccPublicBlob))
   {
      byte[] symmKey = bobAlgorithm.DeriveKeyMaterial(alicePubKey);
      Console.WriteLine("Bob creates this symmetric key with " +
            "Alices public key information: {0}",
            Convert.ToBase64String(symmKey));

      aes.Key = symmKey;
      aes.IV = iv;

      using (ICryptoTransform decryptor = aes.CreateDecryptor())
      using (MemoryStream ms = new MemoryStream())
      {
         var cs = new CryptoStream(ms, decryptor, CryptoStreamMode.Write);
         cs.Write(encryptedData, nBytes, encryptedData.Length - nBytes);
         cs.Close();

         rawData = ms.ToArray();

         Console.WriteLine("Bob decrypts message to: {0}",
               Encoding.UTF8.GetString(rawData));
      }
      aes.Clear();
   }
}
```

When you run the application, you can see output similar to the following on the console. The message from Alice is encrypted, and decrypted by Bob with the securely exchanged symmetric key.

```
Alice sends message: secret message
Alice creates this symmetric key with Bobs public key information:
5NWat8AemzFCYo1IIae9S3Vn4AXyai4aL8ATFo41vbw=
Alice: message is encrypted: 3C5U9CpYxnoFTk3Ew2V0T5Po0Jgryc5R7Te8ztau5N0=

Bob receives encrypted message
Bob creates this symmetric key with Alices public key information:
5NWat8AemzFCYo1IIae9S3Vn4AXyai4aL8ATFo41vbw=
Bob decrypts message to: secret message
```

ACCESS CONTROL TO RESOURCES

With the operating system, resources such as files and registry keys, as well as handles of a named pipe, are secured by using an access control list. Figure 21-3 shows the structure of how this maps. The resource has a security descriptor associated. The security descriptor contains information about the owner of the resource and references two access control lists: a discretionary access control list (DACL) and a system access control list (SACL). The DACL defines who has access or no access; the SACL defines audit rules for security event logging. An ACL contains a list of access control entries (ACE). The ACE contains a type, a security identifier, and rights. With the DACL, the ACE can be of type access allowed or access denied. Some of the rights that you can set and get with a file are create, read, write, delete, modify, change permissions, and take ownership.

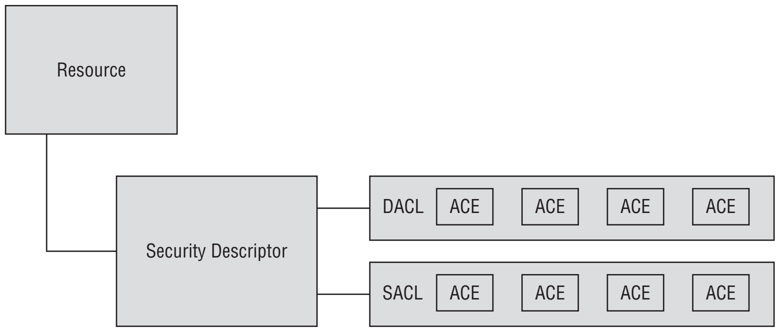

FIGURE 21-3

The classes to read and modify access control are located in the namespace `System.Security.AccessControl`. The following program demonstrates reading the access control list from a file.

The `FileStream` class defines the `GetAccessControl()` method, which returns a `FileSecurity` object. `FileSecurity` is the .NET class that represents a security descriptor for files. `FileSecurity` derives from the base classes `ObjectSecurity`, `CommonObjectSecurity`, `NativeObjectSecurity`, and `FileSystemSecurity`. Other classes that represent a security descriptor are `CryptoKeySecurity`, `EventWaitHandleSecurity`, `MutexSecurity`, `RegistrySecurity`, `SemaphoreSecurity`, `PipeSecurity`, and `ActiveDirectorySecurity`. All of these objects can be secured using an access control list. In general, the corresponding .NET class defines the method `GetAccessControl` to return the corresponding security class; for example, the `Mutex.GetAccessControl()` method returns a `MutexSecurity`, and the `PipeStream.GetAccessControl()` method returns a `PipeSecurity`.

The `FileSecurity` class defines methods to read and change the DACL and SACL. The method `GetAccessRules()` returns the DACL in the form of the class `AuthorizationRuleCollection`. To access the SACL, you can use the method `GetAuditRules()`.

With the method `GetAccessRules()`, you can define if inherited access rules, and not only access rules directly defined with the object, should be used. The last parameter defines the type of the security identifier that should be returned. This type must derive from the base class `IdentityReference`. Possible types are `NTAccount` and `SecurityIdentifier`. Both of these classes represent users or groups; the `NTAccount` class finds the security object by its name and the `SecurityIdentifier` class finds the security object by a unique security identifier.

The returned `AuthorizationRuleCollection` contains `AuthorizationRule` objects. The `AuthorizationRule` is the .NET representation of an ACE. With the sample here, a file is accessed, so the `AuthorizationRule` can be cast to a `FileSystemAccessRule`. With ACEs of other resources, different .NET representations exist, such as `MutexAccessRule` and `PipeAccessRule`. With the `FileSystemAccessRule` class, the properties `AccessControlType`, `FileSystemRights`, and `IdentityReference` return information about the ACE.

```
using System;
using System.IO;
using System.Security.AccessControl;
using System.Security.Principal;
```

```
namespace Wrox.ProCSharp.Security
{
   class Program
   {
      static void Main(string[] args)
      {
         string filename = null;
         if (args.Length == 0)
            return;

         filename = args[0];

         FileStream stream = File.Open(filename, FileMode.Open);
         FileSecurity securityDescriptor = stream.GetAccessControl();
         AuthorizationRuleCollection rules =
               securityDescriptor.GetAccessRules(true, true,
                     typeof(NTAccount));

         foreach (AuthorizationRule rule in rules)
         {
            var fileRule = rule as FileSystemAccessRule;
            Console.WriteLine("Access type: {0}", fileRule.AccessControlType);
            Console.WriteLine("Rights: {0}", fileRule.FileSystemRights);
            Console.WriteLine("Identity: {0}",
                  fileRule.IdentityReference.Value);
            Console.WriteLine();
         }
      }
   }
}
```

code snippet FileAccessControl/Program.cs

By running the application and passing a filename, you can see the access control list for the file. The output shown here lists full control to Administrators and System, modification rights to authenticated users, and read and execute rights to all users belonging to the group Users:

```
Access type: Allow
Rights: FullControl
Identity: BUILTIN\Administrators

Access type: Allow
Rights: FullControl
Identity: NT AUTHORITY\SYSTEM

Access type: Allow
Rights: Modify, Synchronize
Identity: NT AUTHORITY\Authenticated Users

Access type: Allow
Rights: ReadAndExecute, Synchronize
Identity: BUILTIN\Users
```

Setting access rights is very similar to reading access rights. To set access rights, several resource classes that can be secured offer the `SetAccessControl()` and `ModifyAccessControl()` methods. The sample code here modifies the access control list of a file by invoking the `SetAccessControl()` method from the `File` class. To this method a `FileSecurity` object is passed. The `FileSecurity` object is filled with `FileSystemAccessRule` objects. The access rules listed here deny write access to the Sales group, give read access to the Everyone group, and give full control to the Developers group.

This program runs on your system only if the Windows groups Sales and Developers are defined. You can change the program to use groups that are available in your environment.

```
private static void WriteAcl(string filename)
{
   var salesIdentity = new NTAccount("Sales");
   var developersIdentity = new NTAccount("Developers");
   var everyOneIdentity = new NTAccount("Everyone");

   var salesAce = new FileSystemAccessRule(salesIdentity, FileSystemRights.Write,
                                        AccessControlType.Deny);
   var everyoneAce = new FileSystemAccessRule(everyOneIdentity,
                                           FileSystemRights.Read,
                                           AccessControlType.Allow);
   var developersAce = new FileSystemAccessRule(developersIdentity,
                                             FileSystemRights.FullControl,
                                             AccessControlType.Allow);

   var securityDescriptor = new FileSecurity();
   securityDescriptor.SetAccessRule(everyoneAce);
   securityDescriptor.SetAccessRule(developersAce);
   securityDescriptor.SetAccessRule(salesAce);

   File.SetAccessControl(filename, securityDescriptor);
}
```

CODE ACCESS SECURITY

What is the importance of code access security? With role-based security, you can define what the user is allowed to do. Code access security defines what the code is allowed to do. .NET 4 simplifies this model by removing the complex policy configuration that existed up to .NET 3.5 and adding the security transparency level 2. Security transparency level existed before, but Level 2 is new with .NET 4. Security transparency makes a distinction between code that is allowed to do privileged calls (such as calling native code) and code that is not allowed to do so. The code is grouped into three categories:

➤ **Security-critical** code can run any code. This code cannot be called by transparent code.

➤ **Safe-critical** code can be called by transparent code. Security verifications are done with this code.

➤ **Transparent** code is very limited in what it can do. This code is allowed to run in a specified permission set and it runs in a sandbox. It cannot contain unsafe or unverifiable code, and cannot call security critical code.

If you write Windows applications, the restricted code permissions do not apply. Applications running on the desktop have full trust privileges and can contain any code. Sandboxing is used with Silverlight applications as well as ASP.NET applications that are hosted from a web provider, or with custom functionality, such as running add-ins with the Managed Add-In Framework.

Security Transparency Level 2

You can annotate an assembly with the attribute `SecurityRules` and set the `SecurityRuleSet.Level2` for applying the new level with .NET 4. (This is the default with .NET 4.) For backward compatibility, set it to `Level1`.

```
[assembly: SecurityRules(SecurityRuleSet.Level2)]
```

If you set the attribute `SecurityTransparent`, the complete assembly will not do anything privileged or unsafe. This assembly can only call other transparent code or safe-critical code. This attribute can be applied only to the complete assembly.

```
[assembly: SecurityTransparent()]
```

The attribute `AllowPartiallyTrustedCallers` is somewhere between transparent and the other categories. With this attribute, the code defaults to transparent, but individual types or members can have other attributes:

```
[assembly: AllowPartiallyTrustedCallers()]
```

If none of these attributes are applied, the code is security critical. However, you can apply the attribute `SecuritySafeCritical` to individual types and members to make them callable from transparent code:

```
[assembly: SecurityCritical()]
```

Permissions

If code runs inside a sandbox, the sandbox can define what the code is allowed to do by defining .NET permissions. While the full trust applies to applications running on the desktop, applications running in a sandbox are only allowed to do the actions that are defined by the permissions that the host is giving to the sandbox. You can also define permissions for an application domain that is started from a desktop application. This is done with the Sandbox API.

Application domains are discussed in Chapter 18, "Assemblies."

Permissions refer to the actions that each code group is allowed to perform (or prevented from performing). For example, permissions include "read files from the file system," "write to the Active Directory," and "use sockets to open network connections." Several predefined permissions exist, but you can also create your own permissions.

.NET permissions are independent of operating system permissions. .NET permissions are just verified by the CLR. An assembly demands a permission for a specific operation (for example, the `File` class demands the `FileIOPermission`), and the CLR verifies that the assembly has the permission granted so that it can continue.

There is a very fine-grained list of permissions that you can apply to an assembly or request from code. The following list shows a few of the code access permissions provided by the CLR; as you can see, you have great control of what code is or is not permitted to do:

- `DirectoryServicesPermission` controls the ability to access Active Directory through the `System.DirectoryServices` classes.
- `DnsPermission` controls the ability to use the TCP/IP Domain Name System (DNS).
- `EnvironmentPermission` controls the ability to read and write environment variables.
- `EventLogPermission` controls the ability to read and write to the event log.

- `FileDialogPermission` controls the ability to access files that have been selected by the user in the Open dialog box. This permission is commonly used when `FileIOPermission` is not granted to allow limited access to files.
- `FileIOPermission` controls the ability to work with files (reading, writing, and appending to files, as well as creating, altering, and accessing folders).
- `IsolatedStorageFilePermission` controls the ability to access private virtual file systems.
- `IsolatedStoragePermission` controls the ability to access isolated storage; storage that is associated with an individual user and with some aspect of the code's identity. Isolated storage is discussed in Chapter 29, "Manipulating Files and the Registry."
- `MessageQueuePermission` controls the ability to use message queues through the Microsoft Message Queue.
- `PerformanceCounterPermission` controls the ability to make use of performance counters.
- `PrintingPermission` controls the ability to print.
- `ReflectionPermission` controls the ability to discover information about a type at runtime by using `System.Reflection`.
- `RegistryPermission` controls the ability to read, write, create, or delete registry keys and values.
- `SecurityPermission` controls the ability to execute, assert permissions, call into unmanaged code, skip verification, and other rights.
- `ServiceControllerPermission` controls the ability to control Windows services.
- `SocketPermission` controls the ability to make or accept TCP/IP connections on a network transport address.
- `SQLClientPermission` controls the ability to access SQL Server databases with the .NET data provider for SQL Server.
- `UIPermission` controls the ability to access the user interface.
- `WebPermission` controls the ability to make or accept connections to or from the Web.

With each of these permission classes, it is often possible to specify an even deeper level of granularity; for example, the `DirectoryServicesPermission` allows you to differentiate between read and write access, and it also allows you to define which entries in the directory services are allowed or denied access.

Permission Sets

Permission sets are collections of permissions. With permission sets, it is not necessary to apply every single permission to code; permissions are grouped into permission sets. For example, an assembly that has FullTrust permissions has full access to all resources. With intranet permissions, the assembly is restricted; that is, it is not allowed to write to the file system other than using the isolated storage. You can create a custom permission set that includes required permissions.

By assigning the permission to code groups, there is no need to deal with every single permission. Instead, the permissions are applied in blocks, which is why .NET has the concept of permission sets. These are lists of code access permissions grouped into a named set. The following list explains the seven named permission sets you get out of the box:

- **FullTrust** means no permission restrictions.
- **SkipVerification** means that verification is not done.
- **Execution** grants the ability to run, but not to access, any protected resources.
- **Nothing** grants no permissions and prevents the code from executing.
- **LocalIntranet** specifies a subset of the full set of permissions. For example, file IO is restricted to read access on the share where the assembly originates. With .NET 3.5 and earlier editions (before .NET 3.5 SP1) this permission set was used when an application was running from a network share.

- **Internet** specifies the default policy for code of unknown origin. This is the most restrictive policy listed. For example, code executing in this permission set has no file IO capability, cannot read or write event logs, and cannot read or write environment variables.
- **Everything** grants all the permissions that are listed under this set, except the permission to skip code verification. The administrator can alter any of the permissions in this permission set. This is useful when the default policy needs to be tighter.

Note that you can change the definitions of only the Everything permission set — the other sets are fixed and cannot be changed. Of course, you can also create your own permission set.

Demanding Permissions Programmatically

An assembly can demand permissions declaratively or programmatically. The following code snippet demonstrates how permissions can be demanded with the method `DemandFileIOPermissions()`. If you import the namespace `System.Security.Permissions`, you can check for permissions by creating a `FileIOPermission` object, and calling its `Demand()` method. This verifies if the caller of the method, here the caller of the method `DemandFileIOPermissions`, has the required permissions. In case the `Demand()` method fails, an exception of type `SecurityException` is thrown. It's okay not to catch the exception and let it be handled by the caller.

```
using System;
using System.Security;
using System.Security.Permissions;

[assembly: AllowPartiallyTrustedCallers()]

namespace Wrox.ProCSharp.Security
{
    [SecuritySafeCritical]
    public class DemandPermissions
    {
        public void DemandFileIOPermissions(string path)
        {
            var fileIOPermission = new FileIOPermission(PermissionState.Unrestricted);
            fileIOPermission.Demand();

            //...
        }
    }
}
```

code snippet DemandPermissionDemo/DemandPermissions.cs

`FileIOPermission` is contained within the `System.Security.Permissions` namespace, which is home to the full set of permissions and also provides classes for declarative permission attributes and enumerations for the parameters that are used to create permissions objects (for example, creating a `FileIOPermission` specifying whether read-only or full access is needed).

To catch exceptions thrown by the CLR when code attempts to act contrary to its granted permissions, you can catch the exception of the type `SecurityException`, which provides access to a number of useful pieces of information, including a human-readable stack trace (`SecurityException.StackTrace`) and a reference to the method that threw the exception (`SecurityException.TargetSite`). `SecurityException` even provides you with the `SecurityException.PermissionType` property, which returns the type of `Permission` object that caused the security exception to occur.

If you just use the .NET classes for file I/O you don't have to demand the FileIOPermission yourself as this is demanded by the .NET classes doing file I/O. However, you need to make the demand yourself if you wrap native API calls such as CreateFileTransacted(). Also, you can use this mechanism to demand custom permissions from the caller.

Using the Sandbox API to Host Unprivileged Code

By default, with a desktop application, the application has full trust. Using the Sandbox API, you can create an app-domain that doesn't have full trust.

To see the Sandbox API in action, first create a C# library project named RequireFileIOPermissionsDemo. This library contains the class RequirePermissionsDemo with the method RequireFilePermissions(). This method returns true or false, depending on whether the code has file permissions. With the implementation of this code, the File class creates a file where the path is passed with the argument variable path. In case writing the file fails, an exception of type SecurityException is thrown. The File class checks for the FileIOSecurity as you saw earlier with the DemandPermissonDemo sample. If the security check fails, a SecurityException is thrown by the Demand() method of the FileIOSecurity class. Here, the SecurityException is caught to return false from the RequireFilePermissions() method.

```
using System;
using System.IO;
using System.Security;

[assembly: AllowPartiallyTrustedCallers()]

namespace Wrox.ProCSharp.Security
{
    [SecuritySafeCritical]
    public class RequirePermissionsDemo : MarshalByRefObject
    {
        public bool RequireFilePermissions(string path)
        {
            bool accessAllowed = true;

            try
            {
                StreamWriter writer = File.CreateText(path);
                writer.WriteLine("written successfully");
                writer.Close();
            }
            catch (SecurityException)
            {
                accessAllowed = false;
            }

            return accessAllowed;
        }
    }
}
```

code snippet RequireFileIOPermissionsDemo/RequirePermissionsDemo.cs

The hosting application where the Sandbox API is used is the project AppDomainHost that is a simple C# console application. The Sandbox API is an overload of the AppDomain.CreateDomain() method that creates a new app-domain in a sandbox. This method requires four parameters including the name of the app-domain, the evidence that is taken from the current app-domain, the AppDomainSetup information, and a permission set. The permission set that is created only contains SecurityPermission with the flag SecurityPermissionFlag.Execution so that the code is allowed to execute — nothing more. In the new sandboxed app-domain, the object of type DemandPermissions in the assembly DemandPermission is instantiated.

Calling across app-domains requires .NET Remoting. That's why the class `RequirePermissionsDemo` needs to derive from the base class `MarshalByRefObject`. Unwrapping the returned `ObjectHandle` returns a transparent proxy to the object in the other app-domain to invoke the method `RequireFilePermissions()`.

```
using System;
using System.Runtime.Remoting;
using System.Security;
using System.Security.Permissions;

namespace Wrox.ProCSharp.Security
{
    class Program
    {
        static void Main()
        {
            PermissionSet permSet = new PermissionSet(PermissionState.None);
            permSet.AddPermission(new SecurityPermission(
                SecurityPermissionFlag.Execution));

            AppDomainSetup setup = AppDomain.CurrentDomain.SetupInformation;
            AppDomain newDomain = AppDomain.CreateDomain(
                "Sandboxed domain", AppDomain.CurrentDomain.Evidence, setup, permSet);
            ObjectHandle oh = newDomain.CreateInstance("RequireFileIOPermissionsDemo",
                                  "Wrox.ProCSharp.Security.RequirePermissionsDemo");
            object o = oh.Unwrap();
            var io = o as RequirePermissionsDemo;
            string path = @"c:\temp\file.txt";
            Console.WriteLine("has {0}permissions to write to {1}",
                                  io.RequireFilePermissions(path) ? null : "no ",
                                  path);
        }
    }
}
```

code snippet AppDomainHost/Program.cs

Running the application you can see the result that the called assembly doesn't have permissions to create the file. If you add the `FileIOPermissionSet` to the permission set of the created appdomain as shown with the following code change, writing the file succeeds.

```
            PermissionSet permSet = new PermissionSet(PermissionState.None);
            permSet.AddPermission(new SecurityPermission(
                SecurityPermissionFlag.Execution));
            permSet.AddPermission(new FileIOPermission(
                FileIOPermissionAccess.AllAccess, "c:/temp"));
```

Implicit Permissions

When permissions are granted, there is often an implicit statement that you are also granted other permissions. For example, if you assign the `FileIOPermission` for `C:\`, there is an implicit assumption that there is also access to its subdirectories.

To check whether a granted permission implicitly brings another permission as a subset, you can do this:

```
class Program
{
   static void Main()
```

```
            {
               CodeAccessPermission permissionA =
                  new FileIOPermission(FileIOPermissionAccess.AllAccess, @"C:\");
               CodeAccessPermission permissionB =
                  new FileIOPermission(FileIOPermissionAccess.Read, @"C:\temp");
               if (permissionB.IsSubsetOf(permissionA))
               {
                  Console.WriteLine("PermissionB is a subset of PermissionA");
               }
            }
         }
```

code snippet ImplicitPermissions/Program.cs

The output looks like this:

```
PermissionB is a subset of PermissionA
```

DISTRIBUTING CODE USING CERTIFICATES

You can make use of digital certificates and sign assemblies so that consumers of the software can verify the identity of the software publisher. Depending on where the application is used, certificates may be required. For example, with ClickOnce the user installing the application can verify the certificate to trust the publisher. Using Windows Error Reporting, Microsoft uses the certificate to find out which vendor to map to the error report.

ClickOnce is explained in Chapter 17, "Deployment." Windows Error Reporting is discussed in Appendix A, "Guidelines for Windows 7 and Windows Server 2008 R2."

In a commercial environment, you would obtain a certificate from a company such as Verisign or Thawte. The advantage of buying a certificate from a supplier instead of creating your own is that it provides a high level of trust in the authenticity of the certificate; the supplier acts as a trusted third party. For test purposes, however, .NET includes a command-line utility you can use to create a test certificate. The process of creating certificates and using them for publishing software is complex, but we walk through a simple example in this section.

The example code is for a fictitious company called ABC Corporation. The company's software product (simple.exe) should be trusted. First, create a test certificate by typing the following command:

```
makecert -sv abckey.pvk -r -n "CN=ABC Corporation" abccorptest.cer
```

The command creates a test certificate under the name ABC Corporation and saves it to a file called `abccorptest.cer`. The `-sv abckey.pvk` argument creates a key file to store the private key. When creating the key file, you are asked for a password that you should remember.

After creating the certificate, you can create a software publisher test certificate with the Software Publisher Certificate Test tool (`Cert2spc.exe`):

```
>cert2spc abccorptest.cer abccorptest.spc
```

With a certificate that is stored in an `spc` file and the key file that is stored in a `pvk` file, you can create a `pfx` file that contains both with the `pvk2pfx` utility:

```
>pvk2pfx -pvk abckey.pvk -spc abccorptest.spc -pfx abccorptest.pfx
```

Now the assembly can be signed with the `signtool.exe` utility. The `sign` option is used for signing, `-f` specifies the certificate in the pfx file, and `-v` is for verbose output:

```
>signtool sign -f abccorptest.pfx -v simple.exe
```

To establish trust for the certificate, install it with the Trusted Root Certification Authorities and the Trusted Publishers using the Certificate Manager `certmgr` or the MMC snap-in Certificates. Then you can verify the successful signing with the `signtool`:

```
>signtool verify -v -a simple.exe
```

SUMMARY

This chapter covered several aspects of security with .NET applications. Authentication and authorization with role-based security allow you to decide in the application which users are allowed to access application features. Users are represented by identities and principals, classes that implement the interface `IIdentity` and `IPrincipal`. Role verification can be done within the code but also in a simple way using attributes.

Cryptography was shown to demonstrate signing and encrypting of data, to exchange keys in a secure way. .NET offers several cryptography algorithms offering both symmetric and asymmetric algorithms.

With access control lists, you have also seen how to read and modify access to operating system resources such as files. Programming ACLs is done in ways similar to the programming of secure pipes, registry keys, Active Directory entries, and many other operating system resources.

If your applications are used in different regions and with different languages, in the next chapter you can read about globalization and localization features of .NET.

22 Localization

WHAT'S IN THIS CHAPTER?

- ➤ Using classes that represent cultures and regions
- ➤ Globalization of applications
- ➤ Localization of applications

NASA's Mars Climate Orbiter was lost on September 23, 1999, at a cost of $125 million, because one engineering team used metric units, while another one used inches for a key spacecraft operation. When writing applications for international distribution, different cultures and regions must be kept in mind.

Different cultures have diverging calendars and use different number and date formats. Also, sorting strings may lead to various results because the order of A–Z is defined differently based on the culture. To make applications fit for global markets, you have to globalize and localize them.

This chapter covers the globalization and localization of .NET applications. *Globalization* is about internationalizing applications: preparing applications for international markets. With globalization, the application supports number and date formats that vary depending on culture, calendars, and so on. *Localization* is about translating applications for specific cultures. For translations of strings, you can use resources such .NET resources or WPF resource dictionaries.

.NET supports the globalization and localization of Windows and Web applications. To globalize an application, you can use classes from the namespace `System.Globalization`; to localize an application, you can use resources that are supported by the namespace `System.Resources`.

NAMESPACE SYSTEM.GLOBALIZATION

The `System.Globalization` namespace holds all the culture and region classes necessary to support different date formats, different number formats, and even different calendars that are represented in classes such as `GregorianCalendar`, `HebrewCalendar`, `JapaneseCalendar`, and so on. By using these classes, you can display different representations according to the user's locale.

This section looks at the following issues and considerations with using the `System.Globalization` namespace:

- Unicode issues
- Cultures and regions
- An example showing all cultures and their characteristics
- Sorting

Unicode Issues

A Unicode character has 16 bits, so there is room for 65,536 characters. Is this enough for all languages currently used in information technology? In the case of the Chinese language, for example, more than 80,000 characters are needed. However, Unicode has been designed to deal with this issue. With Unicode you have to differentiate between base characters and combining characters. You can add multiple combining characters to a base character to build up a single display character or a text element.

Take, for example, the Icelandic character Ogonek. Ogonek can be combined by using the base character 0x006F (Latin small letter o) and the combining characters 0x0328 (combining Ogonek) and 0x0304 (combining Macron) as shown in Figure 22-1. Combining characters are defined within ranges from 0x0300 to 0x0345. For American and European markets, predefined characters exist to facilitate dealing with special characters. The character Ogonek is also defined by the predefined character 0x01ED.

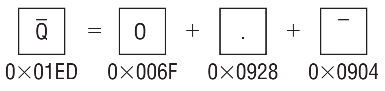

FIGURE 22-1

For Asian markets, where more than 80,000 characters are necessary for Chinese alone, such predefined characters do not exist. In Asian languages, you always have to deal with combining characters. The problem is getting the right number of display characters or text elements, and getting to the base characters instead of the combined characters. The namespace `System.Globalization` offers the class `StringInfo`, which you can use to deal with this issue.

The following table lists the static methods of the class `StringInfo` that help in dealing with combined characters.

METHOD	DESCRIPTION
`GetNextTextElement()`	Returns the first text element (base character and all combining characters) of a specified string
`GetTextElementEnumerator()`	Returns a `TextElementEnumerator` object that allows iterating all text elements of a string
`ParseCombiningCharacters()`	Returns an integer array referencing all base characters of a string

Cultures and Regions

The world is divided into multiple cultures and regions, and applications have to be aware of these cultural and regional differences. A culture is a set of preferences based on a user's language and cultural habits. RFC 1766 (`www.ietf.org/rfc/rfc1766.txt`) defines culture names that are used worldwide, depending on a language and a country or region. Some examples are en-AU, en-CA, en-GB, and en-US for the English language in Australia, Canada, the United Kingdom, and the United States, respectively.

Possibly the most important class in the `System.Globalization` namespace is `CultureInfo`. `CultureInfo` represents a culture and defines calendars, formatting of numbers and dates, and sorting strings used with the culture.

The class `RegionInfo` represents regional settings (such as the currency) and shows whether the region is using the metric system. Some regions can use multiple languages. One example is the region of Spain, which has Basque (eu-ES), Catalan (ca-ES), Spanish (es-ES), and Galician (gl-ES) cultures. Similar to one region having multiple languages, one language can be spoken in different regions; for example, Spanish is spoken in Mexico, Spain, Guatemala, Argentina, and Peru, to name only a few countries.

Later in this chapter, you see a sample application that demonstrates these characteristics of cultures and regions.

Specific, Neutral, and Invariant Cultures

When using cultures in the .NET Framework, you have to differentiate between three types: *specific, neutral*, and *invariant* cultures.

A specific culture is associated with a real, existing culture defined with RFC 1766, as you saw in the preceding section. A specific culture can be mapped to a neutral culture. For example, de is the neutral culture of the specific cultures de-AT, de-DE, de-CH, and others. de is shorthand for the German language (Deutsch); AT, DE, and CH are shorthand for the countries Austria, Germany, and Switzerland, respectively.

When translating applications, it is typically not necessary to do translations for every region; not much difference exists between the German language in the countries Austria and Germany. Instead of using specific cultures, you can use a neutral culture to localize applications.

The invariant culture is independent of a real culture. When storing formatted numbers or dates in files, or sending them across a network to a server, using a culture that is independent of any user settings is the best option.

Figure 22-2 shows how the culture types relate to each other.

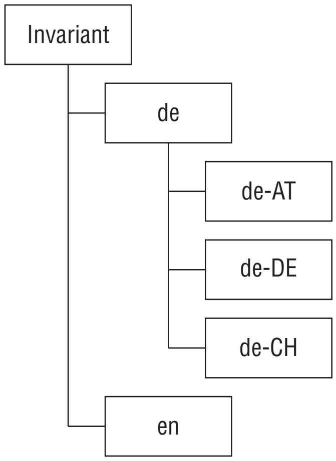

FIGURE 22-2

CurrentCulture and CurrentUICulture

When you set cultures, you need to differentiate between a culture for the user interface and a culture for the number and date formats. Cultures are associated with a thread, and with these two culture types, two culture settings can be applied to a thread. The `Thread` class has the properties `CurrentCulture` and `CurrentUICulture`. The property `CurrentCulture` is for setting the culture that is used with formatting and sort options, whereas the property `CurrentUICulture` is used for the language of the user interface.

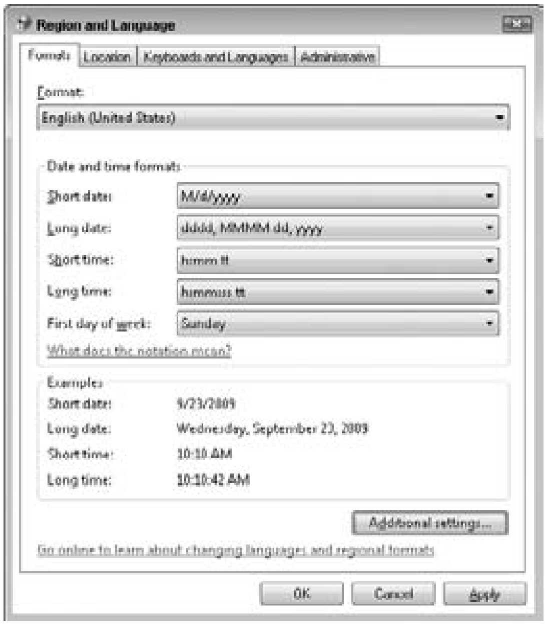
Users can change the default setting of the `CurrentCulture` by using the Regional and Language options in the Windows Control Panel (see Figure 22-3). With this configuration, it is also possible to change the default number, the time, and the date format for the culture.

The `CurrentUICulture` does not depend on this configuration. The `CurrentUICulture` setting depends on the language of the operating system. There is one exception, though: If a multi-language user interface (MUI) is installed with Windows 7, Windows Vista or Windows XP, it is possible to change the language of the user interface with the regional configuration, and this influences the property `CurrentUICulture`.

These settings make a very good default, and in many cases, there is no need to change the default behavior. If the culture should be changed, you can easily do this by changing both cultures of the thread to, say, the Spanish culture, as shown in this code snippet:

```
System.Globalization.CultureInfo ci = new
   System.Globalization.CultureInfo("es-ES");
System.Threading.Thread.CurrentThread.CurrentCulture = ci;
System.Threading.Thread.CurrentThread.CurrentUICulture = ci;
```

Now that you know about setting the culture, the following sections discuss number and date formatting, which are influenced by the `CurrentCulture` setting.



Format:
English (United States)

Date and time formats
Short date: M/d/yyyy
Long date: dddd, MMMM dd, yyyy
Short time: h:mm tt
Long time: h:mm:ss tt
First day of week: Sunday

Examples
Short date: 9/23/2009
Long date: Wednesday, September 23, 2009
Short time: 10:10 AM
Long time: 10:10:42 AM

FIGURE 22-3

Number Formatting

The number structures `Int16`, `Int32`, `Int64`, and so on in the `System` namespace have an overloaded `ToString()` method. This method can be used to create a different representation of the number, depending on the locale. For the `Int32` structure, `ToString()` is overloaded with these four versions:

```
public string ToString();
public string ToString(IFormatProvider);
public string ToString(string);
public string ToString(string,
IFormatProvider);
```

`ToString()` without arguments returns a string without format options. You can also pass a string and a class that implements `IFormatProvider`.

The string specifies the format of the representation. The format can be a standard numeric formatting string or a picture numeric formatting string. For standard numeric formatting, strings are predefined in which `C` specifies the currency notation, `D` creates a decimal output, `E` creates scientific output, `F` creates fixed-point output, `G` creates general output, `N` creates number output, and `X` creates hexadecimal output. With a picture numeric formatting string, it is possible to specify the number of digits, section and group separators, percent notation, and so on. The picture numeric format string `###,###` means two 3-digit blocks separated by a group separator.

The `IFormatProvider` interface is implemented by the `NumberFormatInfo`, `DateTimeFormatInfo`, and `CultureInfo` classes. This interface defines a single method, `GetFormat()`, that returns a format object.

`NumberFormatInfo` can be used to define custom formats for numbers. With the default constructor of `NumberFormatInfo`, a culture-independent or invariant object is created. Using the properties of `NumberFormatInfo`, it is possible to change all the formatting options, such as a positive sign, a percent symbol, a number group separator, a currency symbol, and a lot more. A read-only culture-independent `NumberFormatInfo` object is returned from the static property `InvariantInfo`. A `NumberFormatInfo` object in which the format values are based on the `CultureInfo` of the current thread is returned from the static property `CurrentInfo`.

To create the next example, you can start with a simple console project. In this code, the first example shows a number displayed in the format of the culture of the thread (here: English-US, the setting of the operating system). The second example uses the `ToString()` method with the `IFormatProvider` argument. `CultureInfo` implements `IFormatProvider`, so create a `CultureInfo` object using the French culture. The third example changes the culture of the thread. The culture is changed to German by using the property `CurrentCulture` of the `Thread` instance:

```
using System;
using System.Globalization;
using System.Threading;

namespace NumberAndDateFormatting
{
    class Program
```

```
        {
            static void Main(string[] args)
            {
                NumberFormatDemo();
            }

            private static void NumberFormatDemo()
            {
                int val = 1234567890;

                // culture of the current thread
                Console.WriteLine(val.ToString("N"));

                // use IFormatProvider
                Console.WriteLine(val.ToString("N", new CultureInfo("fr-FR")));

                // change the culture of the thread
                Thread.CurrentThread.CurrentCulture = new CultureInfo("de-DE");
                Console.WriteLine(val.ToString("N"));
            }
        }
    }
```

code snippet NumberAndDateFormatting/Program.cs

The output is shown here. You can compare the different outputs for U.S. English, French, and German, respectively.

```
1,234,567,890.00
1 234 567 890,00
1.234.567.890,00
```

Date Formatting

The same support for numbers is available for dates. The `DateTime` structure has some methods for date-to-string conversions. The public instance methods `ToLongDateString()`, `ToLongTimeString()`, `ToShortDateString()`, and `ToShortTimeString()` create string representations using the current culture. You can use the `ToString()` method to assign a different culture:

```
public string ToString();
public string ToString(IFormatProvider);
public string ToString(string);
public string ToString(string, IFormatProvider);
```

With the string argument of the `ToString()` method, you can specify a predefined format character or a custom format string for converting the date to a string. The class `DateTimeFormatInfo` specifies the possible values. With `DateTimeFormatInfo`, the case of the format strings has a different meaning. `D` defines a long date format, `d` a short date format. Other examples of possible formats are `ddd` for the abbreviated day of the week, `dddd` for the full day of the week, `yyyy` for the year, `T` for a long time, and `t` for a short time format. With the `IFormatProvider` argument, you can specify the culture. Using an overloaded method without the `IFormatProvider` argument implies that the culture of the current thread is used:

```
            DateTime d = new DateTime(2009, 06, 02);

            // current culture
            Console.WriteLine(d.ToLongDateString());

            // use IFormatProvider
            Console.WriteLine(d.ToString("D", new CultureInfo("fr-FR")));

            // use culture of thread
            CultureInfo ci = Thread.CurrentThread.CurrentCulture;
            Console.WriteLine("{0}: {1}", ci.ToString(), d.ToString("D"));
            ci = new CultureInfo("es-ES");
            Thread.CurrentThread.CurrentCulture = ci;
            Console.WriteLine("{0}: {1}", ci.ToString(), d.ToString("D"));
```

The output of this example program shows `ToLongDateString()` with the current culture of the thread, a French version where a `CultureInfo` instance is passed to the `ToString()` method, and a Spanish version where the `CurrentCulture` property of the thread is changed to es-ES:

```
Tuesday, June 02, 2009
mardi 2 juin 2009
en-US: Tuesday, June 02, 2009
es-ES: martes, 02 de junio de 2009
```

Cultures in Action

To see all cultures in action, you can use a sample Windows Presentation Foundation (WPF) application that lists all cultures and demonstrates different characteristics of culture properties. Figure 22-4 shows the user interface of the application in the Visual Studio 2010 WPF Designer.

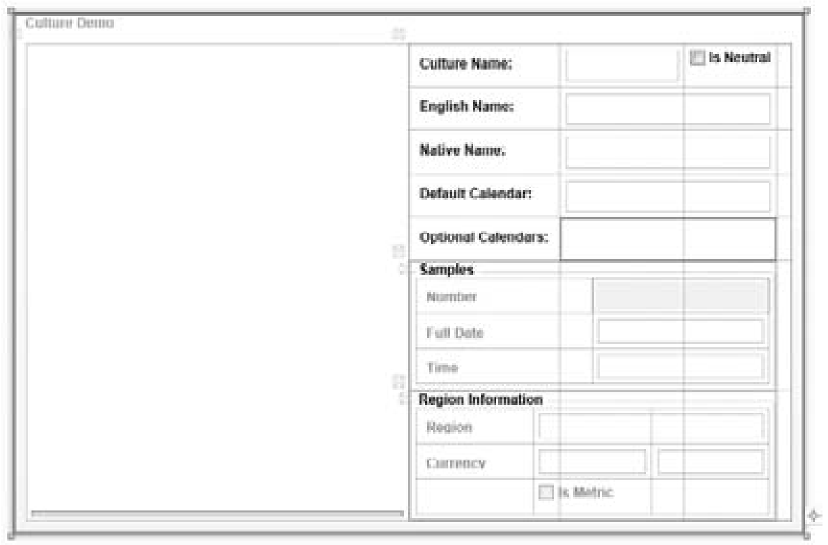


FIGURE 22-4

During initialization of the application, all available cultures are added to the tree view control that is placed on the left side of the application. This initialization happens in the method `AddCulturesToTree()`, which is called in the constructor of the `Window` class `CultureDemoWindow`:

```
        public CultureDemoWindow()
        {
           InitializeComponent();

           AddCulturesToTree();
        }
```

code snippet CultureDemo/MainWindow.xaml.cs

In the method `AddCulturesToTree()`, you get all cultures from the static method `CultureInfo .GetCultures()`. Passing `CultureTypes.AllCultures` to this method returns an unsorted array of all available cultures. The array is sorted using a Lambda expression that is passed to the `Comparison` delegate of the second argument of the `Array.Sort()` method. Next, in the `foreach` loop, every single culture is added to the tree view. A `TreeViewItem` object is created for every single culture because the WPF `TreeView` class uses TreeViewItem objects for display. The Tag property of the TreeViewItem object is set to the CultureInfo object, so that you can access the CultureInfo object at a later time from within the tree.

Where the TreeViewItem is added inside the tree depends on the culture type. If the culture does not have a parent culture, it is added to the root nodes of the tree. To find parent cultures, all cultures are remembered inside a dictionary. Recall Chapter 10, "Collections," for more information about dictionaries and Chapter 8, "Delegates, Lambdas, and Events," for Lambda expressions.

```
// add all cultures to the tree view
public void AddCulturesToTree()
{
   var culturesByName = new Dictionary<string, TreeViewItem>();

   // get all cultures
   var cultures = CultureInfo.GetCultures(CultureTypes.AllCultures);
   Array.Sort(cultures, (c1, c2) = c1.Name.CompareTo(c2.Name));

   var nodes = new TreeViewItem[cultures.Length];

   int i = 0;
   foreach (var ci in cultures)
   {
      nodes[i] = new TreeViewItem();
      nodes[i].Header = ci.DisplayName;
      nodes[i].Tag = ci;
      culturesByName.Add(ci.Name, nodes[i]);

      TreeViewItem parent;
      if (!String.IsNullOrEmpty(ci.Parent.Name) &&
            culturesByName.TryGetValue(ci.Parent.Name, out parent))
      {
         parent.Items.Add(nodes[i]);
      }
      else
      {
         treeCultures.Items.Add(nodes[i]);
      }
      i++;
   }
}
```

When the user selects a node inside the tree, the handler of the SelectedItemChanged event of the TreeView will be called. Here the handler is implemented in the method TreeCultures_SelectedItemChanged(). Within this method, all fields are cleared by calling the method ClearTextFields() before you get the CultureInfo object from the tree by selecting the Tag property of the TreeViewItem. Then some text fields are set using the properties Name, NativeName, and EnglishName of the CultureInfo object. If the CultureInfo is a neutral culture that can be queried with the IsNeutralCulture property, the corresponding check box will be set:

```
private void TreeCultures_SelectedItemChanged(object sender,
                RoutedPropertyChangedEventArgs<object> e)
{
   ClearTextFields();

   // get CultureInfo object from tree
   CultureInfo ci = (CultureInfo)((TreeViewItem)e.NewValue).Tag;

   textCultureName.Text = ci.Name;
   textNativeName.Text = ci.NativeName;
   textEnglishName.Text = ci.EnglishName;

   checkIsNeutral.IsChecked = ci.IsNeutralCulture;
```

Next you get the calendar information about the culture. The `Calendar` property of the `CultureInfo` class returns the default `Calendar` object for the specific culture. Because the `Calendar` class doesn't have a property to tell its name, you use the `ToString()` method of the base class to get the name of the class, and remove the namespace of this string to be displayed in the text field `textCalendar`.

Because a single culture might support multiple calendars, the `OptionalCalendars` property returns an array of additional supported `Calendar` objects. These optional calendars are displayed in the list box `listCalendars`. The `GregorianCalendar` class that derives from `Calendar` has an additional property called `CalendarType` that lists the type of the Gregorian calendar. This type can be a value of the enumeration `GregorianCalendarTypes`: `Arabic`, `MiddleEastFrench`, `TransliteratedFrench`, `USEnglish`, or `Localized`, depending on the culture. With Gregorian calendars, the type is also displayed in the list box:

```
// default calendar
textCalendar.Text = ci.Calendar.ToString().
                        Remove(0, 21).Replace("Calendar", "");

// fill optional calendars
listCalendars.Items.Clear();
foreach (Calendar optCal in ci.OptionalCalendars)
{
   StringBuilder calName = new StringBuilder(50);
   calName.Append(optCal.ToString());
   calName.Remove(0, 21);
   calName.Replace("Calendar", "");

   // for GregorianCalendar add type information
   GregorianCalendar gregCal = optCal as GregorianCalendar;
   if (gregCal != null)
   {
      calName.AppendFormat(" {0}", gregCal.CalendarType.ToString());
   }
   listCalendars.Items.Add(calName.ToString());
}
```

code snippet CultureDemo/MainWindow.xaml.cs

Next, you check whether the culture is a specific culture (not a neutral culture) by using `!ci.IsNeutralCulture` in an `if` statement. The method `ShowSamples()` displays number and date samples. This method is implemented in the next code section. The method `ShowRegionInformation()` is used to display some information about the region. With the invariant culture, you can display only number and date samples, but no region information. The invariant culture is not related to any real language, and therefore it is not associated with a region:

```
// display number and date samples
if (!ci.IsNeutralCulture)
{
   groupSamples.IsEnabled = true;
   ShowSamples(ci);

   // invariant culture doesn't have a region
   if (String.Compare(ci.ThreeLetterISOLanguageName, "IVL", true) == 0)
   {
      groupRegion.IsEnabled = false;
   }
   else
   {
      groupRegion.IsEnabled = true;
      ShowRegionInformation(ci.Name);
   }
}
else // neutral culture: no region, no number/date formatting
```

```
         {
            groupSamples.IsEnabled = false;
            groupRegion.IsEnabled = false;
         }
      }
```

To show some localized sample numbers and dates, the selected object of type `CultureInfo` is passed with the `IFormatProvider` argument of the `ToString()` method:

```
      private void ShowSamples(CultureInfo ci)
      {
         double number = 9876543.21;
         textSampleNumber.Text = number.ToString("N", ci);

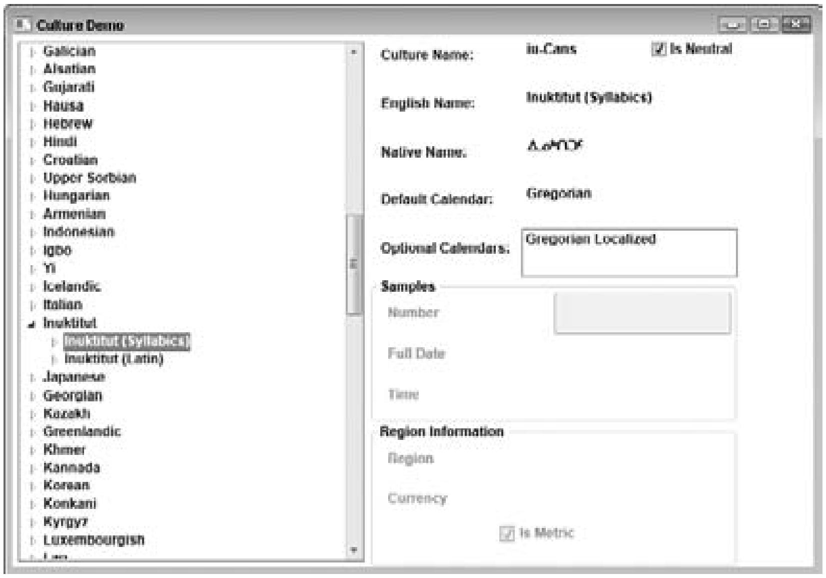
         DateTime today = DateTime.Today;
         textSampleDate.Text = today.ToString("D", ci);

         DateTime now = DateTime.Now;
         textSampleTime.Text = now.ToString("T", ci);
      }
```

To display the information associated with a `RegionInfo` object, in the method `ShowRegionInformation()` a `RegionInfo` object is constructed, passing the selected culture identifier. Then you access the `DisplayName`, `CurrencySymbol`, `ISOCurrencySymbol`, and `IsMetric` properties to display this information:

```
      private void ShowRegionInformation(string culture)
      {
         var ri = new RegionInfo(culture);
         textRegion.Text = ri.DisplayName;
         textCurrency.Text = ri.CurrencySymbol;
         textCurrencyISO.Text = ri.ISOCurrencySymbol;
         checkIsMetric.IsChecked = ri.IsMetric;
      }
```

When you start the application, you can see all available cultures in the tree view, and selecting a culture lists the cultural characteristics, as shown in Figure 22-5.



Culture Name: iu-Cans ☑ Is Neutral

English Name: Inuktitut (Syllabics)

Native Name: ᐃᓄᒃᑎᑐᑦ

Default Calendar: Gregorian

Optional Calendars: Gregorian Localized

☑ Is Metric

FIGURE 22-5

Sorting

Sorting strings is dependent on the culture. Some cultures have different sorting orders. One example is Finnish, where the characters V and W are treated the same. The algorithms that compare strings for sorting by default use a culture-sensitive sort, in which the sort is dependent on the culture.

To demonstrate this behavior with a Finnish sort, the following code creates a small sample console application where some U.S. states are stored unsorted inside an array. You are going to use classes from the namespaces `System.Collections.Generic`, `System.Threading`, and `System.Globalization`, so these namespaces must be declared. The method `DisplayNames()` shown here is used to display all elements of an array or of a collection on the console:

```
static void DisplayNames(string title, IEnumerable<string> e)
{
   Console.WriteLine(title);
   foreach (string s in e)
      Console.Write(s + "-");
   Console.WriteLine();
   Console.WriteLine();
}
```

code snippet SortingDemo/Program.cs

In the `Main()` method, after creating the array with some of the U.S. states, the thread property `CurrentCulture` is set to the Finnish culture, so that the following `Array.Sort()` uses the Finnish sort order. Calling the method `DisplayNames()` displays all the states on the console:

```
static void Main()
{
   string[] names = {"Alabama", "Texas", "Washington",
                     "Virginia", "Wisconsin", "Wyoming",
                     "Kentucky", "Missouri", "Utah", "Hawaii",
                     "Kansas", "Louisiana", "Alaska", "Arizona"};

   Thread.CurrentThread.CurrentCulture =
      new CultureInfo("fi-FI");

   Array.Sort(names);
   DisplayNames("Sorted using the Finnish culture", names);
```

After the first display of some U.S. states in the Finnish sort order, the array is sorted once again. If you want to have a sort that is independent of the users' culture, which would be useful when the sorted array is sent to a server or stored somewhere, you can use the invariant culture.

You can do this by passing a second argument to `Array.Sort()`. The `Sort()` method expects an object implementing `IComparer` with the second argument. The `Comparer` class from the `System.Collections` namespace implements `IComparer`. `Comparer.DefaultInvariant` returns a `Comparer` object that uses the invariant culture for comparing the array values for a culture-independent sort:

```
   // sort using the invariant culture
   Array.Sort(names, System.Collections.Comparer.DefaultInvariant);
   DisplayNames("Sorted using the invariant culture", names);
}
```

The program output shows different sorts with the Finnish and the culture-independent cultures: Virginia goes before Washington when using the invariant sort order and vice versa when using Finnish.

```
Sorted using the Finnish culture
Alabama-Alaska-Arizona-Hawaii-Kansas-Kentucky-Louisiana-Missouri-Texas-Utah-
Washington-Virginia-Wisconsin-Wyoming -

Sorted using the invariant culture
Alabama-Alaska-Arizona-Hawaii-Kansas-Kentucky-Louisiana-Missouri-Texas-Utah-
Virginia-Washington-Wisconsin-Wyoming -
```

If sorting a collection should be independent of a culture, the collection must be sorted with the invariant culture. This can be particularly useful when sending the sort result to a server or storing it inside a file.

In addition to a locale-dependent formatting and measurement system, text and pictures may differ depending on the culture. This is where resources come into play.

RESOURCES

Resources such as pictures or string tables can be put into resource files or satellite assemblies. Such resources can be very helpful when localizing applications, and .NET has built-in support to search for localized resources.

Before you see how to use resources to localize applications, the next sections discuss how resources can be created and read without looking at language aspects.

Creating Resource Files

Resource files can contain items such as pictures and string tables. A resource file is created by using either a normal text file or a `.resX` file that uses XML. This section starts with a simple text file.

A resource that embeds a string table can be created by using a normal text file. The text file just assigns strings to keys. The key is the name that can be used from a program to get the value. Spaces are allowed in both keys and values.

This example shows a simple string table in the file `Wrox.ProCSharp.Localization.MyResources.txt`:

```
Title = Professional C#
Chapter = Localization
Author = Christian Nagel
Publisher = Wrox Press
```

code snippet Resources/Wrox.ProCSharp.Localization.MyResources.txt

When saving text files with Unicode characters, you must save the file with the proper encoding. Select the Unicode encoding with the Save dialog.

Resource File Generator

The Resource File Generator (`Resgen.exe`) utility can be used to create a resource file out of `Wrox.ProCSharp.Localization.MyResources.txt`. Typing the following line:

```
resgen Wrox.ProCSharp.Localization.MyResources.txt
```

creates the file `Wrox.ProCSharp.Localization.MyResources.resources`. The resulting resource file can either be added to an assembly as an external file or embedded into the DLL or EXE. Resgen also supports the creation of XML-based `.resX` resource files. One easy way to build an XML file is by using Resgen itself:

```
resgen Wrox.ProCSharp.Localization.MyResources.txt Wrox.ProCSharp.Localization.MyResources.resX
```

This command creates the XML resource file `Wrox.ProCSharp.LocalizationMyResources.resX`. You see how to work with XML resource files in the section "Windows Forms Localization Using Visual Studio" later in this chapter.

Resgen supports strongly typed resources. A strongly typed resource is represented by a class that accesses the resource. The class can be created with the `/str` option of the Resgen utility:

```
resgen /str:C#,Wrox.ProCSharp.Localization,MyResources,MyResources.cs
Wrox.ProCSharp.Localization.MyResources.resX
```

With the option `/str`, the language, namespace, class name, and the filename for the source code are defined in that order.

The Resgen utility does not support adding pictures. With the .NET Framework SDK samples, you get a ResXGen sample with the tutorials. With ResXGen, it is possible to reference pictures in a `.resX` file. Adding pictures can also be done programmatically by using the `ResourceWriter` or `ResXResourceWriter` classes, as you will see next.

ResourceWriter

Instead of using the Resgen utility to build resource files, it's a simple task to write a program to create resources. The class `ResourceWriter` from the namespace `System.Resources` can be used to write binary resource files; `ResXResourceWriter` writes XML-based resource files. Both of these classes support pictures and any other object that is serializable. When you use the class `ResXResourceWriter`, the assembly `System.Windows.Forms` must be referenced.

In the following code example, you create a `ResXResourceWriter` object, *rw*, using a constructor with the filename `Demo.resx`. After creating an instance, you can add a number of resources of up to 2GB in total size by using the `AddResource()` method of the `ResXResourceWriter` class. The first argument of `AddResource()` specifies the name of the resource, and the second argument specifies the value. A picture resource can be added using an instance of the `Image` class. To use the `Image` class, you have to reference the assembly `System.Drawing`. You also add the `using` directive to open the namespace `System.Drawing`.

Create an `Image` object by opening the file `logo.gif`. You will have to copy the picture to the directory of the executable or specify the full path to the picture in the method argument of `Image.ToFile()`. The `using` statement specifies that the image resource should automatically be disposed of at the end of the using block. Additional simple string resources are added to the `ResXResourceWriter` object. The `Close()` method of the `ResXResourceWriter` class automatically calls `ResXResourceWriter.Generate()` to finally write the resources to the file `Demo.resx`:

```
using System;
using System.Resources;
using System.Drawing;

class Program
{
   static void Main()
   {
      var rw = new ResXResourceWriter("Demo.resx");
      using (Image image = Image.FromFile("logo.gif"))
      {
         rw.AddResource("WroxLogo", image);
         rw.AddResource("Title", "Professional C#");
         rw.AddResource("Chapter", "Localization");
         rw.AddResource("Author", "Christian Nagel");
         rw.AddResource("Publisher", "Wrox Press");
         rw.Close();
      }
   }
}
```

code snippet CreateResource/Program.cs

Starting this small program creates the resource file `Demo.resx`, which embeds the image `logo.gif`. In the next example, the resources will be used with a Windows application.

Using Resource Files

You can add resource files to assemblies with the command-line C# compiler `csc.exe` by using the `/resource` option, or directly with Visual Studio. To see how resource files can be used with Visual Studio, create a Console application and name it `ResourceDemo`.

Use the context menu of the Solution Explorer (Add ➪ Existing Item) to add the previously created resource file `Demo.resx` to this project. By default, Build Action of this resource is set to Embedded Resource so that this resource is embedded into the output assembly.

In the project settings (Application ➪ Assembly information), set the Neutral Language setting of the application to the main language, for example, English (United States), as shown in Figure 22-6. Changing this setting adds the attribute `[NeutralResourceLanguageAttribute]` to the file `assemblyinfo.cs`, as you can see here:

```
[assembly: NeutralResourcesLanguageAttribute("en-US")]
```

Setting this option gives a performance improvement with the `ResourceManager` because it more quickly finds the resources for en-US that are also used as a default fallback. With this attribute, you can also specify the location of the default resource by using the second parameter with the constructor. With the enumeration `UltimateResourceFallbackLocation`, you can specify that the default resource is to be stored in the main assembly or in a satellite assembly (values `MainAssembly` and `Satellite`).

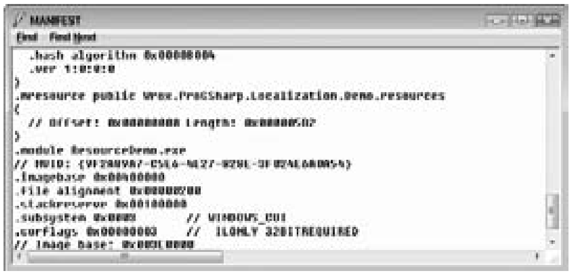
FIGURE 22-6

After building the project, you can check the generated assembly with `ildasm` to see the attribute `.mresource` in the manifest (see Figure 22-7). `.mresource` declares the name for the resource in the assembly. If `.mresource` is declared as `public` (as in the example), the resource is exported from the assembly and can be used from classes in other assemblies. `.mresource private` means that the resource is not exported and is available only within the assembly.



```
  .hash algorithm 0x00008004
  .ver 1:0:0:0
}
.mresource public Wrox.ProCSharp.Localization.Demo.resources
{
  // Offset: 0x00000000 Length: 0x000005D2
}

.subsystem 0x0003       // WINDOWS_CUI
.corflags 0x00000003    //  ILONLY 32BITREQUIRED
// Image base: 0x003E0000
```

FIGURE 22-7

To access the embedded resource, use the `ResourceManager` class from the `System.Resources` namespace. You can pass the assembly that has the resources as an argument to the constructor of the `ResourceManager` class. In this example, the resources are embedded in the executing assembly, so pass the result of `Assembly.GetExecutingAssembly()` as the second argument. The first argument is the root name of the resources. The root name consists of the namespace, with the name of the resource file but without the resources extension. As you saw earlier, `ildasm` shows the name. All you have to do is remove the file extension `resources` from the name shown. You can also get the name programmatically by using the `GetManifestResourceNames()` method of the `System.Reflection.Assembly` class:

```
using System;
using System.Drawing;
using System.Reflection;
using System.Resources;
```

```
namespace Wrox.ProCSharp.Localization
{
    class Program
    {
        static void Main()
        {
            var rm = new ResourceManager("Wrox.ProCSharp.Localization.Demo",
                                         Assembly.GetExecutingAssembly());
```

code snippet ResourceDemo/Program.cs

Using the `ResourceManager` instance *rm*, you can get all the resources by specifying the key to the methods `GetObject()` and `GetString()`:

```
            Console.WriteLine(rm.GetString("Title"));
            Console.WriteLine(rm.GetString("Chapter"));
            Console.WriteLine(rm.GetString("Author"));
            using (Image logo = (Image)rm.GetObject("WroxLogo"))
            {
                logo.Save("logo.bmp");
            }
        }
    }
}
```

With strongly typed resources, the code written earlier can be simplified; there is no need to instantiate the `ResourceManager` and access the resources using indexers. Instead, the names of the resources are accessed with properties:

```
        private static void StronglyTypedResources()
        {
            Console.WriteLine(Demo.Title);
            Console.WriteLine(Demo.Chapter);
            Console.WriteLine(Demo.Author);
            using (Bitmap logo = Demo.WroxLogo)
            {
                logo.Save("logo.bmp");
            }
        }
```

To create a strongly typed resource with the Managed Resources Editor, the Access Modifier can be reset from No Code Generation to Public or Internal. With Public, the generated class has a public access modifier and is available from other assemblies. With Internal, the generated class has an internal access modifier and can only be accessed from within the assembly.

When you set this option, the class `Demo` (it has the same name as the resource) is created. This class has static properties for all the resources to provide a strongly typed resource name. With the implementation of the static properties, a `ResourceManager` object is used that is instantiated on first access and then cached:

```
//------------------------------------------------------------------------------
// <auto-generated>
//     This code was generated by a tool.
//     Runtime Version:4.0.21006.1
//
//     Changes to this file may cause incorrect behavior and will be lost if
//     the code is regenerated.
// </auto-generated>
//------------------------------------------------------------------------------

namespace Wrox.ProCSharp.Localization {
    using System;
```

```
/// <summary>
///   A strongly-typed resource class, for looking up localized strings, etc.
/// </summary>
// This class was auto-generated by the StronglyTypedResourceBuilder
// class via a tool like ResGen or Visual Studio.
// To add or remove a member, edit your .ResX file then rerun ResGen
// with the /str option, or rebuild your VS project.

                get {
                    object obj = ResourceManager.GetObject("WroxLogo", resourceCulture);
                    return ((System.Drawing.Bitmap)(obj));
                }
            }
        }
    }
```

code snippet ResourceDemo/Demo.Designer.cs

The System.Resources Namespace

Before moving on to the next example, this section concludes with a review of the classes contained in the `System.Resources` namespace that deal with resources:

- The `ResourceManager` class can be used to get resources for the current culture from assemblies or resource files. Using the `ResourceManager`, you can also get a `ResourceSet` for a particular culture.
- A `ResourceSet` represents the resources for a particular culture. When a `ResourceSet` instance is created, it enumerates over a class, implementing the interface `IResourceReader`, and it stores all resources in a `Hashtable`.
- The interface `IResourceReader` is used from the `ResourceSet` to enumerate resources. The class `ResourceReader` implements this interface.
- The class `ResourceWriter` is used to create a resource file. `ResourceWriter` implements the interface `IResourceWriter`.
- `ResXResourceSet`, `ResXResourceReader`, and `ResXResourceWriter` are similar to `ResourceSet`, `ResourceReader`, and `ResourceWriter`; however, they are used to create an XML-based resource file, `.resX`, instead of a binary file. You can use `ResXFileRef` to make a link to a resource instead of embedding it inside an XML file.
- The namespace `System.Resources.Tools` contains the class `StronglyTypedResourceBuilder` to create a class from a resource.

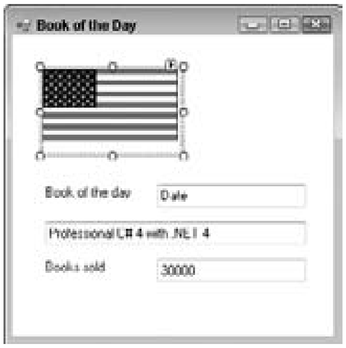
WINDOWS FORMS LOCALIZATION USING VISUAL STUDIO

In this section, you create a simple Windows Forms application that shows how to use Visual Studio 2010 for localization. This application does not use complex Windows Forms and does not have any real inner functionality because the key feature it is intended to demonstrate here is localization. In the automatically generated source code, change the namespace to `Wrox.ProCSharp.Localization` and the class name to `BookOfTheDayForm`. The namespace is not only changed in the source file `BookOfTheDayForm.cs` but also in the project settings, so that all generated resource files will get this namespace, too. You can change the namespace for all new items that are created by selecting Common Properties from the Project ➪ Properties menu.

To show some issues with localization, this program has a picture, some text, a date, and a number. The picture shows a flag that is also localized. Figure 22-8 shows this form of the application as seen in the Windows Forms Designer.

The following table lists the values for the `Name` and `Text` properties of the Windows Forms elements.

NAME	TEXT
`labelBookOfTheDay`	Book of the day
`labelItemsSold`	Books sold
`textDate`	Date
`textTitle`	Professional C#
`textItemsSold`	30000
`pictureFlag`	



Book of the day Date

Professional C# 4 with .NET 4

Books sold 30000

FIGURE 22-8

In addition to this form, you might want a message box that displays a welcome message; this message might change depending on the current time of day. This example demonstrates that the localization for dynamically created dialogs must be done differently. In the method `WelcomeMessage()`, display a message box using `MessageBox.Show()`. Call the method `WelcomeMessage()` in the constructor of the form class `BookOfTheDayForm`, before the call to `InitializeComponent()`.

Here is the code for the method `WelcomeMessage()`:

```
public void WelcomeMessage()
{
   DateTime now = DateTime.Now;
   string message;
   if (now.Hour <= 12)
   {
      message = "Good Morning";
   }
   else if (now.Hour <= 19)
   {
      message = "Good Afternoon";
   }
   else
   {
      message = "Good Evening";
   }
   MessageBox.Show(String.Format("{0}\nThis is a localization sample",
         message));
}
```

The number and date in the form should be set by using formatting options. Add a new method, `SetDateAndNumber()`, to set the values with the format option. In a real application, these values could be received from a Web service or a database, but this example is just concentrating on localization. The date is formatted using the `D` option (to display the long date name). The number is displayed using the picture number format string `###,###,###`, where `#` represents a digit and "`,`" is the group separator.

```
public void SetDateAndNumber()
{
   DateTime today = DateTime.Today;
   textDate.Text = today.ToString("D");
   int itemsSold = 327444;
   textItemsSold.Text = itemsSold.ToString("###,###,###");
}
```

code snippet BookOfTheDay/Demo.BookOfTheDayForm.cs

In the constructor of the BookOfTheDayForm class, both the WelcomeMessage() and SetDateAndNumber() methods are called:

```
public BookOfTheDayForm()
{
   WelcomeMessage();

   InitializeComponent();

   SetDateAndNumber();
}
```

A magic feature of the Windows Forms Designer is started when you set the Localizable property of the form from false to true. This results in the creation of an XML-based resource file for the dialog box that stores all resource strings, properties (including the location and size of Windows Forms elements), embedded pictures, and so on. In addition, the implementation of the InitializeComponent() method is changed; an instance of the class System.Resources.ResourceManager is created, and to get to the values and positions of the text fields and pictures, the GetObject() method is used instead of writing the values directly into the code. GetObject() uses the CurrentUICulture property of the current thread for finding the correct localization of the resources.

Here is part of InitializeComponent() from the file BookOfTheDayForm.Designer.cs before the Localizable property is set to true, where all properties of textboxTitle are set:

```
private void InitializeComponent()
{
      //...
      this.textTitle = new System.Windows.Forms.TextBox();
      //
      // textTitle
      //
      this.textTitle.Anchor = ((System.Windows.Forms.AnchorStyles)
          (((System.Windows.Forms.AnchorStyles.Top
             | System.Windows.Forms.AnchorStyles.Left)
             | System.Windows.Forms.AnchorStyles.Right)));
      this.textTitle.Location = new System.Drawing.Point(29, 164);
      this.textTitle.Name = "textTitle";
      this.textTitle.Size = new System.Drawing.Size(231, 20);
      this.textTitle.TabIndex = 3;
```

The code for the IntializeComponent() method is automatically changed by setting the Localizable property to true:

```
  private void InitializeComponent()
  {
      System.ComponentModel.ComponentResourceManager resources =
           new System.ComponentModel.ComponentResourceManager(
               typeof(BookOfTheDayForm));
      //...
      this.textTitle = new System.Windows.Forms.TextBox();
      //
      // textTitle
      //
      resources.ApplyResources(this.textTitle, "textTitle");
      this.textTitle.Name = "textTitle";
```

code snippet BookOfTheDay/Demo.BookOfTheDayForm.Designer.cs

Where does the resource manager get the data from? When the Localizable property is set to true, the resource file BookOfTheDay.resX is generated. In this file, you can find the scheme of the XML resource, followed by all elements in the form: Type, Text, Location, TabIndex, and so on.

The class ComponentResourceManager is derived from ResourceManager and offers the method ApplyResources(). With ApplyResources(), the resources that are defined with the second argument are applied to the object in the first argument.

The following XML segment shows a few of the properties of textBoxTitle: the Location property has a value of 29, 164; the Size property has a value of 231, 20; the Text property is set to Professional C# 4 with .NET 4; and so on. For every value, the type of the value is stored as well. For example, the Location property is of type System.Drawing.Point, and this class can be found in the assembly System.Drawing.

Why are the locations and sizes stored in this XML file? With translations, many strings have completely different sizes and no longer fit into the original positions. When the locations and sizes are all stored inside the resource file, everything that is needed for localization is stored in these files, separate from the C# code:

```
<data name="textTitle.Anchor" type=
    "System.Windows.Forms.AnchorStyles, System.Windows.Forms">
  <value>Top, Left, Right</value>
</data>
<data name="textTitle.Location" type="System.Drawing.Point, System.Drawing">
  <value>29, 164</value>
</data>
<data name="textTitle.Size" type="System.Drawing.Size, System.Drawing">
  <value>231, 20</value>
</data>
<data name="textTitle.TabIndex" type="System.Int32, mscorlib">
  <value>3</value>
</data>
<data name="textTitle.Text" xml:space="preserve">
  <value>Professional C# 4 with .NET 4</value>
</data>
<data name="&gt;&gt;textTitle.Name" xml:space="preserve">
  <value>textTitle</value>
</data>
<data name="&gt;&gt;textTitle.Type" xml:space="preserve">
  <value>System.Windows.Forms.TextBox, System.Windows.Forms, Version=4.0.0.0,
         Culture=neutral, PublicKeyToken=b77a5c561934e089</value>
</data>
<data name="&gt;&gt;textTitle.Parent" xml:space="preserve">
  <value>$this</value>
</data>
<data name="&gt;&gt;textTitle.ZOrder" xml:space="preserve">
  <value>2</value>
</data>
```

code snippet BookOfTheDay/BookOfTheDayForm.resx

When changing some of these resource values, it is not necessary to work directly with the XML code. You can change these resources directly in the Visual Studio Designer. Whenever you change the Language property of the form and the properties of some form elements, a new resource file is generated for the specified language. Create a German version of the form by setting the Language property to German, and a French version by setting the Language property to French. For every language, you get a resource file with the changed properties: in this case, BookOfTheDayForm.de.resX and BookOfTheDayForm.fr.resX.

The following table shows the changes needed for the German version.

GERMAN NAME	VALUE
$this.Text (title of the form)	Buch des Tages
labelItemsSold.Text	Bücher verkauft:
labelBookOfTheDay.Text	Buch des Tages:

The following table lists the changes for the French version.

FRENCH NAME	VALUE
`$this.Text` (title of the form)	Le livre du jour
`labelItemsSold.Text`	Des livres vendus:
`labelBookOfTheDay.Text`	Le livre du jour:

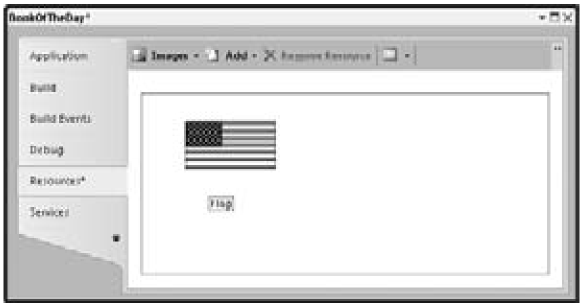


FIGURE 22-9

By default, images are not moved to satellite assemblies. However, in the sample application, the flag should be different depending on the country. To achieve this, you have to add the image of the American flag to the file `Resources.resx`. You can find this file in the Properties section of the Visual Studio Solution Explorer. With the resource editor, select the Images category, as shown in Figure 22-9, and add the file `americanflag.bmp`. To make localization with images possible, the image must have the same name in all languages. Here, the image in the file `Resources.resx` has the name Flag. You can rename the image in the properties editor. Within the properties editor, you can also change whether the image should be linked or embedded. For best performance with resources, images are linked by default. With linked images, the image file must be delivered together with the application. If you want to embed the image within the assembly, you can change the `Persistence` property to `Embedded`.

The localized versions of the flags can be added by copying the file `Resource.resx` to `Resource.de.resx` and `Resource.fr.resx` and replacing the flags with `GermanFlag.bmp` and `FranceFlag.bmp`. Because a strongly typed resource class is needed only with the neutral resource, the property `CustomTool` can be cleared with the resource files of all specific languages.

Compiling the project now creates a *satellite assembly* for each language. Inside the debug directory (or the release, depending on your active configuration), language subdirectories like `de` and `fr` are created. In such a subdirectory, you will find the file `BookOfTheDay.resources.dll`. Such a file is a satellite assembly that includes only localized resources. Opening this assembly with `ildasm`, you see a manifest with the embedded resources and a defined locale. The assembly has the locale `de` in the assembly attributes, so it can be found in the `de` subdirectory. You can also see the name of the resource with `.mresource`; it is prefixed with the namespace name `Wrox.ProCSharp.Localization`, followed by the class name `BookOfTheDayForm` and the language code `de`.

Changing the Culture Programmatically

After translating the resources and building the satellite assemblies, you will get the correct translations according to the configured culture for the user. The welcome message is not translated at this time. This needs to be done in a different way, as you'll see shortly.

In addition to the system configuration, it should be possible to send the language code as a command-line argument to your application for testing purposes. The `BookOfTheDayForm` constructor is changed to allow the passing of a culture string and the setting of the culture according to this string. A `CultureInfo` instance is created to pass it to the `CurrentCulture` and `CurrentUICulture` properties of the current thread. Remember that the `CurrentCulture` is used for formatting, and the `CurrentUICulture` is used for loading resources.

```
public BookOfTheDayForm(string culture)
{
   if (!String.IsNullOrEmpty(culture))
   {
      CultureInfo ci = new CultureInfo(culture);
      // set culture for formatting
      Thread.CurrentThread.CurrentCulture = ci;
      // set culture for resources
      Thread.CurrentThread.CurrentUICulture = ci;
   }

   WelcomeMessage();

   InitializeComponent();
   SetDateAndNumber();
}
```

code snippet BookOfTheDay/BookOfTheDayForm.cs

The `BookOfTheDayForm` is instantiated in the `Main()` method, which can be found in the file `Program.cs`. In this method, you pass the culture string to the `BookOfTheDayForm` constructor:

```
[STAThread]
static void Main(string[] args)
{
   string culture = String.Empty;
   if (args.Length == 1)
   {
       culture = args[0];
   }

   Application.EnableVisualStyles();
   Application.SetCompatibleTextRenderingDefault(false);
   Application.Run(new BookOfTheDayForm(culture));
}
```

code snippet BookOfTheDay/Program.cs

Now you can start the application by using command-line options. With the running application, you can see that the formatting options and the resources that were generated from the Windows Forms Designer show up. Figures 22-10 and 22-11 show two localizations in which the application is started with the command-line options `de-DE` and `fr-FR`, respectively.

There is still a problem with the welcome message box: the strings are hard-coded inside the program. Because these strings are not properties of elements inside the form, the Forms Designer does not extract XML resources as it does from the properties for Windows controls when changing the `Localizable` property of the form. You have to change this code yourself.

FIGURE 22-11

Using Custom Resource Messages

For the welcome message, you have to translate the hard-coded strings. The following table shows the translations for German and French. You can write custom resource messages directly in the file `Resources.resx` and the language-specific derivations. Of course, you can also create a new resource file.

NAME	ENGLISH	GERMAN	FRENCH
GoodMorning	Good Morning	Guten Morgen	Bonjour
GoodAfternoon	Good Afternoon	Guten Tag	Bonjour
GoodEvening	Good Evening	Guten Abend	Bonsoir
Message1	This is a localization sample.	Das ist ein Beispiel mit Lokalisierung.	C'est un exemple avec la localisation.

The source code of the method `WelcomeMessage()` must also be changed to use the resources. With strongly typed resources, there is no need to instantiate the `ResourceManager` class. Instead, the properties of the strongly typed resource can be used:

```
public static void WelcomeMessage()
{
   DateTime now = DateTime.Now;
   string message;
   if (now.Hour <= 12)
   {
      message = Properties.Resources.GoodMorning;
   }
   else if (now.Hour <= 19)
   {
      message = Properties.Resources.GoodAfternoon;
   }
   else
   {
      message = Properties.Resources.GoodEvening;
   }
   MessageBox.Show(String.Format("{0}\n{1}", message,
      Properties.Resources.Message1);
}
```

code snippet BookOfTheDay/BookOfTheDayForm.cs

When the program is started using English, German, or French, you will get the message box with the appropriate language.

Automatic Fallback for Resources

For the French and German versions in the example, all the resources are located inside the satellite assemblies. If you are not using these versions, then all the values of labels or text boxes are changed; this is not a problem at all. You must have only the values that will change in the satellite assembly; the other values will be taken from the parent assembly. For example, for `de-AT` (Austria), you could change the value for the *Good Afternoon* resource to *Grüß Gott* while leaving the other values intact. During runtime, when looking for the value of the resource *Good Morning*, which is not located in the `de-AT` satellite assembly, the parent assembly would be searched. The parent for `de-AT` is `de`. In cases where the `de` assembly does not have this resource either, the value would be searched for in the parent assembly of `de`, the neutral assembly. The neutral assembly does not have a culture code.

Outsourcing Translations

It is an easy task to outsource translations using resource files. It is not necessary to install Visual Studio to translate resource files; a simple XML editor will suffice. The disadvantage of using an XML editor is that there is no real chance to rearrange Windows Forms elements and change the sizes if the translated text does not fit into the original borders of a label or button. Using a Windows Forms Designer to do translations is a natural choice.

Microsoft provides a tool as part of the .NET Framework SDK that fulfills all these requirements: the Windows Resource Localization Editor, `winres.exe` (see Figure 22-12). Users working with this tool do not need access to the C# source files; only binary or XML-based resource files are needed for translations. After these translations are completed, you can import the resource files to the Visual Studio project to build satellite assemblies.

FIGURE 22-12

If you don't want your translation bureau to change the sizes and locations of labels and buttons, and they cannot deal with XML files, you can send a simple text-based file. With the command-line utility `resgen .exe`, you can create a text file from an XML file:

```
resgen myresource.resX myresource.txt
```

And after you have received the translation from the translation bureau, you can create an XML file from the returned text file. Remember to add the culture name to the filename:

```
resgen myresource.es.txt myresource.es.resX
```

LOCALIZATION WITH ASP.NET

With ASP.NET applications, localization happens in a similar way to Windows applications. Chapter 40, "Core ASP.NET," discusses the functionality of ASP.NET applications; this section discusses the localization issues of ASP.NET applications. ASP.NET 4 and Visual Studio 2010 have many features to support localization. The basic concepts of localization and globalization are the same as discussed before. However, some specific issues are associated with ASP.NET.

As you have already learned, with ASP.NET you have to differentiate between the user interface culture and the culture used for formatting. Both of these cultures can be defined on a web and page level, as well as programmatically.

To be independent of the web server's operating system, the culture and user interface culture can be defined with the `<globalization>` element in the configuration file `web.config`:

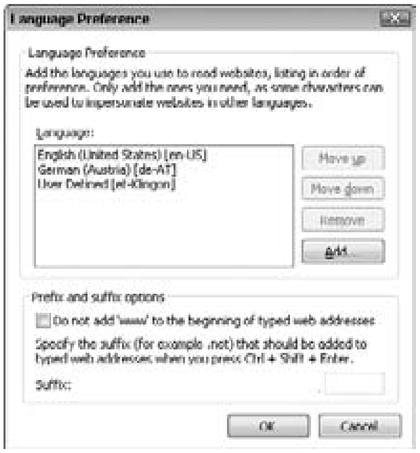
```
<configuration>
   <system.web>
      <globalization culture="en-US" uiCulture="en-US" />
   </system.web>
</configuration>
```

code snippet WebApplication/Web.config

If the configuration should be different for specific web pages, the `Page` directive allows you to assign the culture:

```
<%Page Language="C#" Culture="en-US" UICulture="en-US" %>
```

The user can configure the language with the browser. With Internet Explorer, this setting is defined with the Language Preference options (see Figure 22-13).



Language Preference

Language Preference

Add the languages you use to read websites, listing in order of preference. Only add the ones you need, as some characters can be used to impersonate websites in other languages.

Language:

English (United States) [en-US]
German (Austria) [de-AT]
User Defined [x-Klingon]

Prefix and suffix options

☐ Do not add 'www' to the beginning of typed web addresses

Specify the suffix (for example .net) that should be added to typed web addresses when you press Ctrl + Shift + Enter.

Suffix:

FIGURE 22-13

If the page language should be set according to the language setting of the client, the culture of the thread can be set programmatically to the language setting that is received from the client. ASP.NET has an automatic setting that does just that. Setting the culture to the value `Auto` sets the culture of the thread according to the client's settings.

```
<%Page Language="C#" Culture="Auto" UICulture="Auto" %>
```

In dealing with resources, ASP.NET differentiates resources that are used for the complete web site and resources that are needed only within a page.

If a resource is used within a page, you can create resources for the page by selecting the Visual Studio menu Tools ➪Generate Local Resource in the design view. This way, the subdirectory `App_LocalResources` is created, where a resource file for every page is stored. These resources can be localized similarly to the way they are in Windows applications. The association between the web controls and the local resource files is achieved by using a `meta:resourcekey` attribute, as shown here with the ASP.NET `Label` control. `Label1Resource1` is the name of the resource that can be changed in the local resource file:

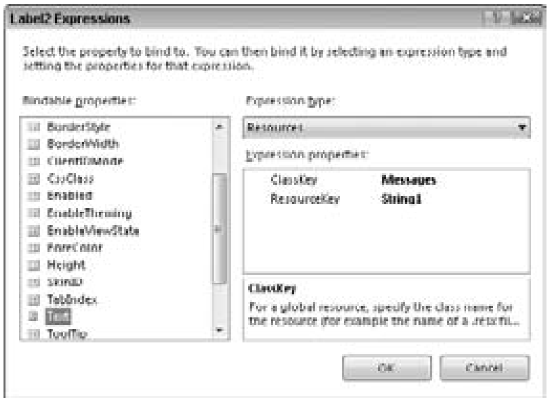
```
<asp:Label ID="Label1" Runat="server" Text="English Text"
    meta:resourcekey="Label1Resource1"></asp:Label>
```

code snippet WebApplication/MultiLanguage.aspx

For the resources that should be shared between multiple pages, you have to create an ASP.NET folder, `Appl_GlobalResources`. In this directory, you can add resource files, for example, `Messages.resx` with its resources. To associate the web controls with these resources, you can use Expressions in the property editor. Clicking the Expressions button opens the Expressions dialog (see Figure 22-14). Here, you can select the expression type Resources, set the name of the `ClassKey` (which is the name of the resource file — here, a strongly typed resource file is generated), and the name of the `ResourceKey`, which is the name of the resource.

In the ASPX file, you can see the association to the resource with the binding expressions syntax `<%$`:

```
<asp:Label ID="Label2" Runat="server"
    Text="<%$ Resources:Messages, String1 %>">
</asp:Label>
```



Label2 Expressions

Select the property to bind to. You can then bind it by selecting an expression type and setting the properties for that expression.

Bindable properties:

BorderStyle
BorderWidth
ClientIDMode
CssClass
Enabled
EnableTheming
EnableViewState
ForeColor
Height
SkinID
TabIndex
Text
ToolTip

Expression type: Resources

Expression properties:

ClassKey	Messages
ResourceKey	String1

ClassKey
For a global resource, specify the class name for the resource (for example the name of a .resx fil...

FIGURE 22-14

LOCALIZATION WITH WPF

Visual Studio 2010 still does not have great support for the localization of WPF applications. However, you do not have to wait until the next version to localize your WPF application. WPF has localization support built-in. With WPF, you need to decide between different options: You can use .NET resources similar to what you've done with Windows Forms and ASP.NET applications, but you can also use an XAML (XML for Applications Markup Language) resource dictionary.

These options are discussed next. You can read more about WPF and XAML in Chapters 35, "Core WPF," and 36, "Business Applications with WPF."

To demonstrate the use of resources with a WPF application, create a simple WPF application containing just one button, as shown in Figure 22-15.

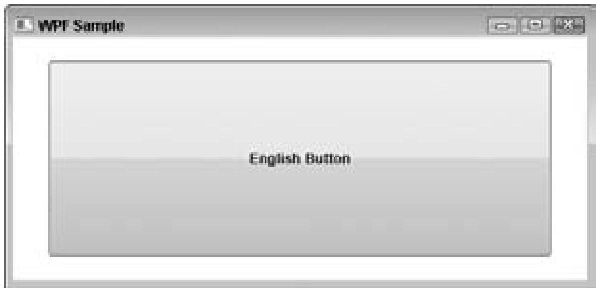


FIGURE 22-15

The XAML code for this application is shown here:

```
<Window x:Class="Wrox.ProCSharp.Localization.MainWindow"
      xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
      xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
      Title="WPF Sample" Height="240" Width="500">
   <Grid>
      <Button Name="button1" Margin="30,20,30,20" Click="Button_Click"
            Content="English Button" />
   </Grid>
</Window>
```

code snippet WPFApplicationUsingResources/MainWindow.xaml

With the handler code for the `Click` event of the button, just a message box containing a sample message pops up:

```
      private void Button_Click(object sender, RoutedEventArgs e)
      {
         MessageBox.Show("English Message");
      }
```

.NET Resources with WPF

You can add .NET resources to a WPF application similar to the way you do with other applications. Define the resources named `Button1Text` and `Button1Message` in the file `Resources.resx`. By default this resource file has an `Internal` access modifier to create the `Resources` class. To use it from within XAML, you need to change this to `Public` within the Managed Resources Editor.

To use the generated resource class, you need to change the XAML code. Add an XML namespace alias to reference the .NET namespace `Wrox.ProCSharp.Localization.Properties` as shown. Here, the alias is set to the value `props`. From XAML elements, properties of this class can be used with the `x:Static` markup extension. The `Content` property of the `Button` is set to the `Button1Text` property of the `Resources` class.

```
<Window x:Class="Wrox.ProCSharp.Localization.Window1"
      xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
      xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
      xmlns:props="clr-namespace:Wrox.ProCSharp.Localization.Properties"
      Title="WPF Sample" Height="300" Width="300">
   <Grid>
      <Button Name="button1" Margin="30,20,30,20" Click="Button_Click"
            Content="{x:Static props:Resources.Button1Text}" />
   </Grid>
</Window>
```

code snippet WPFApplicationUsingResources/MainWindow.xaml

To use the .NET resource from code-behind, you can just access the `Button1Message` property directly in the same way you did with Windows Forms applications:

```
private void Button_Click(object sender, RoutedEventArgs e)
{
   MessageBox.Show(Properties.Resources.Button1Message);
}
```

Now the resources can be localized in the same way as you've done before.

The advantages of using .NET resources for localization of WPF applications are:

- .NET resources can be easily managed.
- x:Static bindings are checked by the compiler.

Of course, there are also disadvantages:

- You need to add the x:Static bindings to the XAML file, and there's no designer support for this.
- Binding is done to the generated resource classes that use the `ResourceManager`. You would need to do some additional plumbing to support other resource managers, such as the `DatabaseResourceManager`, which is discussed later in this chapter.
- There's no type-converter support that can be used with other XAML elements.

XAML Resource Dictionaries

Instead of using .NET resources for localization of WPF applications, you can work directly with XAML to create localized content. This has its own advantages and disadvantages. The steps for a localization process can be described by these actions:

- Create a satellite assembly from the main content.
- Use resource dictionaries for localizable content.
- Add `x:Uid` attributes to elements that should be localized.
- Extract localization content from an assembly.

- ➤ Translate the content.
- ➤ Create satellite assemblies for every language.

These steps are described in the following sections.

Create Satellite Assemblies

When compiling a WPF application, the XAML code is compiled to a binary format, BAML, that is stored into an assembly. To move the BAML code from the main assembly to a separate satellite assembly, you can change the `.csproj` build file and add a `<UICulture>` element as shown as a child to the `<PropertyGroup>` element. The culture, here `en-US`, defines the default culture of the project. Building the project with this build setting creates a subdirectory en-US and creates a satellite assembly containing BAML code for the default language.

```
<UICulture>en-US</UICulture>
```

code snippet WPFApplicationUsingXAMLDictionaries/WPFApplicationUsingXAMLDictionaries.csproj

The easiest way to modify the project settings that are not available from the UI is to unload the project by selecting the project in the Solution Explorer and select Unload Project from the context menu, and next click Edit project-file from the context menu. After the project file is changed, the project can be loaded again.

Separating the BAML into a satellite assembly, you should also apply the `NeutralResourcesLanguage` attribute and supply the resource fallback location to a satellite assembly. If you decide to keep BAML in the main assembly (by not defining the `<UICulture>` to the `.csproj` file), the `UltimateResourceFallbackLocation` should be set to `MainAssembly`.

```
 [assembly: NeutralResourcesLanguage("en-US",
UltimateResourceFallbackLocation.Satellite)]
```

code snippet WPFApplicationUsingXAMLDictionaries/AssemblyInfo.cs

Add a Resource Dictionary

For code-behind content that needs to be localized, a resource dictionary can be added. Using XAML, you can define resources within the `<ResourceDictionary>` element as shown. With Visual Studio, you can create a new resource dictionary by adding a new resource dictionary item and defining the filename. In the example here, the resource dictionary contains one string item. To get access to the `String` type from the `System` namespace, an XML namespace alias needs to be defined. Here, the alias `system` is set to the clr-namespace `System` in the assembly `mscorlib`. The string that is defined can be accessed with the key `message1`. This resource dictionary is defined in the file `LocalizedStrings.xaml`.

```
<ResourceDictionary
      xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
      xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
      xmlns:system="clr-namespace:System;assembly=mscorlib">
   <system:String x:Key="Message1">English Message</system:String>
</ResourceDictionary>
```

code snippet WPFApplicationUsingXAMLDictionaries/LocalizationStrings.xaml

To have the resource dictionary available with the application, it must be added to the resources. If the resource dictionary is required only within a window or just within a specific WPF element, it can be added to the resources collection of the specific window or WPF element. If the same resource dictionary is needed by multiple windows, it can be added to the file `App.xaml` within the `<Application>` element, and thus be available to the complete application. Here, the resource dictionary is added within the resources of the main window:

```
        <Window.Resources>
            <ResourceDictionary>
                <ResourceDictionary.MergedDictionaries>
                    <ResourceDictionary Source="LocalizationStrings.xaml" />
                </ResourceDictionary.MergedDictionaries>
                                  </ResourceDictionary>
                               </Window.Resources>
```

code snippet WPFApplicationUsingXAMLDictionaries/MainWindow.xaml

To use the XAML resource dictionary from code behind, you can use the indexer of the `Resources` property, the `FindResource()` method or the `TryFindResource()` method. Because the resource is defined with the window, the indexer of the `Resources` property of the `Window` class can be used to access the resource. `FindResource()` does a hierarchical search for a resource. If you use the `FindResource()` method of the `Button`, and if it is not found with the `Button` resources, then resources are searched in the `Grid`. If the resource is not there, a lookup to the `Window` resources is done before the `Application` resources are consulted.

```
            private void Button_Click(object sender, RoutedEventArgs e)
            {
                MessageBox.Show(this.Resources["Message1"] as string);
                MessageBox.Show(this.FindResource("Message1") as string);
            }
```

code snippet WPFApplicationUsingXAMLDictionaries/MainWindow.xaml.cs

Uid Attributes for Localization

With the custom resource dictionary file, the text from the code that should be localized can be referenced. For localizing XAML code with WPF elements, the `x:Uid` attribute is used as a unique identifier for the elements that need localization. You don't have to apply this attribute manually to the XAML content; instead, you can use the `msbuild` command with this option:

```
    msbuild /t:updateuid
```

When you call this command in the directory where the project file is located, the XAML files of the project are modified to add an `x:Uid` attribute with a unique identifier to every element. If the control already has a `Name` or `x:Name` attribute applied, the `x:Uid` has the same value; otherwise, a new value is generated. The same XAML that was shown before now has the new attributes applied:

```
    <Window x:Uid="Window_1"
            x:Class="WPFApplicationUsingXAMLDictionaries.MainWindow"
            xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
            xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
            Title="Main Window" Height="240" Width="500">
        <Window.Resources>
            <ResourceDictionary x:Uid="ResourceDictionary_1">
                <ResourceDictionary.MergedDictionaries>
                    <ResourceDictionary x:Uid="ResourceDictionary_2"
                                        Source="LocalizationStrings.xaml" />
                </ResourceDictionary.MergedDictionaries>
            </ResourceDictionary>
        </Window.Resources>
        <Grid x:Uid="Grid_1">
            <Button x:Uid="button1" Name="button1" Margin="30,20,30,20" Click="Button_Click"
                Content="English Button" />
        </Grid>
    </Window>
```

If you change the XAML file after `x:Uid` attributes have been added, you can verify correctness of the `x:Uid` attributes with the option `/t:checkuid`.

Now you can compile the project to create BAML code containing the `x:Uid` attributes and use a tool to extract this information.

LocBaml Tool for Localization

Compiling the project creates a satellite assembly containing the BAML code. From this satellite assembly, you can extract the content that needs to be localized with classes from the `System.Windows.Markup.Localizer` namespace. With the Windows SDK, you will find the sample program LocBaml. This program can be used to extract localization content from BAML. You need to copy the executable, the satellite assembly with the default content, and `LocBaml.exe` to one directory and start the sample program to produce a `.csv` file with the localization content:

```
LocBaml /parse WPFApplicationUsingXAMLDictionaries.resources.dll /out: trans.csv
```

To use the LocBaml with a WPF application that is built with .NET 4, the tool also must be built with .NET 4 or a newer version. If you have an old version of the LocBaml tool that was built with .NET 2.0, it cannot load the .NET 4 assemblies. The Windows SDK contains the source of the tool, so you can rebuild it with the newest version of .NET.

You can use Microsoft Excel to open the `.csv` file and translate its content. An extract from the `.csv` file that lists the content of the button and the message from the resource dictionary is shown here:

```
WPFandXAMLResources.g.en-US.resources:localizationstrings.baml,
system:String_1:System.String.$Content,None,True,True,,English Message
WPFandXAMLResources.g.en-US.resources:window1.baml,
button1:System.Windows.Controls.ContentControl.Content,Button,True,True,,
English Button
```

This file contains these fields:

- ➤ Name of the BAML
- ➤ The identifier of the resource
- ➤ The category of the resource that gives the type of the content
- ➤ A Boolean value if the resource is visible for translation (readable)
- ➤ A Boolean value if the resource can be modified for the translation (modifiable)
- ➤ Localization comments
- ➤ The value of the resource

After localization of the resource, you can create a new directory for the new language (for example, `de` for German). The directory structure follows the same convention that was shown earlier in this chapter with satellite assemblies. With the LocBaml tool, you can create satellite assemblies with the translated content:

```
LocBaml /generate WPFandXAMLResources.resources.dll /trans:trans_de.csv
    /out: ./de /cul:de-DE
```

Now the same rules for setting the culture of the thread and finding satellite assemblies that were shown with Windows Forms applications apply here.

As you've seen, it's quite a chore to do the localization with XAML dictionaries. This is one of the disadvantages. Luckily it's not necessary to do this day by day. What are the advantages?

- ➤ You can delay the localization process within the XAML file until the application is completed. There's no special markup or resource-mapping syntax needed. The localization process can be separated from the development process.
- ➤ Using XAML resource dictionaries is very efficient at runtime.
- ➤ Localization can be done easily with a CSV editor.

The disadvantages are:

- ➤ LocBaml is an unsupported tool found in the samples of the SDK.
- ➤ Localization is a one-time process. It's hard to make changes to the localization.

A CUSTOM RESOURCE READER

With the resource readers that are part of .NET Framework 4, you can read resources from resource files and satellite assemblies. If you want to put the resources into a different store (such as a database), you can use a custom resource reader to read these resources.

To use a custom resource reader, you also need to create a custom resource set and a custom resource manager. Doing this is not a difficult task, however, because you can derive the custom classes from existing classes.

For the sample application, you need to create a simple database with just one table for storing messages that has one column for every supported language. The following table lists the columns and their corresponding values.

KEY	DEFAULT	DE	ES	FR	IT
Welcome	Welcome	Willkommen	Bienvenido	Bienvenue	Benvenuto
GoodMorning	Good morning	Guten Morgen	Buenos díaz	Bonjour	Buona mattina
GoodEvening	Good evening	Guten Abend	Buenos noches	Bonsoir	Buona sera
ThankYou	Thank you	Danke	Gracias	Merci	Grazie
Goodbye	Goodbye	Auf Wiedersehen	Adiós	Au revoir	Arrivederci

For the custom resource reader, you create a component library with three classes. The classes are `DatabaseResourceReader`, `DatabaseResourceSet`, and `DatabaseResourceManager`.

Creating a DatabaseResourceReader

With the class `DatabaseResourceReader`, you define two fields: the connection string that is needed to access the database and the language that should be returned by the reader. These fields are filled inside the constructor of this class. The field `language` is set to the name of the culture that is passed with the `CultureInfo` object to the constructor:

```
public class DatabaseResourceReader: IResourceReader
{
   private string connectionString;
   private string language;

   public DatabaseResourceReader(string connectionString,
         CultureInfo culture)
   {
      this.connectionString = connectionString;
      this.language = culture.Name;
   }
```

code snippet DatabaseResourceReader/DatabaseResourceReader.cs

A resource reader has to implement the interface IResourceReader. This interface defines the methods Close() and GetEnumerator() to return an IDictionaryEnumerator that returns keys and values for the resources. In the implementation of GetEnumerator(), create a Hashtable where all keys and values for a specific language are stored. Next, you can use the SqlConnection class in the namespace System.Data.SqlClient to access the database in SQL Server. Connection.CreateCommand() creates a SqlCommand() object that you use to specify the SQL SELECT statement to access the data in the database. If the language is set to de, the SELECT statement is SELECT [key], [de] FROM Messages. Then you use a SqlDataReader object to read all values from the database and put them into a Hashtable. Finally, the enumerator of the Hashtable is returned.

For more information about accessing data with ADO.NET, see Chapter 30, "Core ADO.NET."

```
public System.Collections.IDictionaryEnumerator GetEnumerator()
{
   Dictionary<string, string> dict = new Dictionary<string, string>();

   SqlConnection connection = new SqlConnection(connectionString);
   SqlCommand command = connection.CreateCommand();
   if (String.IsNullOrEmpty(language))
      language = "Default";

   command.CommandText = "SELECT [key], [" + language + "] " +
                         "FROM Messages";

   try
   {
      connection.Open();

      SqlDataReader reader = command.ExecuteReader();
      while (reader.Read())
      {
         if (reader.GetValue(1) != System.DBNull.Value)
         {
            dict.Add(reader.GetString(0).Trim(), reader.GetString(1));
         }
      }

      reader.Close();
   }
   catch (SqlException ex)
   {
      if (ex.Number != 207)  // ignore missing columns in the database
         throw;              // rethrow all other exceptions
   }
   finally
   {
      connection.Close();
   }
   return dict.GetEnumerator();
}

public void Close()
{
}
```

Because the interface `IResourceReader` is derived from `IEnumerable` and `IDisposable`, the methods `GetEnumerator()`, which returns an `IEnumerator` interface, and `Dispose()` must be implemented, too:

```
      IEnumerator IEnumerable.GetEnumerator()
      {
         return this.GetEnumerator();
      }

      void IDisposable.Dispose()
      {
      }
   }
```

Creating a DatabaseResourceSet

The class `DatabaseResourceSet` can use nearly all implementations of the base class `ResourceSet`. You just need a different constructor that initializes the base class with your own resource reader, `DatabaseResourceReader`. The constructor of `ResourceSet` allows passing an object by implementing `IResourceReader`; this requirement is fulfilled by `DatabaseResourceReader`:

```
   public class DatabaseResourceSet: ResourceSet
   {
      internal DatabaseResourceSet(string connectionString, CultureInfo culture)
          : base(new DatabaseResourceReader(connectionString, culture))
      {
      }

      public override Type GetDefaultReader()
      {
         return typeof(DatabaseResourceReader);
      }
   }
```

code snippet DatabaseResourceReader/DatabaseResourceSet.cs

Creating a DatabaseResourceManager

The third class you have to create is the custom resource manager. `DatabaseResourceManager` is derived from the class `ResourceManager`, and you only have to implement a new constructor and override the method `InternalGetResourceSet()`.

In the constructor, create a new `Dictionary<string, DatabaseResourceSet>` to store all queried resource sets and set it into the field `ResourceSets` defined by the base class:

```
   public class DatabaseResourceManager: ResourceManager
   {
      private string connectionString;
      private Dictionary<string, DatabaseResourceSet> resourceSets;

      public DatabaseResourceManager(string connectionString)
      {
         this.connectionString = connectionString;
         resourceSets = new Dictionary<string, DatabaseResourceSet>();
      }
```

code snippet DatabaseResourceReader/DatabaseResourceManager.cs

The methods of the `ResourceManager` class that you can use to access resources (such as `GetString()` and `GetObject()`) invoke the method `InternalGetResourceSet()` to access a resource set where the appropriate values can be returned.

In the implementation of `InternalGetResourceSet()`, check first if the resource set for the culture queried for a resource is already in the hash table; if it already exists, return it to the caller. If the resource set is not available, create a new `DatabaseResourceSet` object with the queried culture, add it to the dictionary, and return it to the caller:

```
          protected override ResourceSet InternalGetResourceSet(
                CultureInfo culture, bool createIfNotExists, bool tryParents)
          {
             DatabaseResourceSet rs = null;

             if (resourceSets.ContainsKey(culture.Name))
             {
                rs = resourceSets[culture.Name];
             }
             else
             {
                rs = new DatabaseResourceSet(connectionString, culture);
                resourceSets.Add(culture.Name, rs);
             }
             return rs;
          }
       }
```

Client Application for DatabaseResourceReader

The way the class `ResourceManager` is used from the client application here does not differ much from the previous use of the `ResourceManager` class. The only difference is that the custom class `DatabaseResourceManager` is used instead of the class `ResourceManager`. The following code snippet demonstrates how you can use your own resource manager.

A new `DatabaseResourceManager` object is created by passing the database connection string to the constructor. Then, you can invoke the `GetString()` method that is implemented in the base class as you did earlier, passing the key and an optional object of type `CultureInfo` to specify a culture. In turn, you get a resource value from the database because this resource manager is using the classes `DatabaseResourceSet` and `DatabaseResourceReader`.

```
var rm = new DatabaseResourceManager(
            @"server=(local)\sqlexpress;database=LocalizationDemo;" +
             "trusted_connection=true");

string spanishWelcome = rm.GetString("Welcome", new CultureInfo("es-ES"));
string italianThankyou = rm.GetString("ThankYou", new CultureInfo("it"));
string threadDefaultGoodMorning = rm.GetString("GoodMorning");
```

code snippet DatabaseResourceReaderClient/Program.cs

CREATING CUSTOM CULTURES

Over time, more and more languages have become supported by the .NET Framework. However, not all languages of the world are available with .NET. You can create a custom culture. Some examples of when creating custom cultures can be useful are to support a minority within a region or to create subcultures for different dialects.

Custom cultures and regions can be created with the class `CultureAndRegionInfoBuilder` in the namespace `System.Globalization`. This class is located in the assembly `sysglobl`.

With the constructor of the class `CultureAndRegionInfoBuilder`, you can pass the culture's name. The second argument of the constructor requires an enumeration of type `CultureAndRegionModifiers`. This enumeration allows one of three values: `Neutral` for a neutral culture, `Replacement` if an existing Framework culture should be replaced, or `None`.

After the `CultureAndRegionInfoBuilder` object is instantiated, you can configure the culture by setting properties. With the properties of this class, you can define all the cultural and regional information such as name, calendar, number format, metric information, and so on. If the culture should be based on existing cultures and regions, you can set the properties of the instance using the methods `LoadDataFromCultureInfo()` and `LoadDataFromRegionInfo()`, and change the values that are different by setting the properties afterward.

Calling the method `Register()` registers the new culture with the operating system. Indeed, you can find the file that describes the culture in the directory `<windows>\Globalization`. Look for files with the extension `.nlp`.

```
using System;
using System.Globalization;

namespace CustomCultures
{
    class Program
    {
        static void Main()
        {
            try
            {
                // Create a Styria culture
                var styria = new CultureAndRegionInfoBuilder("de-AT-ST",
                                     CultureAndRegionModifiers.None);
                var cultureParent = new CultureInfo("de-AT");
                styria.LoadDataFromCultureInfo(cultureParent);
                styria.LoadDataFromRegionInfo(new RegionInfo("AT"));
                styria.Parent = cultureParent;
                styria.RegionNativeName = "Steiermark";
                styria.RegionEnglishName = "Styria";
                styria.CultureEnglishName = "Styria (Austria)";
                styria.CultureNativeName = "Steirisch";

                styria.Register();
            }
            catch (UnauthorizedAccessException ex)
            {
                Console.WriteLine(ex.Message);
            }

        }
    }
}
```

code snippet CustomCultures/Program.cs

Because registering custom languages on the system requires administrative privileges, an application manifest file is required that specifies the requested execution rights. In the project properties, the manifest file needs to be set in the Application settings.

```
<?xml version="1.0" encoding="utf-8"?>
<asmv1:assembly manifestVersion="1.0" xmlns="urn:schemas-microsoft-com:asm.v1"
xmlsn:asmv1="urn:schemas-microsoft-com:asm.v1" xmlns:asmv2="urn:schemas-microsoft-
com:asm.v2" xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance">
  <assemblyIdentity version="1.0.0.0" name="MyApplication.app"/>
  <trustInfo xmlns="urn:schemas-microsoft-com:asm.v2">
    <security>
      <requestedPrivileges xmlns="urn:schemas-microsoft-com:asm.v3">
        <requestedExecutionLevel level="requireAdministrator" uiAccess="false" />
      </requestedPrivileges>
    </security>
  </trustInfo>
</asmv1:assembly>
```

code snippet CustomCultures/app.manifest

The newly created culture can now be used like other cultures:

```
var ci = new CultureInfo("de-AT-ST");
Thread.CurrentThread.CurrentCulture = ci;
Thread.CurrentThread.CurrentUICulture = ci;
```

You can use the culture for formatting and also for resources. If you start the Cultures in Action application that was written earlier in this chapter again, you can see the custom culture as well.

SUMMARY

This chapter discussed the globalization and localization of .NET applications.

In the context of globalization of applications, you learned about using the namespace `System.Globalization` to format culture-dependent numbers and dates. Furthermore, you learned that sorting strings by default depends on the culture, and you used the invariant culture for a culture-independent sort. Using the `CultureAndRegionInfoBuilder` class, you've learned how to create a custom culture.

Localization of applications is accomplished by using resources. Resources can be packed into files, satellite assemblies, or a custom store such as a database. The classes used with localization are in the namespace `System.Resources`. For reading resources from other places, such as satellite assemblies or resource files, you can create a custom resource reader.

You have seen how to localize Windows Forms, WPF, and ASP.NET applications. Besides all that, you've learned some important vocabulary in different languages.

The next chapter provides information about a completely different topic — transactions. Don't expect that transactions will only be useful with databases. In addition to database transactions, the chapter gives you information on memory-based transactional resources and a transactional file system.

23

System.Transactions

WHAT'S IN THIS CHAPTER?

- Transaction phases and ACID properties
- Traditional transactions
- Committable transactions
- Transaction promotions
- Dependent transactions
- Ambient transactions
- Transaction isolation levels
- Custom resource managers
- Transactions with Windows 7 and Windows Server 2008

All or nothing — this is the main characteristic of a transaction. When writing a few records, either all are written, or everything will be undone. If there is even one failure when writing one record, all the other things that are done within the transaction will be rolled back.

Transactions are commonly used with databases, but with classes from the namespace `System.Transactions`, you can also perform transactions on volatile or in-memory-based objects such as a list of objects. With a list that supports transactions, if an object is added or removed and the transaction fails, the list action is automatically undone. Writing to a memory-based list can be done in the same transaction as writing to a database.

Since Windows Vista, the file system and registry also get transactional support. Writing a file and making changes within the registry supports transactions.

OVERVIEW

What are transactions? Think about ordering a book from a web site. The book-ordering process removes the book you want to buy from stock and puts it in your order box, and the cost of your book is charged to your credit card. With these two actions, either both actions should complete successfully or neither of these actions should happen. If there is a failure when getting the book from stock, the credit card should not be charged. Transactions address such scenarios.

The most common use of transactions is writing or updating data within the database. Transactions can also be performed when writing a message to a message queue, or writing data to a file or the registry. Multiple actions can be part of a single transaction.

Figure 23-1 shows the main actors in a transaction. Transactions are managed and coordinated by the transaction manager, and a resource manager manages every resource that influences the outcome of the transaction. The transaction manager communicates with resource managers to define the outcome of the transaction.

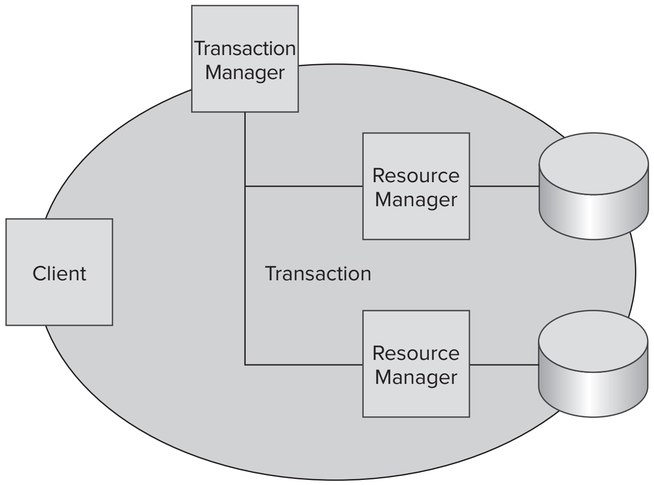

FIGURE 23-1

Transaction Phases

The timely phases of a transaction are the *active, preparing,* and *committing* phases:

- **Active phase** — During the active phase, the transaction is created. Resource managers that manage the transaction for resources can enlist with the transaction.
- **Preparing phase** — During the preparing phase, every resource manager can define the outcome of the transaction. This phase starts when the creator of the transaction sends a commit to end the transaction. The transaction manager sends a *Prepare* message to all resource managers. If the resource manager can produce the transaction outcome successfully, it sends a *Prepared* message to the transaction manager. Resource managers can abort the transaction if they fail to prepare by forcing a rollback with the transaction manager by sending a *Rollback* message. After the Prepared message is sent, the resource managers must guarantee to finish the work successfully in the committing phase. To make this possible, durable resource managers must write a log with the information from the prepared state, so that they can continue from there in case of, for example, a power failure between the prepared and committing phases.
- **Committing phase** — The committing phase begins when all resource managers have prepared successfully. This is when the *Prepared* message is received from all resource managers. Then the transaction manager can complete the work by sending a *Commit* message to all participants. The resource managers can now finish the work on the transaction and return a *Committed* message.

ACID Properties

A transaction has specific requirements; for example, a transaction must result in a valid state, even if the server has a power failure. The characteristics of transactions can be defined by the term ACID. *ACID* is a four-letter acronym for *atomicity, consistency, isolation,* and *durability*:

- **Atomicity** — Represents one unit of work. With a transaction, either the complete unit of work succeeds or nothing is changed.
- **Consistency** — The state before the transaction was started and after the transaction is completed must be valid. During the transaction, the state may have interim values.
- **Isolation** — Means that transactions that happen concurrently are isolated from the state, which is changed during a transaction. Transaction A cannot see the interim state of transaction B until the transaction is completed.
- **Durability** — After the transaction is completed, it must be stored in a durable way. This means that if the power goes down or the server crashes, the state must be recovered at reboot.

Not every transaction requires all four ACID properties. For example, a memory-based transaction (for example, writing an entry into a list) does not need to be durable. Also, a complete isolation from the outside is not always required, as we discuss later with transaction isolation levels.

DATABASE AND ENTITY CLASSES

The sample database `CourseManagement` that is used with the transactions in this chapter is defined by the structure from Figure 23-2. The table `Courses` contains information about courses: course number and title. The table `CourseDates` contains the date of specific courses and is linked to the `Courses` table. The table `Students` contains information about persons attending a course. The table `CourseAttendees` is the link between `Students` and `CourseDates`. It defines which student is attending what course.

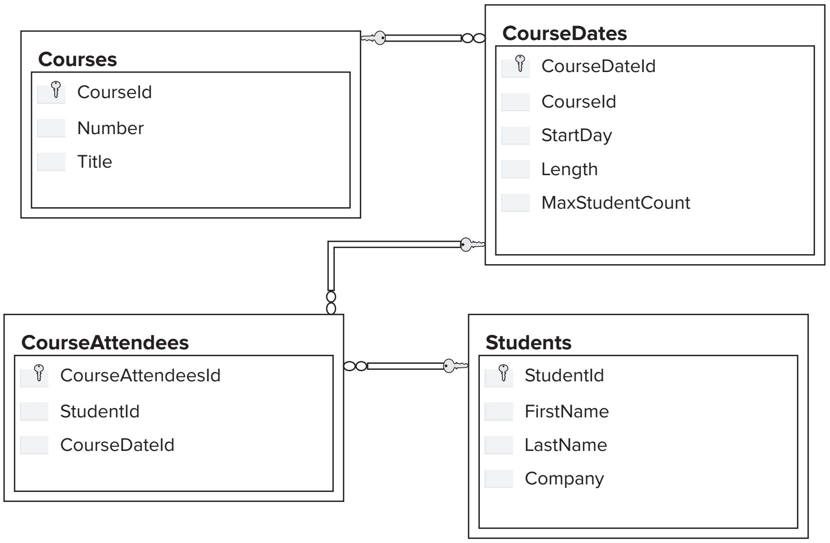

FIGURE 23-2

The sample applications in this chapter use a library with entity and data access classes. The class `Student` contains properties to define a student; for example, `FirstName`, `LastName`, and `Company`:

```
using System;

namespace Wrox.ProCSharp.Transactions
{
   [Serializable]
   public class Student
   {
      public string FirstName { get; set; }
      public string LastName { get; set; }
      public string Company { get; set; }
      public int Id { get; set; }

      public override string ToString()
      {
         return String.Format("{0} {1}", FirstName, LastName);
      }
   }
}
```

code snippet DataLib/Student.cs

Adding student information to the database is done in the method `AddStudent()` of the class `StudentData`. Here, an ADO.NET connection is created to connect to the SQL Server database, the `SqlCommand` object defines the SQL statement, and the command is executed by invoking `ExecuteNonQuery()`:

```
using System;
using System.Collections.Generic;
using System.Data;
using System.Data.SqlClient;
using System.Transactions;

namespace Wrox.ProCSharp.Transactions
{
   public class StudentData
   {
      public void AddStudent(Student student)
      {
         var connection = new SqlConnection(
             Properties.Settings.Default.CourseManagementConnectionString);
         connection.Open();
         try
         {
            SqlCommand command = connection.CreateCommand();

            command.CommandText = "INSERT INTO Students " +
                  "(FirstName, LastName, Company) VALUES " +
                  "(@FirstName, @LastName, @Company)";
            command.Parameters.AddWithValue("@FirstName", student.FirstName);
            command.Parameters.AddWithValue("@LastName", student.LastName);
            command.Parameters.AddWithValue("@Company", student.Company);

            command.ExecuteNonQuery();
         }
         finally
         {
            connection.Close();
         }
      }
   }
}
```

code snippet DataLib/StudentData.cs

ADO.NET is covered in detail in Chapter 30, "Core ADO.NET."

TRADITIONAL TRANSACTIONS

Before `System.Transaction` was released, you could create transactions directly with ADO.NET, or you could do transactions with the help of components, attributes, and the COM+ runtime, which is covered in the namespace `System.EnterpriseServices`. To show you how the new transaction model compares to the traditional ways of working with transactions, we present a short look at how ADO.NET transactions and transactions with Enterprise Services are done.

ADO.NET Transactions

Let's start with traditional ADO.NET transactions. If you don't create transactions manually, there is a single transaction with every SQL statement. If multiple statements need to participate with the same transaction, however, you must create a transaction manually to achieve this.

The following code segment shows how to work with ADO.NET transactions. The `SqlConnection` class defines the method `BeginTransaction()`, which returns an object of type `SqlTransaction`. This transaction object must then be associated with every command that participates with the transaction. To associate a command with a transaction, set the `Transaction` property of the `SqlCommand` class to the `SqlTransaction` instance. For the transaction to be successful, you must invoke the `Commit()` method of the `SqlTransaction` object. If there is an error, you have to invoke the `Rollback()` method, and every change is undone. You can check for an error with the help of a `try`/`catch` and do the rollback inside the catch:

```
using System;
using System.Data.SqlClient;
using System.Diagnostics;

namespace Wrox.ProCSharp.Transactions
{
   public class CourseData
   {
      public void AddCourse(Course course)
      {
         var connection = new SqlConnection(
               Properties.Settings.Default.CourseManagementConnectionString);
         SqlCommand courseCommand = connection.CreateCommand();
         courseCommand.CommandText =
                "INSERT INTO Courses (Number, Title) VALUES (@Number, @Title)";
         connection.Open();
         SqlTransaction tx = connection.BeginTransaction();

         try
         {
            courseCommand.Transaction = tx;

            courseCommand.Parameters.AddWithValue("@Number", course.Number);
            courseCommand.Parameters.AddWithValue("@Title", course.Title);
            courseCommand.ExecuteNonQuery();

            tx.Commit();
         }
         catch (Exception ex)
         {
            Trace.WriteLine("Error: " + ex.Message);
            tx.Rollback();
         }
         finally
         {
            connection.Close();
         }
      }
   }
}
```

If you have multiple commands that should run in the same transaction, every command must be associated with the transaction. Because the transaction is associated with a connection, every one of these commands must also be associated with the same connection instance. ADO.NET transactions do not support transactions across multiple connections; it is always a local transaction associated with one connection.

When you create an object persistence model using multiple objects, for example, classes `Course` and `CourseDate`, which should be persisted inside one transaction, it gets very difficult using ADO.NET transactions. Here, it is necessary to pass the transaction to all the objects participating in the same transaction.

System.EnterpriseServices

With Enterprise Services, you get a lot of services for free. One of them is automatic transactions. Using transactions with `System.EnterpriseServices` has the advantage that it is not necessary to deal with transactions explicitly; transactions are automatically created by the runtime. You just have to add the attribute `[Transaction]` with the transactional requirements to the class. The `[AutoComplete]` attribute marks the method to automatically set the status bit for the transaction: if the method succeeds, the success bit is set, so the transaction can commit. If an exception happens, the transaction is aborted:

```
using System;
using System.Data.SqlClient;
using System.EnterpriseServices;
using System.Diagnostics;

namespace Wrox.ProCSharp.Transactions
{
    [Transaction(TransactionOption.Required)]
    public class CourseData: ServicedComponent
    {
        [AutoComplete]
        public void AddCourse(Course course)
        {
            var connection = new SqlConnection(
                   Properties.Settings.Default.CourseManagementConnectionString);
            SqlCommand courseCommand = connection.CreateCommand();
            courseCommand.CommandText =
                   "INSERT INTO Courses (Number, Title) VALUES (@Number, @Title)";
            connection.Open();
            try
            {
                courseCommand.Parameters.AddWithValue("@Number", course.Number);
                courseCommand.Parameters.AddWithValue("@Title", course.Title);
                courseCommand.ExecuteNonQuery();
                }
                finally
                {
                    connection.Close();
                }
            }
        }
    }
```

A big advantage of creating transactions with `System.EnterpriseServices` is that multiple objects can easily run within the same transaction, and transactions are automatically enlisted. The disadvantages are that it requires the COM+ hosting model, and the class using the features of this technology must be derived from the base class `ServicedComponent`.

SYSTEM.TRANSACTIONS

The namespace `System.Transactions` became available with .NET 2.0 and brings a modern transaction programming model to .NET applications.

This namespace offers a few dependent `TransactionXXX` classes. `Transaction` is the base class of all transaction classes and defines properties, methods, and events available with all transaction classes. `CommittableTransaction` is the only transaction class that supports committing. This class has a `Commit()` method; all other transaction classes can do only a rollback. The class `DependentTransaction` is used with transactions that are dependent on another transaction. A dependent transaction can depend on a transaction created from the committable transaction. Then the dependent transaction adds to the outcome of the committable transaction whether or not it is successful. The class `SubordinateTransaction` is used in conjunction with the Distributed Transaction Coordinator (DTC). This class represents a transaction that is not a root transaction but can be managed by the DTC.

The following table describes the properties and methods of the `Transaction` class.

TRANSACTION CLASS MEMBER	DESCRIPTION
`Current`	The property `Current` is a static property without the need to have an instance. `Transaction.Current` returns an ambient transaction if one exists. Ambient transactions are discussed later in this chapter.
`IsolationLevel`	The `IsolationLevel` property returns an object of type `IsolationLevel`. `IsolationLevel` is an enumeration that defines what access other transactions have to the interim results of the transaction. This affects the *I* in ACID; not all transactions are isolated.
`TransactionInformation`	The `TransactionInformation` property returns a `TransactionInformation` object. `TransactionInformation` gives you information about the current state of the transaction, the time when the transaction was created, and transaction identifiers.

`EnlistVolatile()`
`EnlistDurable()`
`EnlistPromotableSinglePhase()`
	With the enlist methods `EnlistVolatile()`, `EnlistDurable()`, and `EnlistPromotableSinglePhase()`, you can enlist custom resource managers that participate with the transaction.

`Rollback()`	With the `Rollback()` method, you can abort a transaction and undo everything to set all results to the state before the transaction.

continues

(continued)

TRANSACTION CLASS MEMBER	DESCRIPTION
`DependentClone()`	With the `DependentClone()` method, you can create a transaction that depends on the current transaction.
`TransactionCompleted`	`TransactionCompleted` is an event that is fired when the transaction is completed — either successfully or unsuccessfully. With an event handler object of type `TransactionCompletedEventHandler`, you get access to the `Transaction` object and can read its status.

For demonstrating the features of `System.Transaction`, the class `Utilities` inside a separate assembly offers some static methods. The method `AbortTx()` returns `true` or `false` depending on the input from the user. The method `DisplayTransactionInformation()` gets a `TransactionInformation` object as parameter and displays all the information from the transaction: creation time, status, local, and distributed identifiers:

```
public static class Utilities
{
   public static bool AbortTx()
   {
      Console.Write("Abort the Transaction (y/n)?");
      return Console.ReadLine() == "y";
   }

   public static void DisplayTransactionInformation(string title,
         TransactionInformation ti)
   {
      if (ti != null)
      {
         Console.WriteLine(title);

         Console.WriteLine("Creation Time: {0:T}", ti.CreationTime);
         Console.WriteLine("Status: {0}", ti.Status);
         Console.WriteLine("Local ID: {0}", ti.LocalIdentifier);
         Console.WriteLine("Distributed ID: {0}", ti.DistributedIdentifier);
         Console.WriteLine();
      }
   }
}
```

code snippet Utilities/Utilities.cs

Committable Transactions

The `Transaction` class cannot be committed programmatically; it does not have a method to commit the transaction. The base class `Transaction` just supports aborting the transaction. The only transaction class that supports a commit is the class `CommittableTransaction`.

With ADO.NET, a transaction can be enlisted with the connection. To make this possible, an `AddStudent()` method is added to the class `StudentData` that accepts a `System.Transactions.Transaction` object as second parameter. The object `tx` is enlisted with the connection by calling the method `EnlistTransaction` of the `SqlConnection` class. This way, the ADO.NET connection is associated with the transaction:

```
public void AddStudent(Student student, Transaction tx)
{
    var connection = new SqlConnection(
          Properties.Settings.Default.CourseManagementConnectionString);
    connection.Open();
```

```
            try
            {
               if (tx != null)
                  connection.EnlistTransaction(tx);
               SqlCommand command = connection.CreateCommand();

               command.CommandText = "INSERT INTO Students (FirstName, " +
                     "LastName, Company)" +
                     "VALUES (@FirstName, @LastName, @Company)";
               command.Parameters.AddWithValue("@FirstName", student.FirstName);
               command.Parameters.AddWithValue("@LastName", student.LastName);
               command.Parameters.AddWithValue("@Company", student.Company);

               command.ExecuteNonQuery();
            }
            finally
            {
               connection.Close();
            }
        }
```

code snippet DataLib/StudentData.cs

In the `CommittableTransaction()` method of the console application TransactionSamples, first a transaction of type `CommittableTransaction` is created, and information is shown on the console. Then a `Student` object is created, and this object is written to the database from the `AddStudent()` method. If you verify the record in the database from outside the transaction, you cannot see the student added until the transaction is completed. In case the transaction fails, there is a rollback, and the student is not written to the database.

After the `AddStudent()` method is invoked, the helper method `Utilities.AbortTx()` is called to ask if the transaction should be aborted. If the user aborts, an exception of type `ApplicationException` is thrown and, in the catch block, a rollback with the transaction is done by calling the method `Rollback()` of the `Transaction` class. The record is not written to the database. If the user does not abort, the `Commit()` method commits the transaction, and the final state of the transaction is committed:

```
static void CommittableTransaction()
{
   var tx = new CommittableTransaction();
   Utilities.DisplayTransactionInformation("TX created",
         tx.TransactionInformation);

   try
   {
      var s1 = new Student
      {
          FirstName = "Jörg",
          LastName = "Neumann",
          Company = "thinktecture"
      };
      var db = new StudentData();
      db.AddStudent(s1, tx);

      if (Utilities.AbortTx())
      {
         throw new ApplicationException("transaction abort");
      }

      tx.Commit();
   }
   catch (Exception ex)
```

```
            {
               Console.WriteLine(ex.Message);
               Console.WriteLine();
               tx.Rollback();
            }

            Utilities.DisplayTransactionInformation("TX completed",
                  tx.TransactionInformation);

         }
```

code snippet TransactionSamples/Program.cs

Here, you can see the output of the application where the transaction is active and has a local identifier. The output of the application that follows shows the result with the user choice to abort the transaction. After the transaction is finished, you can see the aborted state:

```
TX created
Creation Time: 7:30:49 PM
Status: Active
Local ID: bdcf1cdc-a67e-4ccc-9a5c-cbdfe0fe9177:1
Distributed ID: 00000000-0000-0000-0000-000000000000

Abort the Transaction (y/n)? y
Transaction abort

TX completed
Creation Time: 7:30:49 PM
Status: Aborted
Local ID: bdcf1cdc-a67e-4ccc-9a5c-cbdfe0fe9177:1
Distributed ID: 00000000-0000-0000-0000-000000000000
```

With the second output of the application that you can see here, the transaction is not aborted by the user. The transaction has the status committed, and the data is written to the database:

```
TX Created
Creation Time: 7:33:04 PM
Status: Active
Local ID: 708bda71-fa24-46a9-86b4-18b83120f6af:1
Distributed ID: 00000000-0000-0000-0000-000000000000

Abort the Transaction (y/n)? n

TX completed
Creation Time: 7:33:04 PM
Status: Committed
Local ID: 708bda71-fa24-46a9-86b4-18b83120f6af:1
Distributed ID: 00000000-0000-0000-0000-000000000000
```

Transaction Promotion

`System.Transactions` supports promotable transactions. Depending on the resources that participate with the transaction, either a local or a distributed transaction is created. SQL Server 2005 and 2008 support promotable transactions. So far you have seen only local transactions. With all previous samples, the distributed transaction ID was always set to 0, and only the local ID was assigned. With a resource that does not support promotable transactions, a distributed transaction is created. If multiple resources are added to the transaction, the transaction may start with a local transaction and promote to a distributed transaction as required. Such a promotion happens when multiple SQL Server database connections are added to the transaction. The transaction starts as a local transaction and then is promoted to a distributed transaction.

The console application is now changed in that a second student is added by using the same transaction object `tx`. Because every `AddStudent()` method opens a new connection, two connections are associated with the transaction after the second student is added:

```
static void TransactionPromotion()
{
   var tx = new CommittableTransaction();
   Utilities.DisplayTransactionInformation("TX created",
         tx.TransactionInformation);

   try
   {
      var s1 = new Student
      {
          FirstName = "Jörg",
          LastName = "Neumann",
          Company = "thinktecture"
      };
      var db = new StudentData();
      db.AddStudent(s1, tx);

      var s2 = new Student
      {
          FirstName = "Richard",
          LastName = "Blewett",
          Company = "thinktecture"
      };
      db.AddStudent(s2, tx);

      Utilities.DisplayTransactionInformation("2nd connection enlisted",
            tx.TransactionInformation);

      if (Utilities.AbortTx())
      {
         throw new ApplicationException("transaction abort");
      }

      tx.Commit();
   }
   catch (Exception ex)
   {
      Console.WriteLine(ex.Message);
      Console.WriteLine();
      tx.Rollback();
   }

   Utilities.DisplayTransactionInformation("TX finished",
         tx.TransactionInformation);
}
```

code snippet TransactionSamples/Program.cs

Running the application now, you can see that with the first student added the distributed identifier is 0, but with the second student added the transaction was promoted, so a distributed identifier is associated with the transaction:

```
TX created
Creation Time: 7:56:24 PM
Status: Active
Local ID: 0d2f5ada-32aa-40eb-b9d7-cc6aa9a2a554:1
Distributed ID: 00000000-0000-0000-0000-0000000000

2nd connection enlisted
```

```
    Creation Time: 7:56:24 PM
    Status: Active
    Local ID: 0d2f5ada-32aa-40eb-b9d7-cc6aa9a2a554:1
    Distributed ID: 501abd91-e512-47f3-95d5-f0488743293d

    Abort the Transaction (y/n)?
```

Transaction promotion requires the DTC to be started. If promoting transactions fails with your system, verify that the DTC service is started. Starting the Component Services MMC snap-in, you can see the actual status of all DTC transactions running on your system.

By selecting Transaction List on the tree view, you can see all active transactions. In Figure 23-3, you can see that there is a transaction active with the same distributed identifier as was shown with the console output earlier. If you verify the output on your system, make sure that the transaction has a timeout and aborts in case the timeout is reached. After the timeout, you cannot see the transaction in the transaction list anymore. You can also verify the transaction statistics with the same tool. Transaction Statistics shows the number of committed and aborted transactions.

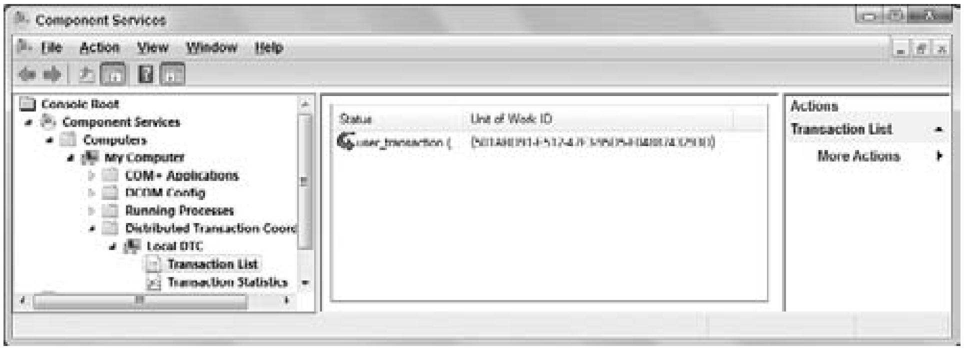

FIGURE 23-3

Dependent Transactions

With dependent transactions, you can influence one transaction from multiple threads. A dependent transaction depends on another transaction and influences the outcome of the transaction.

The sample application `DependentTransactions` creates a dependent transaction for a new thread. The method `TxThread()` is the method of the new thread where a `DependentTransaction` object is passed as a parameter. Information about the dependent transaction is shown with the helper method `DisplayTransactionInformation()`. Before the thread exits, the `Complete()` method of the dependent transaction is invoked to define the outcome of the transaction. A dependent transaction can define the outcome of the transaction by calling either the `Complete()` or `Rollback()` method. The `Complete()` method sets the success bit. If the root transaction finishes, and if all dependent transactions have set the success bit to `true`, the transaction commits. If any of the dependent transactions set the abort bit by invoking the `Rollback()` method, the complete transaction aborts:

```
static void TxThread(object obj)
{
   DependentTransaction tx = obj as DependentTransaction;
   Utilities.DisplayTransactionInformation("Dependent Transaction",
         tx.TransactionInformation);

   Thread.Sleep(3000);
```

```
      tx.Complete();

      Utilities.DisplayTransactionInformation("Dependent TX Complete",
            tx.TransactionInformation);
   }
```

code snippet TransactionSamples/Program.cs

With the `DependentTransaction()` method, first a root transaction is created by instantiating the class `CommittableTransaction`, and the transaction information is shown. Next, the method `tx.DependentClone()` creates a dependent transaction. This dependent transaction is passed to the method `TxThread()` that is defined as the entry point of a new thread.

The method `DependentClone()` requires an argument of type `DependentCloneOption`, which is an enumeration with the values `BlockCommitUntilComplete` and `RollbackIfNotComplete`. This option is important if the root transaction completes before the dependent transaction. Setting the option to `RollbackIfNotComplete`, the transaction aborts if the dependent transaction didn't invoke the `Complete()` method before the `Commit()` method of the root transaction. Setting the option to `BlockCommitUntilComplete`, the method `Commit()` waits until the outcome is defined by all dependent transactions.

Next, the `Commit()` method of the `CommittableTransaction` class is invoked if the user does not abort the transaction.

```
static void DependentTransaction()
{
   var tx = new CommittableTransaction();
   Utilities.DisplayTransactionInformation("Root TX created",
         tx.TransactionInformation);

   try
   {
      new Thread(TxThread).Start(tx.DependentClone(
            DependentCloneOption.BlockCommitUntilComplete));

      if (Utilities.AbortTx())
      {
         throw new ApplicationException("transaction abort");
      }

      tx.Commit();
   }
   catch (Exception ex)
   {
      Console.WriteLine(ex.Message);
      tx.Rollback();
   }

   Utilities.DisplayTransactionInformation("TX finished",
         tx.TransactionInformation);
}
```

code snippet TransactionSamples/Program.cs

With the output of the application, you can see the root transaction with its identifier. Because of the option `DependentCloneOption.BlockCommitUntilComplete`, the root transaction waits in the `Commit()` method until the outcome of the dependent transaction is defined. As soon as the dependent transaction is finished, the transaction is committed:

```
Root TX created
Creation Time: 8:35:25 PM
Status: Active
Local ID: 50126e07-cd28-4e0f-a21f-a81a8e14a1a8:1
Distributed ID: 00000000-0000-0000-0000-0000000000

Abort the Transaction (y/n)? n

Dependent Transaction
Creation Time: 8:35:25 PM
Status: Active
Local ID: 50126e07-cd28-4e0f-a21f-a81a8e14a1a8:1
Distributed ID: 00000000-0000-0000-0000-0000000000

Dependent TX Complete
Root TX finished
Creation Time: 8:35:25 PM
Status: Committed
Local ID: 50126e07-cd28-4e0f-a21f-a81a8e14a1a8:1
Distributed ID: 00000000-0000-0000-0000-0000000000

Creation Time: 8:35:25 PM
Status: Committed
Local ID: 50126e07-cd28-4e0f-a21f-a81a8e14a1a8:1
Distributed ID: 00000000-0000-0000-0000-0000000000
```

Ambient Transactions

The really big advantage of `System.Transactions` is the ambient transactions feature. With ambient transactions, there is no need to manually enlist a connection with a transaction; this is done automatically from the resources supporting ambient transactions.

An ambient transaction is associated with the current thread. You can get and set the ambient transaction with the static property `Transaction.Current`. APIs supporting ambient transactions check this property to get an ambient transaction and enlist with the transaction. ADO.NET connections support ambient transactions.

You can create a `CommittableTransaction` object and assign it to the property `Transaction.Current` to initialize the ambient transaction. Another way to create ambient transactions is with the `TransactionScope` class. The constructor of the `TransactionScope` creates an ambient transaction.

Important methods of the `TransactionScope` are the `Complete()` and the `Dispose()` methods. The `Complete()` method sets the happy bit for the scope, and the `Dispose()` method finishes the scope and commits or rolls back the transaction if the scope is a root scope.

Because the `TransactionScope` class implements the `IDisposable` interface, you can define the scope with the `using` statement. The default constructor creates a new transaction. Immediately after creating the `TransactionScope` instance, the transaction is accessed with the get accessor of the property `Transaction.Current` to display the transaction information on the console.

To get the information when the transaction is completed, the method `OnTransactionCompleted()` is set to the `TransactionCompleted` event of the ambient transaction.

Then a new `Student` object is created and written to the database by calling the `StudentData.AddStudent()` method. With ambient transactions, it is no longer necessary to pass a `Transaction` object to this method because the `SqlConnection` class supports ambient transactions and automatically enlists it with the connection. Then the `Complete()` method of the `TransactionScope` class sets the success bit. With the end of the `using` statement, the `TransactionScope` is disposed, and a commit is done. If the `Complete()` method is not invoked, the `Dispose()` method aborts the transaction.

If an ADO.NET connection should not enlist with an ambient transaction, you can set the value `Enlist=false` *with the connection string.*

```
static void TransactionScope()
{
   using (var scope = new TransactionScope())
   {
      Transaction.Current.TransactionCompleted +=
            OnTransactionCompleted;

      Utilities.DisplayTransactionInformation("Ambient TX created",
            Transaction.Current.TransactionInformation);

      var s1 = new Student
      {
          FirstName = "Ingo",
          LastName = "Rammer",
          Company = "thinktecture"
      };
      var db = new StudentData();
      db.AddStudent(s1);

      if (!Utilities.AbortTx())
         scope.Complete();
      else
         Console.WriteLine("transaction will be aborted");

   } // scope.Dispose()
}

static void OnTransactionCompleted(object sender, TransactionEventArgs e)
{
   Utilities.DisplayTransactionInformation("TX completed",
         e.Transaction.TransactionInformation);
}
```

code snippet TransactionSamples/Program.cs

Running the application, you can see an active ambient transaction after an instance of the `TransactionScope` class is created. The last output of the application is the output from the `TransactionCompleted` event handler to display the finished transaction state:

```
Ambient TX created
Creation Time: 9:55:40 PM
Status: Active
Local ID: a06df6fb-7266-435e-b90e-f024f1d6966e:1
Distributed ID: 00000000-0000-0000-0000-0000000000

Abort the Transaction (y/n)? n

TX completed
Creation Time: 9:55:40 PM
Status: Committed
Local ID: a06df6fb-7266-435e-b90e-f024f1d6966e:1
Distributed ID: 00000000-0000-0000-0000-0000000000
```

Nested Scopes with Ambient Transactions

With the `TransactionScope` class you can also nest scopes. The nested scope can be directly inside the scope or within a method that is invoked from a scope. A nested scope can use the same transaction as the outer scope, suppress the transaction, or create a new transaction that is independent from the outer scope. The requirement for the scope is defined with a `TransactionScopeOption` enumeration that is passed to the constructor of the `TransactionScope` class.

The values available with the `TransactionScopeOption` enumeration and their functionality are described in the following table:

TRANSACTIONSCOPEOPTION MEMBER	DESCRIPTION
`Required`	`Required` defines that the scope requires a transaction. If the outer scope already contains an ambient transaction, the inner scope uses the existing transaction. If an ambient transaction does not exist, a new transaction is created. If both scopes share the same transaction, every scope influences the outcome of the transaction. Only if all scopes set the success bit can the transaction commit. If one scope does not invoke the `Complete()` method before the root scope is disposed of, the transaction is aborted.
`RequiresNew`	`RequiresNew` always creates a new transaction. If the outer scope already defines a transaction, the transaction from the inner scope is completely independent. Both transactions can commit or abort independently.
`Suppress`	With `Suppress`, the scope does not contain an ambient transaction, whether or not the outer scope contains a transaction.

The next sample defines two scopes, in which the inner scope is configured to require a new transaction with the option `TransactionScopeOption.RequiresNew`:

```
using (var scope = new TransactionScope())
{
   Transaction.Current.TransactionCompleted +=
         OnTransactionCompleted;

   Utilities.DisplayTransactionInformation("Ambient TX created",
         Transaction.Current.TransactionInformation);

   using (var scope2 =
         new TransactionScope(TransactionScopeOption.RequiresNew))
   {
      Transaction.Current.TransactionCompleted +=
            OnTransactionCompleted;

      Utilities.DisplayTransactionInformation(
             "Inner Transaction Scope",
             Transaction.Current.TransactionInformation);

      scope2.Complete();
   }
   scope.Complete();
}
```

code snippet TransactionSamples/Program.cs

Running the application, you can see that both scopes have different transaction identifiers, although the same thread is used. Having one thread with different ambient transactions because of different scopes, the transaction identifier differs in the last number following the GUID.

A GUID is a globally unique identifier consisting of a 128-bit unique value.

```
Ambient TX created
Creation Time: 11:01:09 PM
Status: Active
Local ID: 54ac1276-5c2d-4159-84ab-36b0217c9c84:1
Distributed ID: 00000000-0000-0000-0000-0000000000

Inner Transaction Scope
Creation Time: 11:01:09 PM
Status: Active
Local ID: 54ac1276-5c2d-4159-84ab-36b0217c9c84:2
Distributed ID: 00000000-0000-0000-0000-0000000000

TX completed
Creation Time: 11:01:09 PM
Status: Committed
Local ID: 54ac1276-5c2d-4159-84ab-36b0217c9c84:2
Distributed ID: 00000000-0000-0000-0000-0000000000

TX completed
Creation Time: 11:01:09 PM
Status: Committed
Local ID: 54ac1276-5c2d-4159-84ab-36b0217c9c84:1
Distributed ID: 00000000-0000-0000-0000-0000000000
```

If you change the inner scope to the setting `TransactionScopeOption.Required`, you will find that both scopes are using the same transaction, and both scopes influence the outcome of the transaction.

Multithreading with Ambient Transactions

If multiple threads should use the same ambient transaction, you need to do some extra work. An ambient transaction is bound to a thread, so if a new thread is created, it does not have the ambient transaction from the starter thread.

This behavior is demonstrated in the next example. In the `Main()` method, a `TransactionScope` is created. Within this transaction scope, a new thread is started. The main method of the new thread `ThreadMethod()` creates a new transaction scope. With the creation of the scope, no parameters are passed, and therefore, the default option `TransactionScopeOption.Required` gets into play. If an ambient transaction exists, the existing transaction is used. If there is no ambient transaction, a new transaction is created:

```
using System;
using System.Threading;
using System.Transactions;

namespace Wrox.ProCSharp.Transactions
{
   class Program
   {
      static void Main()
      {
         try
         {
            using (var scope = new TransactionScope())
            {
               Transaction.Current.TransactionCompleted +=
                     TransactionCompleted;

               Utilities.DisplayTransactionInformation("Main thread TX",
                        Transaction.Current.TransactionInformation);

                  new Thread(ThreadMethod).Start();

                  scope.Complete();
               }
            }
            catch (TransactionAbortedException ex)
            {
               Console.WriteLine("Main—Transaction was aborted, {0}",
                                 ex.Message);
            }
         }

         static void TransactionCompleted(object sender, TransactionEventArgs e)
         {
            Utilities.DisplayTransactionInformation("TX completed",
                  e.Transaction.TransactionInformation);
         }

         static void ThreadMethod(object dependentTx)
         {
            try
            {
               using (var scope = new TransactionScope())
               {
                  Transaction.Current.TransactionCompleted +=
                        TransactionCompleted;

                  Utilities.DisplayTransactionInformation("Thread TX",
                        Transaction.Current.TransactionInformation);
                  scope.Complete();
               }
            }
            catch (TransactionAbortedException ex)
            {
                Console.WriteLine("ThreadMethod—Transaction was aborted, {0}",
                     ex.Message);
            }
         }
      }
   }
```

code snippet MultithreadingAmbientTx/Program.cs

As you start the application, you can see that the transactions from the two threads are completely independent. The transaction from the new thread has a different transaction ID. The transaction ID differs by the last number after the GUID in the same way as you have seen with nested scopes when the nested scope required a new transaction:

```
Main thread TX
Creation Time: 21:41:25
Status: Active
Local ID: f1e736ae-84ab-4540-b71e-3de272ffc476:1
Distributed ID: 00000000-0000-0000-0000-000000000000

TX completed
Creation Time: 21:41:25
Status: Committed
Local ID: f1e736ae-84ab-4540-b71e-3de272ffc476:1
Distributed ID: 00000000-0000-0000-0000-000000000000

Thread TX
```

```
Creation Time: 21:41:25
Status: Active
Local ID: f1e736ae-84ab-4540-b71e-3de272ffc476:2
Distributed ID: 00000000-0000-0000-0000-000000000000

TX completed
Creation Time: 21:41:25
Status: Committed
Local ID: f1e736ae-84ab-4540-b71e-3de272ffc476:2
Distributed ID: 00000000-0000-0000-0000-000000000000
```

To use the same ambient transaction in another thread, you need the help of dependent transactions. Now, the sample is changed to pass a dependent transaction to the new thread. The dependent transaction is created from the ambient transaction by calling the `DependentClone()` method on the ambient transaction. With this method, the setting `DependentCloneOption.BlockCommitUntilComplete` is set so that the calling thread waits until the new thread is completed before committing the transaction:

```
class Program
{
   static void Main()
   {
      try
      {
         using (var scope = new TransactionScope())
         {
            Transaction.Current.TransactionCompleted +=
                  TransactionCompleted;

            Utilities.DisplayTransactionInformation("Main thread TX",
                  Transaction.Current.TransactionInformation);

            new Thread(ThreadMethod).Start(
                  Transaction.Current.DependentClone(
                  DependentCloneOption.BlockCommitUntilComplete));

            scope.Complete();
         }
      }
      catch (TransactionAbortedException ex)
      {
         Console.WriteLine("Main—Transaction was aborted, {0}",
                           ex.Message);
      }
   }
```

In the method of the thread, the dependent transaction that is passed is assigned to the ambient transaction by using the set accessor of the `Transaction.Current` property. Now the transaction scope is using the same transaction by using the dependent transaction. When you are finished using the dependent transaction, you need to invoke the `Complete()` method of the `DependentTransaction` object:

```
   static void ThreadMethod(object dependentTx)
   {
      DependentTransaction dTx = dependentTx as DependentTransaction;

      try
      {
         Transaction.Current = dTx;

         using (var scope = new TransactionScope())
         {
            Transaction.Current.TransactionCompleted +=
                  TransactionCompleted;

            Utilities.DisplayTransactionInformation("Thread TX",
                  Transaction.Current.TransactionInformation);
            scope.Complete();
         }
      }
      catch (TransactionAbortedException ex)
      {
          Console.WriteLine("ThreadMethod — Transaction was aborted, {0}",
                ex.Message);
      }
      finally
      {
         if (dTx != null)
         {
            dTx.Complete();
         }
      }
   }

   static void TransactionCompleted(object sender, TransactionEventArgs e)
   {
      Utilities.DisplayTransactionInformation("TX completed",
           e.Transaction.TransactionInformation);
   }
}
```

Running the application now, you can see that the main thread and the newly created thread are using, and influencing, the same transaction. The transaction listed by the threads has the same identifier. If with one thread the success bit is not set by calling the `Complete()` method, the complete transaction aborts:

```
Main thread TX
Creation Time: 23:00:57
Status: Active
Local ID: 2fb1b54d-61f5-4d4e-a55e-f4a9e04778be:1
Distributed ID: 00000000-0000-0000-0000-000000000000

Thread TX
Creation Time: 23:00:57
Status: Active
Local ID: 2fb1b54d-61f5-4d4e-a55e-f4a9e04778be:1

```

ISOLATION LEVEL

At the beginning of this chapter, you see the ACID properties used to describe transactions. The letter *I* (Isolation) in *ACID* is not always fully required. For performance reasons, you might reduce isolation requirements, but you must be aware of the issues that you will encounter if you change the isolation level.

The problems that you can encounter if you don't completely isolate the scope outside the transaction can be divided into three categories:

- **Dirty reads** — Another transaction can read records that are changed within the transaction. Because the data that is changed within the transaction might roll back to its original state, reading this intermediate state from another transaction is considered "dirty" — the data has not been committed. You can avoid this by locking the records to be changed.
- **Nonrepeatable reads** — When data is read inside a transaction, and while the transaction is running, another transaction changes the same records. If the record is read once more inside the transaction, the result is different — nonrepeatable. You can avoid this by locking the read records.
- **Phantom reads** — When a range of data is read, for example, with a `WHERE` clause. Another transaction can add a new record that belongs to the range that is read within the transaction. A new read with the same `WHERE` clause returns a different number of rows. Phantom reads can be a specific problem when doing an `UPDATE` of a range of rows. For example, `UPDATE Addresses SET Zip=4711 WHERE (Zip=2315)` updates the ZIP code of all records from 2315 to 4711. After doing the update, there may still be records with a ZIP code of 2315 if another user added a new record with ZIP 2315 while the update was running. You can avoid this by doing a range lock.

When defining the isolation requirements, you can set the isolation level. This is set with an `IsolationLevel` enumeration that is configured when the transaction is created (either with the constructor of the `CommittableTransaction` class or with the constructor of the `TransactionScope` class). The `IsolationLevel` defines the locking behavior. The next table lists the values of the `IsolationLevel` enumeration.

ISOLATION LEVEL	DESCRIPTION
`ReadUncommitted`	With `ReadUncommitted`, transactions are not isolated from each other. With this level, there is no wait for locked records from other transactions. This way, uncommitted data can be read from other transactions — dirty reads. This level is usually used just for reading records where it does not matter if you read interim changes (for example, reports).
`ReadCommitted`	`ReadCommitted` waits for records with a write-lock from other transactions. This way, a dirty read cannot happen. This level sets a read-lock for the current record read and a write-lock for the records being written until the transaction is completed. Reading a sequence of records, with every new record that is read, the prior record is unlocked. That's why nonrepeatable reads can happen.
`RepeatableRead`	`RepeatableRead` holds the lock for the records read until the transaction is completed. This way, the problem of nonrepeatable reads is avoided. Phantom reads can still occur.
`Serializable`	`Serializable` holds a range lock. While the transaction is running, it is not possible to add a new record that belongs to the same range from which the data is being read.
`Snapshot`	The isolation level `Snapshot` is possible only with SQL Server 2005 and later versions. This level reduces the locks as modified rows are copied. This way, other transactions can still read the old data without the need to wait for an unlock.
`Unspecified`	The level `Unspecified` indicates that the provider is using an isolation level value that is different from the values defined by the `IsolationLevel` enumeration.
`Chaos`	The level `Chaos` is similar to `ReadUncommitted`, but in addition to performing the actions of the `ReadUncommitted` value, `Chaos` does not lock updated records.

The next table gives you a summary of the problems that can occur as a result of setting the most commonly used transaction isolation levels.

ISOLATION LEVEL	DIRTY READS	NONREPEATABLE READS	PHANTOM READS
Read Uncommitted	Y	Y	Y
Read Committed	N	Y	Y
Repeatable Read	N	N	Y
Serializable	N	N	N

The following code segment shows how the isolation level can be set with the `TransactionScope` class. With the constructor of `TransactionScope`, you can set the `TransactionScopeOption` that was discussed earlier and the `TransactionOptions`. The `TransactionOptions` class allows you to define the `IsolationLevel` and the `Timeout`:

```
var options = new TransactionOptions();
options.IsolationLevel = IsolationLevel.ReadUncommitted;
options.Timeout = TimeSpan.FromSeconds(90);
using (TransactionScope scope =
      new TransactionScope(TransactionScopeOption.Required,
      options))
{
   // Read data without waiting for locks from other transactions,
   // dirty reads are possible.
}
```

CUSTOM RESOURCE MANAGERS

One of the biggest advantages of the new transaction model is that it is relatively easy to create custom resource managers that participate in the transaction. A resource manager does not manage only durable resources but can also manage volatile or in-memory resources — for example, a simple `int` and a generic list.

Figure 23-4 shows the relationship between a resource manager and transaction classes. The resource manager implements the interface `IEnlistmentNotification` that defines the methods `Prepare()`, `InDoubt()`, `Commit()`, and `Rollback()`. The resource manager implements this interface to manage transactions for a resource. To be part of a transaction, the resource manager must enlist with the `Transaction` class. Volatile resource managers invoke the method `EnlistVolatile()`; durable resource managers invoke `EnlistDurable()`. Depending on the transaction's outcome, the transaction manager invokes the methods from the interface `IEnlistmentNotification` with the resource manager.

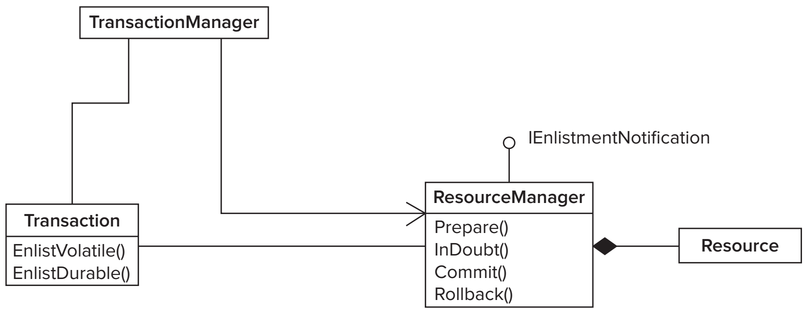

FIGURE 23-4

The next table explains the methods of the `IEnlistmentNotification` interface that you must implement with resource managers. As you review the table, recall the active, prepared, and committing phases explained earlier in this chapter in the "Transaction Phases" section.

IENLISTMENTNOTIFICATION MEMBER	DESCRIPTION
`Prepare()`	The transaction manager invokes the `Prepare()` method for preparation of the transaction. The resource manager completes the preparation by invoking the `Prepared()` method of the `PreparingEnlistment` parameter, which is passed to the `Prepare()` method. If the work cannot be done successfully, the resource manager informs the transaction manager by invoking the method `ForceRollback()`. A durable resource manager must write a log so that it can finish the transaction successfully after the prepare phase.
`Commit()`	When all resource managers have successfully prepared for the transaction, the transaction manager invokes the `Commit()` method. The resource manager can now complete the work to make it visible outside the transaction and invoke the `Done()` method of the `Enlistment` parameter.
`Rollback()`	If one of the resources could not successfully prepare for the transaction, the transaction manager invokes the `Rollback()` method with all resource managers. After the state is returned to the state prior to the transaction, the resource manager invokes the `Done()` method of the `Enlistment` parameter.
`InDoubt()`	If there is a problem after the transaction manager invokes the `Commit()` method (and the resources don't return completion information with the `Done()` method), the transaction manager invokes the `InDoubt()` method.

Transactional Resources

A transactional resource must keep the live value and a temporary value. The live value is read from outside the transaction and defines the valid state when the transaction rolls back. The temporary value defines the valid state of the transaction when the transaction commits.

To make non-transactional types transactional, the generic sample class `Transactional<T>` wraps a non-generic type, so you can use it like this:

```
Transactional<int> txInt = new Transactional<int>();
Transactional<string> txString = new Transactional<string>();
```

Let's look at the implementation of the class `Transactional<T>`. The live value of the managed resource has the variable `liveValue`; the temporary value that is associated with a transaction is stored within the `ResourceManager<T>`. The variable `enlistedTransaction` is associated with the ambient transaction if there is one:

```
using System.Diagnostics;
Insert IconMargin    [FILENAME]
using System.Transactions;

namespace Wrox.ProCSharp.Transactions
{
    public partial class Transactional<T>
    {
        private T liveValue;
        private ResourceManager<T> enlistment;
        private Transaction enlistedTransaction;
```

code snippet CustomResource/Transactional.cs

With the `Transactional` constructor, the live value is set to the variable `liveValue`. If the constructor is invoked from within an ambient transaction, the `GetEnlistment()` helper method is invoked. `GetEnlistment()` first checks if there is an ambient transaction and asserts if there is none. If the transaction is not already enlisted, the `ResourceManager<T>` helper class is instantiated, and the resource manager is enlisted with the transaction by invoking the method `EnlistVolatile()`. Also, the variable `enlistedTransaction` is set to the ambient transaction.

If the ambient transaction is different from the enlisted transaction, an exception is thrown. The implementation does not support changing the same value from within two different transactions. If you have this requirement, you can create a lock and wait for the lock to be released from one transaction before changing it within another transaction:

```
public Transactional(T value)
{
    if (Transaction.Current == null)
    {
        this.liveValue = value;
    }
    else
    {
        this.liveValue = default(T);
        GetEnlistment().Value = value;
    }
}

public Transactional()
    : this(default(T)) {}

private ResourceManager<T> GetEnlistment()
{
    Transaction tx = Transaction.Current;
    Trace.Assert(tx != null, "Must be invoked with ambient transaction");

    if (enlistedTransaction == null)
    {
        enlistment = new ResourceManager<T>(this, tx);
        tx.EnlistVolatile(enlistment, EnlistmentOptions.None);
        enlistedTransaction = tx;
        return enlistment;
    }
    else if (enlistedTransaction == Transaction.Current)
    {
        return enlistment;
    }
    else
    {
        throw new TransactionException(
            "This class only supports enlisting with one transaction");
    }
}
```

The property `Value` returns the value of the contained class and sets it. However, with transactions, you cannot just set and return the `liveValue` variable. This would be the case only if the object were outside a transaction. To make the code more readable, the property `Value` uses the methods `GetValue()` and `SetValue()` in the implementation:

```
public T Value
{
    get { return GetValue(); }
    set { SetValue(value); }
}
```

The method `GetValue()` checks if an ambient transaction exists. If one doesn't exist, the `liveValue` is returned. If there is an ambient transaction, the `GetEnlistment()` method shown earlier returns the resource manager, and with the `Value` property, the temporary value for the contained object within the transaction is returned.

The method SetValue() is very similar to GetValue(); the difference is that it changes the live or temporary value:

```
            protected virtual T GetValue()
            {
                if (Transaction.Current == null)
                {
                    return liveValue;
                }
                else
                {
                    return GetEnlistment().Value;
                }
            }

            protected virtual void SetValue(T value)
            {
                if (Transaction.Current == null)
                {
                    liveValue = value;
                }
                else
                {
                    GetEnlistment().Value = value;
                }
            }
```

The Commit() and Rollback() methods that are implemented in the class Transactional<T> are invoked from the resource manager. The Commit() method sets the live value from the temporary value received with the first argument and nullifies the variable enlistedTransaction as the transaction is completed. With the Rollback() method, the transaction is completed as well, but here the temporary value is ignored, and the live value is kept in use:

```
            internal void Commit(T value, Transaction tx)
            {
                liveValue = value;
                enlistedTransaction = null;
            }

            internal void Rollback(Transaction tx)
            {
                enlistedTransaction = null;
            }
        }
```

Because the resource manager that is used by the class Transactional<T> is used only within the Transactional<T> class itself, it is implemented as an inner class. With the constructor, the parent variable is set to have an association with the transactional wrapper class. The temporary value used within the transaction is copied from the live value. Remember the isolation requirements with transactions:

```
    using System;
    using System.Diagnostics;
    using System.IO;
    using System.Runtime.Serialization.Formatters.Binary;
    using System.Transactions;

    namespace Wrox.ProCSharp.Transactions
    {
        public partial class Transactional<T>
        {
            internal class ResourceManager<T1>: IEnlistmentNotification
            {
                private Transactional<T1> parent;
        private Transaction currentTransaction;

        internal ResourceManager(Transactional<T1> parent, Transaction tx)
        {
            this.parent = parent;
            Value = DeepCopy(parent.liveValue);
            currentTransaction = tx;
        }

        public T1 Value { get; set; }
```

code snippet** **CustomResource/ResourceManager.cs

Because the temporary value may change within the transaction, the live value of the wrapper class may not be changed within the transaction. When creating a copy with some classes, it is possible to invoke the `Clone()` method that is defined with the `ICloneable` interface. However, as the `Clone()` method is defined, it allows implementations to create either a shallow or a deep copy. If type `T` contains reference types and implements a shallow copy, changing the temporary value would also change the original value. This would be in conflict with the isolation and consistency features of transactions. Here, a deep copy is required.

To do a deep copy, the method `DeepCopy()` serializes and deserializes the object to and from a stream. Because in C# 4 it is not possible to define a constraint to the type `T` indicating that serialization is required, the static constructor of the class `Transactional<T>` checks if the type is serializable by checking the property `IsSerializable` of the `Type` object.

```
        static ResourceManager()
        {
            Type t = typeof(T1);
            Trace.Assert(t.IsSerializable, "Type " + t.Name +
                " is not serializable");
        }

        private T1 DeepCopy(T1 value)
        {
            using (MemoryStream stream = new MemoryStream())
            {
                BinaryFormatter formatter = new BinaryFormatter();
                formatter.Serialize(stream, value);
                stream.Flush();
                stream.Seek(0, SeekOrigin.Begin);

                return (T1)formatter.Deserialize(stream);
            }
        }
```

The interface `IEnlistmentNotification` is implemented by the class `ResourceManager<T>`. This is the requirement for enlisting with transactions.

The implementation of the `Prepare()` method just answers by invoking `Prepared()` with `preparingEnlistment`. There should not be a problem assigning the temporary value to the live value, so the `Prepare()` method succeeds. With the implementation of the `Commit()` method, the `Commit()` method of the parent is invoked, where the variable `liveValue` is set to the value of the `ResourceManager` that is used within the transaction. The `Rollback()` method just completes the work and leaves the live value where it was. With a volatile resource, there is not a lot you can do in the `InDoubt()` method. Writing a log entry could be useful:

```
        public void Prepare(PreparingEnlistment preparingEnlistment)
        {
            preparingEnlistment.Prepared();
        }
```

```
                public void Commit(Enlistment enlistment)
                {
                    parent.Commit(Value, currentTransaction);
                    enlistment.Done();
                }

                public void Rollback(Enlistment enlistment)
                {
                    parent.Rollback(currentTransaction);
                    enlistment.Done();
                }

                public void InDoubt(Enlistment enlistment)
                {
                    enlistment.Done();
                }
            }
        }
    }
```

The class `Transactional<T>` can now be used to make non-transactional classes transactional — for example, `int` and `string` but also more complex classes such as `Student` — as long as the type is serializable:

```
using System;
using System.Transactions;

namespace Wrox.ProCSharp.Transactions
{
   class Program
   {
      static void Main()
      {
         var intVal = new Transactional<int>(1);
         var student1 = new Transactional<Student>(new Student());
         student1.Value.FirstName = "Andrew";
         student1.Value.LastName = "Wilson";

         Console.WriteLine("before the transaction, value: {0}",
               intVal.Value);
         Console.WriteLine("before the transaction, student: {0}",
               student1.Value);

         using (var scope = new TransactionScope())
         {
            intVal.Value = 2;
            Console.WriteLine("inside transaction, value: {0}", intVal.Value);

            student1.Value.FirstName = "Ten";
            student1.Value.LastName = "SixtyNine";

            if (!Utilities.AbortTx())
               scope.Complete();
         }
         Console.WriteLine("outside of transaction, value: {0}",
               intVal.Value);
         Console.WriteLine("outside of transaction, student: {0}",
               student1.Value);
      }
   }
}
```

code snippet CustomResource/Program.cs

The following console output shows a run of the application with a committed transaction:

```
before the transaction, value: 1
before the transaction: student: Andrew Wilson
inside transaction, value: 2

Abort the Transaction (y/n)? n

outside of transaction, value: 2
outside of transaction, student: Ten SixtyNine
```

TRANSACTIONS WITH WINDOWS 7 AND WINDOWS SERVER 2008

You can write a custom durable resource manager that works with the `File` and `Registry` classes. A file-based durable resource manager can copy the original file and write changes to the temporary file inside a temporary directory to make the changes persistent. When committing the transaction, the original file is replaced by the temporary file. Writing custom durable resource managers for files and the registry is no longer necessary since Windows Vista and Windows Server 2008. With these and follow-on operating systems, native transactions with the file system and with the registry are supported. For this, there are new API calls such as `CreateFileTransacted()`, `CreateHardLinkTransacted()`, `CreateSymbolicLinkTransacted()`, `CopyFileTransacted()`, and so on. What these API calls have in common is that they require a handle to a transaction passed as an argument; they do not support ambient transactions. The transactional API calls are not available from .NET 4, but you can create a custom wrapper by using `Platform Invoke`.

The sample application wraps the native method `CreateFileTransacted()` for creating transactional file streams from .NET applications.

When invoking native methods, the parameters of the native methods must be mapped to .NET data types. Because of security issues, the base class `SafeHandle` is used to map a native `HANDLE` type. `SafeHandle` is an abstract type that wraps operating system handles and supports critical finalization of handle resources. Depending on the allowed values of a handle, the derived classes `SafeHandleMinusOneIsInvalid` and `SafeHandleZeroOrMinusOneIsInvalid` can be used to wrap native handles. `SafeFileHandle` itself derives from `SafeHandleZeroOrMinusOneIsInvalid`. To map a handle to a transaction, the class `SafeTransactionHandle` is defined:

```
using System;
using System.Runtime.Versioning;
using System.Security.Permissions;
using Microsoft.Win32.SafeHandles;

namespace Wrox.ProCSharp.Transactions
{
    [SecurityPermission(SecurityAction.LinkDemand, UnmanagedCode = true)]
    internal sealed class SafeTransactionHandle: SafeHandleZeroOrMinusOneIsInvalid
    {
        private SafeTransactionHandle()
            : base(true) { }

        public SafeTransactionHandle(IntPtr preexistingHandle, bool ownsHandle)
            : base(ownsHandle)
        {
                SetHandle(preexistingHandle);
            }

            [ResourceExposure(ResourceScope.Machine)]
            [ResourceConsumption(ResourceScope.Machine)]
            protected override bool ReleaseHandle()
            {
                return NativeMethods.CloseHandle(handle);
            }
        }
    }
```

code snippet FileSystemTransactions/SafeTransactionHandle.cs

All native methods used from .NET are defined with the class `NativeMethods` shown here. With the sample, the native APIs needed are `CreateFileTransacted()` and `CloseHandle()`, which are defined as static members of the class. The methods are declared extern because there is no C# implementation. Instead, the implementation is found in the native DLL as defined by the attribute `DllImport`. Both of these methods can be found in the native DLL `Kernel32.dll`. With the method declaration, the parameters defined with the Windows API call are mapped to .NET data types. The parameter `txHandle` represents a handle to a transaction and is of the previously defined type `SafeTransactionHandle`:

```
using System;
using System.Runtime.ConstrainedExecution;
using System.Runtime.InteropServices;
using System.Runtime.Versioning;
using Microsoft.Win32.SafeHandles;

namespace Wrox.ProCSharp.Transactions
{
   internal static class NativeMethods
   {
      [DllImport("Kernel32.dll", CallingConvention = CallingConvention.StdCall,
                 CharSet = CharSet.Unicode)]
      internal static extern SafeFileHandle CreateFileTransacted(
          String lpFileName,
          uint dwDesiredAccess,
          uint dwShareMode,
          IntPtr lpSecurityAttributes,
          uint dwCreationDisposition,
          int dwFlagsAndAttributes,
          IntPtr hTemplateFile,
          SafeTransactionHandle txHandle,
          IntPtr miniVersion,
          IntPtr extendedParameter);

      [DllImport("Kernel32.dll", SetLastError = true)]
      [ResourceExposure(ResourceScope.Machine)]
      [ReliabilityContract(Consistency.WillNotCorruptState, Cer.Success)]
      [return: MarshalAs(UnmanagedType.Bool)]
      internal static extern bool CloseHandle(IntPtr handle);

   }
}
```

code snippet FileSystemTransactions/NativeMethods.cs

The interface `IKernelTransaction` is used to get a transaction handle and pass it to the transacted Windows API calls. This is a COM interface and must be wrapped to .NET by using COM interop attributes as shown. The attribute GUID must have exactly the identifier as it is used here with the interface definition, because this is the identifier used with the definition of the COM interface:

```
using System;
using System.Runtime.InteropServices;

namespace Wrox.ProCSharp.Transactions
{
   [ComImport]
   [Guid("79427A2B-F895-40e0-BE79-B57DC82ED231")]
   [InterfaceType(ComInterfaceType.InterfaceIsIUnknown)]
   internal interface IKernelTransaction
   {
      void GetHandle(out SafeTransactionHandle ktmHandle);
   }
}
```

code snippet FileSystemTransactions/IKernelTransaction.cs

Finally, the class `TransactedFile` is the class that will be used by .NET applications. This class defines the method `GetTransactedFileStream()` that requires a filename as parameter and returns a `System.IO.FileStream`. The returned stream is a normal .NET stream; it just references a transacted file.

With the implementation, `TransactionInterop.GetDtcTransaction()` creates an interface pointer of the `IKernelTransaction` to the ambient transaction that is passed as an argument to `GetDtcTransaction()`. Using the interface `IKernelTransaction`, the handle of type `SafeTransactionHandle` is created. This handle is then passed to the wrapped API called `NativeMethods.CreateFileTransacted()`. With the returned file handle, a new `FileStream` instance is created and returned to the caller:

```
using System;
using System.IO;
using System.Security.Permissions;
using System.Transactions;
using Microsoft.Win32.SafeHandles;

namespace Wrox.ProCSharp.Transactions
{
   public static class TransactedFile
   {
      internal const short FILE_ATTRIBUTE_NORMAL = 0x80;
      internal const short INVALID_HANDLE_VALUE = -1;
      internal const uint GENERIC_READ = 0x80000000;
      internal const uint GENERIC_WRITE = 0x40000000;
      internal const uint CREATE_NEW = 1;
      internal const uint CREATE_ALWAYS = 2;
      internal const uint OPEN_EXISTING = 3;

      [FileIOPermission(SecurityAction.Demand, Unrestricted=true)]
      public static FileStream GetTransactedFileStream(string fileName)
      {
         IKernelTransaction ktx = (IKernelTransaction)
               TransactionInterop.GetDtcTransaction(Transaction.Current);

         SafeTransactionHandle txHandle;
         ktx.GetHandle(out txHandle);

         SafeFileHandle fileHandle = NativeMethods.CreateFileTransacted(
               fileName, GENERIC_WRITE, 0,
               IntPtr.Zero, CREATE_ALWAYS, FILE_ATTRIBUTE_NORMAL,
               IntPtr.Zero,
                txHandle, IntPtr.Zero, IntPtr.Zero);

            return new FileStream(fileHandle, FileAccess.Write);
         }
      }
   }
```

code snippet FileSystemTransactions/TransactedFile.cs

Now it is very easy to use the transactional API from .NET code. You can create an ambient transaction with the `TransactionScope` class and use the `TransactedFile` class within the context of the ambient transaction scope. If the transaction is aborted, the file is not written. If the transaction is committed, you can find the file in the temp directory:

```
using System;
using System.IO;
using System.Transactions;

namespace Wrox.ProCSharp.Transactions
{
   class Program
   {
      static void Main()
      {
         using (var scope = new TransactionScope())
         {
            FileStream stream = TransactedFile.GetTransactedFileStream(
                  "sample.txt");

            var writer = new StreamWriter(stream);
            writer.WriteLine("Write a transactional file");
            writer.Close();

            if (!Utilities.AbortTx())
               scope.Complete();
         }
      }
   }
}
```

code snippet Windows7Transactions/Program.cs

Now you can use databases, volatile resources, and files within the same transaction.

SUMMARY

In this chapter, you learned the attributes of transactions and how you can create and manage transactions with the classes from the `System.Transactions` namespace.

Transactions are described with ACID properties: atomicity, consistency, isolation, and durability. Not all these properties are always required, as you have seen with volatile resources that don't support durability but have isolation options.

The easiest way to deal with transactions is by creating ambient transactions and using the `TransactionScope` class. Ambient transactions are very useful working with the ADO.NET data adapter and the ADO.NET Entity Framework, where usually you do not open and close database connections explicitly. ADO.NET is covered in Chapter 30, "Core ADO.NET." Entity Framework is explained in Chapter 31, "ADO.NET Entity Framework."

Using the same transaction across multiple threads, you can use the `DependentTransaction` class to create a dependency on another transaction. By enlisting a resource manager that implements the interface `IEnlistmentNotification`, you can create custom resources that participate with transactions.

Finally, you have seen how to use Windows 7 and Windows Server 2008 transactions with the .NET Framework and C#.

With .NET Enterprise Services, you can create automatic transactions that make use of `System.Transactions`. You can read about this technology in the online Chapter 51, "Enterprise Services."

In the next chapter, you can learn how to create a Windows service that can be automatically started when the operating system boots. Transactions can be useful within a service as well.

24 Networking

WHAT'S IN THIS CHAPTER?

- Downloading files from the Web
- Using the WebBrowser control in a Windows Forms application
- Manipulating IP addresses and performing DNS lookups
- Socket programming with TCP, UDP, and socket classes

This chapter takes a fairly practical approach, mixing examples with a discussion of the relevant theory and networking concepts as appropriate. This chapter is not a guide to computer networking but an introduction to using the .NET Framework for network communication.

You will learn how to use the `WebBrowser` control in a Windows Forms environment. You will also learn how the `WebBrowser` control can make some specific Internet access tasks easier to accomplish. However, the chapter starts with the simplest case, sending a request to a server and storing the information sent back in the response.

This chapter covers facilities provided through the .NET base classes for using various network protocols, particularly HTTP and TCP, to access networks and the Internet as a client. We cover some of the lower-level means of getting at these protocols through the .NET Framework. You will also find other means of communicating via these items using technologies, such as the Windows Communication Foundation (WCF), covered in Chapter 43.

The two namespaces of most interest for networking are `System.Net` and `System.Net.Sockets`. The `System.Net` namespace is generally concerned with higher-level operations, for example, downloading and uploading files, and making web requests using HTTP and other protocols, whereas `System.Net.Sockets` contains classes to perform lower-level operations. You will find these classes useful when you want to work directly with sockets or protocols, such as TCP/IP. The methods in these classes closely mimic the Windows socket (Winsock) API functions derived from the Berkeley sockets interface. You will also find that some of the objects that this chapter works with are found in the `System.IO` namespace.

Chapters 40 through 42 discuss how you can use C# to write powerful, efficient, and dynamic web pages using ASP.NET. For the most part, the clients accessing ASP.NET pages will be users running Internet Explorer or other web browsers such as Opera or Firefox. However, you might want to add web-browsing features to your own application, or you might need your applications to programmatically obtain information from a web site. In this latter case, it is usually better for the site to implement a web service. However, when you are accessing public Internet sites, you might not have any control over how the site is implemented.

THE WEBCLIENT CLASS

If you only want to request a file from a particular URI (Uniform Resource Identifier), then you will find that the easiest .NET class to use is `System.Net.WebClient`. This is an extremely high-level class designed to perform basic operations with only one or two commands. The .NET Framework currently supports URIs beginning with the `http:`, `https:`, and `file:` identifiers.

Downloading Files

Two methods are available for downloading a file using `WebClient`. The method you choose depends on how you want to process the file's contents. If you simply want to save the file to disk, then you use the `DownloadFile()` method. This method takes two parameters: the URI of the file and a location (path and filename) to save the requested data:

```
WebClient Client = new WebClient();
Client.DownloadFile("http://www.reuters.com/", "ReutersHomepage.htm");
```

More commonly, your application will want to process the data retrieved in response from the web site. To do this, use the `OpenRead()` method, which returns a `Stream` reference that you can then use to retrieve the data into memory:

```
WebClient Client = new WebClient();
Stream strm = Client.OpenRead("http://www.reuters.com/");
```

Basic WebClient Example

The first example demonstrates the `WebClient.OpenRead()` method. You will display the contents of the downloaded page in a `ListBox` control. To begin, create a new project as a standard C# Windows Forms application and add a `ListBox` called `listBox1` with the docking property set to `DockStyle.Fill`. At the beginning of the file, you need to add the `System.Net` and `System.IO` namespaces references to your list of `using` directives. You then make the following changes to the constructor of the main form:

```
public Form1()
{
   InitializeComponent();
   WebClient client = new WebClient();
   Stream strm = client.OpenRead("http://www.reuters.com");
   StreamReader sr = new StreamReader(strm);
   string line;

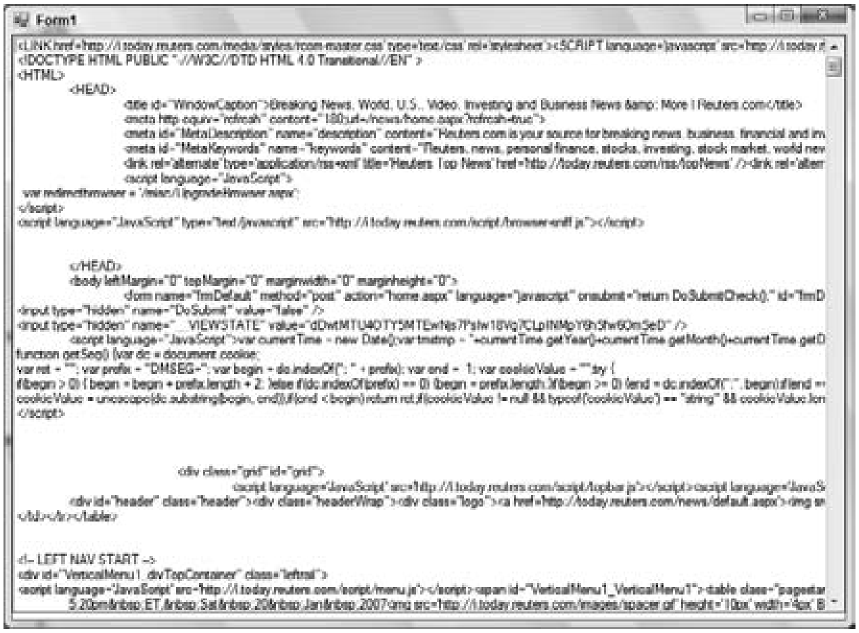
   while ( (line=sr.ReadLine()) != null )
   {
      listBox1.Items.Add(line);
   }

   strm.Close();
}
```

code download BasicWebClient.sln

In this example, you connect a `StreamReader` class from the `System.IO` namespace to the network stream. This allows you to obtain data from the stream as text through the use of higher-level methods, such as `ReadLine()`. This is an excellent example of the point made in Chapter 29, "Manipulating Files and the Registry," about the benefits of abstracting data movement into the concept of a stream.

Figure 24-1 shows the results of running this sample code.



```

FIGURE 24-1

The `WebClient` class also has an `OpenWrite()` method. This method returns a writable stream for you to send data to a URI. You can also specify the method used to send the data to the host; the default method is `POST`. The following code snippet assumes a writable directory named `accept` on the local machine. The code will create a file in the directory with the name `newfile.txt` and the contents `Hello World`:

```
WebClient webClient = new WebClient();
Stream stream = webClient.OpenWrite("http://localhost/accept/newfile.txt", "PUT");
StreamWriter streamWriter = new StreamWriter(stream);
streamWriter.WriteLine("Hello World");
streamWriter.Close();
```

Uploading Files

The `WebClient` class also features `UploadFile()` and `UploadData()` methods. You use these methods when you need to post an HTML form or to upload an entire file. `UploadFile()` uploads a file to a specified location given the local filename, whereas `UploadData()` uploads binary data supplied as an array of bytes to the specified URI (there is also a `DownloadData()` method for retrieving an array of bytes from a URI):

```
WebClient client = new WebClient();
client.UploadFile("http://www.ourwebsite.com/NewFile.htm",
                  "C:\\WebSiteFiles\\NewFile.htm");
byte[] image;
// code to initialize image so it contains all the binary data for
// some jpg file
client.UploadData("http://www.ourwebsite.com/NewFile.jpg", image);
```

Although the WebClient class is very simple to use, it has very limited features. In particular, you cannot use it to supply authentication credentials — a particular problem with uploading data is that not many sites will accept uploaded files without authentication! It is possible to add header information to requests and to examine any headers in the response, but only in a very generic sense — there is no specific support for any one protocol. This is because WebClient is a very general-purpose class designed to work with any protocol for sending a request and receiving a response (such as HTTP or FTP). It cannot handle any features specific to any one protocol, such as cookies, which are specific to HTTP. To take advantage of these features, you need to use a family of classes based on two other classes in the System.Net namespace: WebRequest and WebResponse.

WEBREQUEST AND WEBRESPONSE CLASSES

The WebRequest class represents the request for information to send to a particular URI. The URI is passed as a parameter to the Create() method. A WebResponse represents the data you retrieve from the server. By calling the WebRequest.GetResponse() method, you actually send the request to the web server and create a WebResponse object to examine the return data. As with the WebClient object, you can obtain a stream to represent the data, but in this case you use the WebResponse.GetResponseStream() method.

This section briefly discusses a few of the other areas supported by WebRequest, WebResponse, and other related classes.

You start off by downloading a web page using these classes, which is the same example as before, but using WebRequest and WebResponse. In the process, you uncover the class hierarchy involved, and then see how to take advantage of extra HTTP features that are supported by this hierarchy.

The following code shows the modifications you need to make to the BasicWebClient sample to use the WebRequest and WebResponse classes:

```
public Form1()
{
   InitializeComponent();

   WebRequest wrq = WebRequest.Create("http://www.reuters.com");
   WebResponse wrs = wrq.GetResponse();
   Stream strm = wrs.GetResponseStream();
   StreamReader sr = new StreamReader(strm);
   string line;

   while ( (line = sr.ReadLine()) != null)
   {
      listBox1.Items.Add(line);
   }

   strm.Close();
}
```

In the code example, you start by instantiating an object representing a web request. You don't do this using a constructor, but instead call the static method WebRequest.Create(). As you learn in more detail later in this chapter (see "The Web Request and Web Response Hierarchy" section), the WebRequest class is part of a hierarchy of classes supporting different network protocols. To receive a reference to the correct object for the request type, a factory mechanism is in place. The WebRequest.Create() method will create the appropriate object for the given protocol.

An important part of the HTTP protocol is the ability to send extensive header information with both request and response streams. This information can include cookies and the details of the particular browser sending the request (the user agent). As you would expect, the .NET Framework provides full support for accessing the most significant data. The WebRequest and WebResponse classes provide some support for reading the header information. However, two derived classes provide additional HTTP-specific information: `HttpWebRequest` and `HttpWebResponse`.

As you will see in more detail later in the section "The WebRequest and WebResponse Classes Hierarchy," creating a `WebRequest` with an HTTP URI results in an `HttpWebRequest` object instance. Because `HttpWebRequest` is derived from `WebRequest`, you can use the new instance whenever a `WebRequest` is required. In addition, you can cast the instance to an `HttpWebRequest` reference and access properties specific to the HTTP protocol. Likewise, the `GetResponse()` method call will actually return an `HttpWebResponse` instance as a `WebResponse` reference when dealing with HTTP. Again, you can perform a simple cast to access the HTTP-specific features.

You can examine a few of the header properties by adding the following code before the `GetResponse()` method call:

```
WebRequest wrq = WebRequest.Create("http://www.reuters.com");
HttpWebRequest hwrq = (HttpWebRequest)wrq;
listBox1.Items.Add("Request Timeout (ms) = " + wrq.Timeout);
listBox1.Items.Add("Request Keep Alive = " + hwrq.KeepAlive);
listBox1.Items.Add("Request AllowAutoRedirect = " + hwrq.AllowAutoRedirect);
```

The `Timeout` property is specified in milliseconds, and the default value is `100,000`. You can set the `Timeout` property to control how long the `WebRequest` object will wait for the response before throwing a `WebException`. You can check the `WebException.Status` property to view the reason for an exception. This enumeration includes status codes for timeouts, connection failures, protocol errors, and more.

The `KeepAlive` property is a specific extension to the HTTP protocol, so you access this property through an `HttpWebRequest` reference. `KeepAlive` allows multiple requests to use the same connection, saving time in closing and reopening connections on subsequent requests. The default value for this property is `true`.

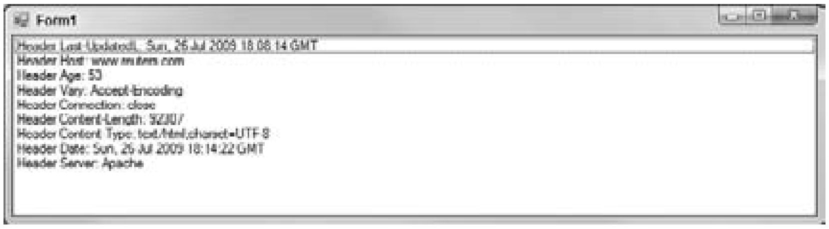
The `AllowAutoRedirect` property is also specific to the `HttpWebRequest` class. Use this property to control whether the web request should automatically follow redirection responses from the web server. Again, the default value is `true`. If you want to allow only a limited number of redirections, then set the `MaximumAutomaticRedirections` property of the `HttpWebRequest` to the desired number.

Although the request and response classes expose most of the important headers as properties, you can also use the `Headers` property itself to view the entire collection of headers. Add the following code after the `GetResponse()` method call to place all the headers in the `ListBox` control:

```
WebRequest wrq = WebRequest.Create("http://www.reuters.com");
WebResponse wrs = wrq.GetResponse();
WebHeaderCollection whc = wrs.Headers;

for(int i = 0; i < whc.Count; i++)
{
    listBox1.Items.Add(string.Format("Header {0}: {1}",
       whc.GetKey(i), whc[i]));
}
```

This example code produces the list of headers shown in Figure 24-2.



```
Header Last-Updated1: Sun, 26 Jul 2009 18:08:14 GMT
Header Host: www.reuters.com
Header Age: 53
Header Vary: Accept-Encoding
Header Connection: close
Header Content-Length: 92307
Header Content-Type: text/html;charset=UTF-8
Header Date: Sun, 26 Jul 2009 18:14:22 GMT
Header Server: Apache
```

FIGURE 24-2

Authentication

Another property in the `WebRequest` class is the `Credentials` property. If you need authentication credentials to accompany your request, then you can create an instance of the `NetworkCredential` class (also from the `System.Net` namespace) with a username and password. You can place the following code *before* the call to `GetResponse()`:

```
NetworkCredential myCred = new NetworkCredential("myusername", "mypassword");
wrq.Credentials = myCred;
```

Working with Proxies

You will find in enterprises that many firms must deal with a proxy server to make any type of HTTP or FTP request. Many times, the proxy server, which routes all the organization's requests and responses, uses some form of security (usually a username and a password). For your applications that use the `WebClient` or the `WebRequest` objects, you might need to take these proxy servers into account. As with the preceding `NetworkCredential` object, you are going to want to use the `WebProxy` object *before* you make a call to make the actual request:

```
WebProxy wp = new WebProxy("192.168.1.100", true);
wp.Credentials = new NetworkCredential("user1", "user1Password");
WebRequest wrq = WebRequest.Create("http://www.reuters.com");
wrq.Proxy = wp;
WebResponse wrs = wrq.GetResponse();
```

If you also require a designation of the user's domain in addition to its credentials, then you would use a different signature on the `NetworkCredential` instantiation:

```
WebProxy wp = new WebProxy("192.168.1.100", true);
wp.Credentials = new NetworkCredential("user1", "user1Password", "myDomain");
WebRequest wrq = WebRequest.Create("http://www.reuters.com");
wrq.Proxy = wp;
WebResponse wrs = wrq.GetResponse();
```

Asynchronous Page Requests

An additional feature of the `WebRequest` class is the ability to request pages asynchronously. This feature is significant because there can be quite a long delay between sending a request to a host and receiving the response. Methods such as `WebClient.DownloadData()` and `WebRequest.GetResponse()` will not return until the response from the server is complete. You might not want your application frozen due to a long period of inactivity, and in such scenarios it is better to use the `BeginGetResponse()` and `EndGetResponse()` methods. `BeginGetResponse()` works asynchronously and returns almost immediately. Under the covers, the runtime will asynchronously manage a background thread to retrieve the response from the server. Instead of returning a `WebResponse` object, `BeginGetResponse()` returns an object implementing the `IAsyncResult` interface. With this interface, you can poll or wait for the response to become available and then invoke `EndGetResponse()` to gather the results.

You can also pass a callback delegate into the `BeginGetResponse()` method. The target of a callback delegate is a method returning `void` and accepting an `IAsyncResult` reference as a parameter. When the worker thread is finished gathering the response, the runtime invokes the callback delegate to inform you of the completed work. As shown in the following code, calling `EndGetResponse()` in the callback method allows you to retrieve the `WebResponse` object:

```
public Form1()
{
   InitializeComponent();
   WebRequest wrq = WebRequest.Create("http://www.reuters.com");
```

```
      wrq.BeginGetResponse(new AsyncCallback(OnResponse), wrq);
   }

   protected static void OnResponse(IAsyncResult ar)
   {
      WebRequest wrq = (WebRequest)ar.AsyncState;
      WebResponse wrs = wrq.EndGetResponse(ar);
      // read the response...
   }
```

Notice that you can retrieve the original `WebRequest` object by passing the object as the second parameter to `BeginGetResponse()`. The second parameter is an object reference known as the state parameter. During the callback method, you can retrieve the same state object using the `AsyncState` property of `IAsyncResult`.

DISPLAYING OUTPUT AS AN HTML PAGE

The examples so far in this chapter show how the .NET base classes make it very easy to download and process data from the Internet. However, so far you have displayed files only as plain text. Quite often, you will want to view an HTML file in an Internet Explorer-style interface in which the rendered HTML allows you to see what the web document actually looks like. Unfortunately, there is no .NET version of Microsoft's Internet Explorer, but that does not mean that you cannot easily accomplish this task.

Before the release of the .NET Framework 2.0, you could make reference to a Component Object Model (COM) object that was an encapsulation of Internet Explorer and use the .NET-interop capabilities to have aspects of your application work as a browser. Now, since the release of the .NET Framework 2.0, you can use the built-in `WebBrowser` control available for your Windows Forms applications.

The `WebBrowser` control encapsulates the COM object even further for you and makes the tasks that were once more complicated, even easier. In addition to the `WebBrowser` control, another option is to use the programmatic ability to call up Internet Explorer instances from your code.

When not using the new `WebBrowser` control, you can programmatically start an Internet Explorer process and navigate to a web page using the `Process` class in the `System.Diagnostics` namespace:

```
Process myProcess = new Process();
myProcess.StartInfo.FileName = "iexplore.exe";
myProcess.StartInfo.Arguments = "http://www.wrox.com";
myProcess.Start();
```

However, the preceding code launches Internet Explorer as a separate window. Your application has no connection to the new window and therefore cannot control the browser.

Using the new `WebBrowser` control, however, allows you to display and control the browser as an integrated part of your application. The new `WebBrowser` control is quite sophisticated, featuring a large number of methods, properties, and events.

Allowing Simple Web Browsing from Your Applications

For the sake of simplicity, start by creating a Windows Forms application that simply has a `TextBox` control and a `WebBrowser` control. You will build the application so that the end user will simply enter a URL into the text box and press Enter, and the `WebBrowser` control will do all the work of fetching the web page and displaying the resulting document.

In Visual Studio 2010 Designer, your application should look like Figure 24-3.

With this application, when the end user types a URL and presses Enter, this key press will register with the application. Then the `WebBrowser` control will go off to retrieve the requested page, subsequently displaying it in the control itself.

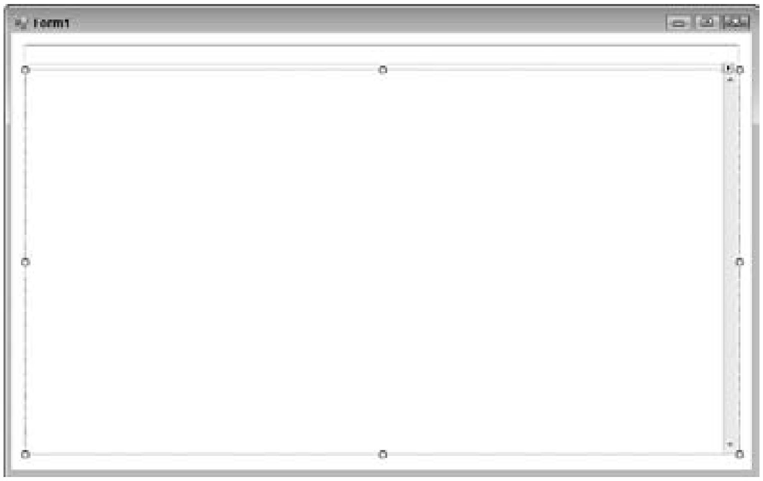


FIGURE 24-3

The code behind this application is illustrated here:

```
using System;
using System.Windows.Forms;

namespace Browser
{
    partial class Form1: Form
    {
        public Form1()
        {
            InitializeComponent();
        }

        private void textBox1_KeyPress(object sender, KeyPressEventArgs e)
        {
            if (e.KeyChar == (char)13)
            {
                webBrowser1.Navigate(textBox1.Text);
            }
        }
    }
}
```

code download Browser.sln

From this example, you can see that each key press that the end user makes in the text box is captured by the `textBox1_KeyPress` event. If the character input is a carriage return (a press of the Enter key, which is `(char)13`), then you take action with the `WebBrowser` control. Using the `WebBrowser` control's `Navigate` method, you specify the URL (as a `string`) using the `textBox1.Text` property. The end result is shown in Figure 24-4.

FIGURE 24-4

Launching Internet Explorer Instances

It might be that you are not interested in hosting a browser inside your application, as shown in the previous section, but instead are only interested in allowing the user to find your web site in a typical browser (for example, by clicking a link inside your application). For an example of this task, create a Windows Forms application that has a `LinkLabel` control on it. For instance, you can have a form that has a `LinkLabel` control on it that states "Visit our company web site!"

When you have this control in place, use the following code to launch your company's web site in an independent browser as opposed to directly being in the form of your application:

```
private void linkLabel1_LinkClicked(object sender, LinkLabelLinkClickedEventArgs e)
{
   WebBrowser wb = new WebBrowser();
   wb.Navigate("http://www.wrox.com", true);
}
```

In this example, when the `LinkLabel` control is clicked by the user, a new instance of the `WebBrowser` class is created. Then, using the `WebBrowser` class's `Navigate()` method, the code specifies the location of the web page as well as a Boolean value that specifies whether this endpoint should be opened within the Windows Forms application (a `false` value) or from within an independent browser (using a `true` value). By default, this is set to `false`. With the preceding construct, when the end user clicks the link found in the Windows application, a browser instance will be instantiated, and the Wrox web site at `www.wrox.com` will be launched.

Giving Your Application More IE-Type Features

In the previous example, in which you used the `WebBrowser` control directly in the Windows Forms application, you may notice that when you click on the links contained in the page, the text within the `TextBox` control is not updated to show the URL of the exact location where you are in the browsing process. You can fix this by listening for events coming from the `WebBrowser` control and adding handlers to the control.

Updating the form's title with the title of the HTML page is easy. You just need to use the `Navigated` event and update the `Text` property of the form:

```
private void webBrowser1_Navigated(object sender, EventArgs e)
{
   this.Text = webBrowser1.DocumentTitle.ToString();
}
```

In this case, when the `WebBrowser` control moves onto another page, the `Navigated` event will fire, and this will cause the form's title to change to the title of the page being viewed. In some instances when working with pages on the Web, even though you have typed in a specific address, you are going to be redirected to another page altogether. You are most likely going to want to reflect this in the textbox (address bar) of the form; to do this, you change the form's text box based on the complete URL of the page being viewed. To accomplish this task, you can use the `WebBrowser` control's `Navigated` event as well:

```
private void webBrowser1_Navigated(object sender, WebBrowserNavigatedEventArgs e)
{
   textBox1.Text = webBrowser1.Url.ToString();
   this.Text = webBrowser1.DocumentTitle.ToString();
}
```

In this case, when the requested page has finished downloading in the `WebBrowser` control, the `Navigated` event is fired. In your case, you simply update the `Text` value of the `textBox1` control to the URL of the page. This means that after a page is loaded in the `WebBrowser` control's HTML container, and if the URL changes in this process (for instance, if there is a redirect), then the new URL will be shown in the text box. If you employ these steps and navigate to the Wrox web site (`www.wrox.com`), then you will notice that the page's URL will immediately change to `www.wrox.com/WileyCDA/`. This process also means that if the end user clicks one of the links contained within the HTML view, then the URL of the newly requested page will also be shown in the text box.

Now if you run the application with the preceding changes in place, you will find that the form's title and address bar work as they do in Microsoft's Internet Explorer, as demonstrated in Figure 24-5.

Powerful, Intuitive Programming

Our books are written for programmers by programmers. We extend that philosophy online with p2p.wrox.com, featuring our invaluable discussion forums.

FIGURE 24-5

The next step is to create an IE-like toolbar that will allow the end user to control the `WebBrowser` control a little better. This means that you will incorporate buttons such as Back, Forward, Stop, Home, and Refresh.

Rather than using the `ToolBar` control, you will just add a set of `Button` controls at the top of the form where you currently have the address bar. Add five buttons to the top of the control, as illustrated in Figure 24-6.

In this example, the text on the button face is changed to indicate the function of the button. Of course, you can even go as far as to use a screen capture utility to "borrow" button images from IE and use those. The buttons should be named `buttonBack`, `buttonForward`, `buttonStop`, `buttonRefresh`, and `buttonHome`. To get the resizing to work properly, make sure that you set the `Anchor` property of the three buttons on the right to `Top`, `Right`.

On startup, `buttonBack`, `buttonForward`, and `buttonStop` should be disabled because there is no point to the buttons if there is no initial page loaded in the `WebBrowser` control. You will later tell the application when to enable and disable the Back and Forward buttons yourself, depending on where the user is in the page stack. In addition, when a page is being loaded, you will need to enable the Stop button — but also, you will need to disable the Stop button when the page has finished being loaded. You will also have a Submit button on the page that will allow for the submission of the URL being requested.

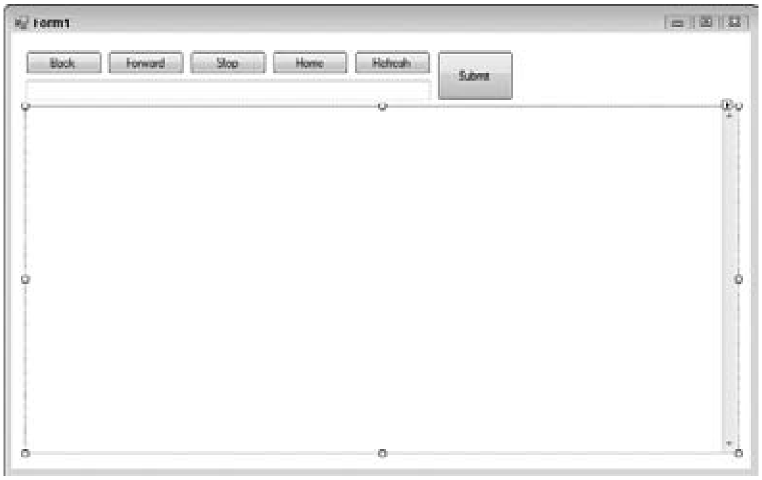

FIGURE 24-6

First, however, you will add the functionality behind the buttons. The `WebBrowser` class itself has all the methods that you need, so this is all very straightforward:

```
using System;
using System.Windows.Forms;

namespace Browser
{
    partial class Form1: Form
    {
        public Form1()
        {
            InitializeComponent();
        }

        private void textBox1_KeyPress(object sender, KeyPressEventArgs e)
        {
```

```
    if (e.KeyChar == (char)13)
    {
        webBrowser1.Navigate(textBox1.Text);
    }
}

private void webBrowser1_Navigated(object sender,
   WebBrowserNavigatedEventArgs e)
{
    textBox1.Text = webBrowser1.Url.ToString();
    this.Text = webBrowser1.DocumentTitle.ToString();
}

private void Form1_Load(object sender, EventArgs e)
{
    buttonBack.Enabled = false;
    buttonForward.Enabled = false;
    buttonStop.Enabled = false;

    this.webBrowser1.CanGoBackChanged +=
       new EventHandler(webBrowser1_CanGoBackChanged);
    this.webBrowser1.CanGoForwardChanged +=
       new EventHandler(webBrowser1_CanGoForwardChanged);
    this.webBrowser1.DocumentTitleChanged +=
       new EventHandler(webBrowser1_DocumentTitleChanged);
}

private void buttonBack_Click(object sender, EventArgs e)
{
    webBrowser1.GoBack();
    textBox1.Text = webBrowser1.Url.ToString();
}

private void buttonForward_Click(object sender, EventArgs e)
{
    webBrowser1.GoForward();
    textBox1.Text = webBrowser1.Url.ToString();
}

private void buttonStop_Click(object sender, EventArgs e)
{
    webBrowser1.Stop();
}

private void buttonHome_Click(object sender, EventArgs e)
{
    webBrowser1.GoHome();
    textBox1.Text = webBrowser1.Url.ToString();
}

private void buttonRefresh_Click(object sender, EventArgs e)
{
    webBrowser1.Refresh();
}

private void buttonSubmit_Click(object sender, EventArgs e)
{
    webBrowser1.Navigate(textBox1.Text);
}
```

```
            private void webBrowser1_Navigating(object sender,
               WebBrowserNavigatingEventArgs e)
            {
                buttonStop.Enabled = true;
            }

            private void webBrowser1_DocumentCompleted(object sender,
               WebBrowserDocumentCompletedEventArgs e)
            {
                buttonStop.Enabled = false;
                if (webBrowser1.CanGoBack)
                {
                    buttonBack.Enabled = true;
                }
                else
                {
                    buttonBack.Enabled = false;
                }
                if (webBrowser1.CanGoForward)
                {
                    buttonForward.Enabled = true;
                }
                else
                {
                    buttonForward.Enabled = false;
                }
            }
        }
    }
```

code download Browser.sln

Many different activities are going on in this example because there are so many options for the end user when using this application. For each of the button-click events, there is a specific `WebBrowser` class method assigned as the action to initiate. For instance, for the Back button on the form, you simply use the `WebBrowser` control's `GoBack()` method; for the Forward button you have the `GoForward()` method; and for the others, you have methods such as `Stop()`, `Refresh()`, and `GoHome()`. This makes it fairly simple and straightforward to create a toolbar that will give you action similar to that of Microsoft's Internet Explorer.

When the form is first loaded, the `Form1_Load` event disables the appropriate buttons. From there, the end user can enter a URL into the text box and click the Submit button to have the application retrieve the desired page.

To manage the enabling and disabling of the buttons, you must key in to a couple of events. As mentioned before, whenever downloading begins, you need to enable the Stop button. For this, you simply added an event handler for the `Navigating` event to enable the Stop button:

```
            private void webBrowser1_Navigating(object sender,
               WebBrowserNavigatingEventArgs e)
            {
                buttonStop.Enabled = true;
            }
```

Then, the Stop button is again disabled when the document has finished loading:

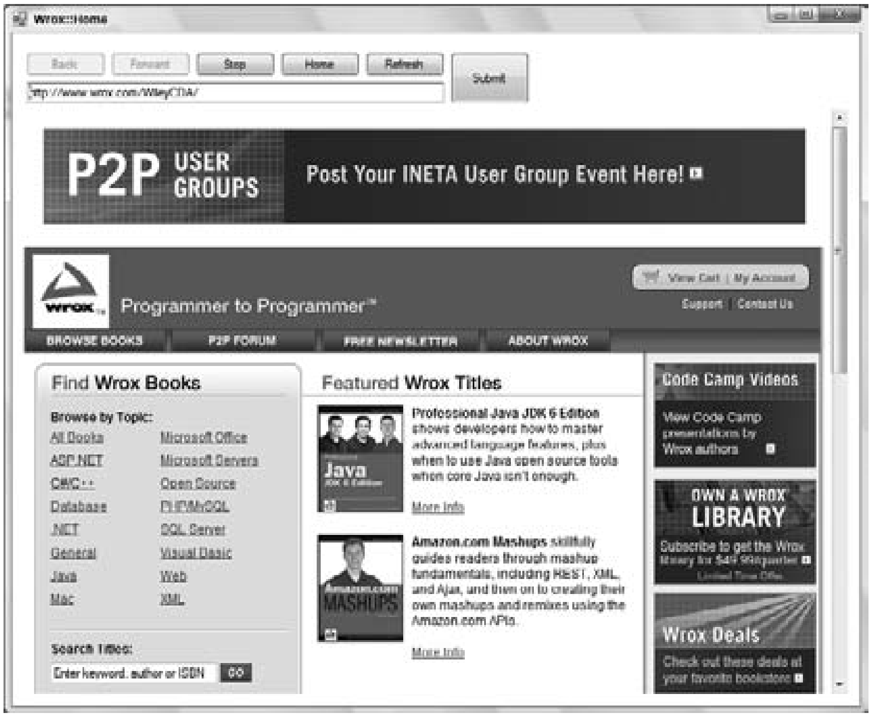
```
            private void webBrowser1_DocumentCompleted(object sender,
               WebBrowserDocumentCompletedEventArgs e)
            {
                buttonStop.Enabled = false;
            }
```

Enabling and disabling the appropriate Back and Forward buttons really depends on the ability to go backward or forward in the page stack. This is achieved by using both the `CanGoForwardChanged()` and the `CanGoBackChanged()` events:

```
private void webBrowser1_CanGoBackChanged(object sender, EventArgs e)
{
    if (webBrowser1.CanGoBack)
    {
        buttonBack.Enabled = true;
    }
    else
    {
        buttonBack.Enabled = false;
    }
}

private void webBrowser1_CanGoForwardChanged(object sender, EventArgs e)
{
    if (webBrowser1.CanGoForward)
    {
        buttonForward.Enabled = true;
    }
    else
    {
        buttonForward.Enabled = false;
    }
}
```

Run the project now, visit a web page, and click through a few links. You should also be able to use the toolbar to enhance your browsing experience. The end product is shown in Figure 24-7.



Professional Java JDK 6 Edition shows developers how to master advanced language features, plus when to use Java open source tools when core Java isn't enough.

FIGURE 24-7

Printing Using the WebBrowser Control

Not only can users use the WebBrowser control to view pages and documents, but they can also use the control to send these pages and documents to the printer for printing. To print the page or document being viewed in the control, simply use the following construct:

```
webBrowser1.Print();
```

As before, you do not need to view the page or document to print it. For instance, you can use the WebBrowser class to load an HTML document and print it without even displaying the loaded document. This can be accomplished as shown here:

```
WebBrowser wb = new WebBrowser();
wb.Navigate("http://www.wrox.com");
wb.Print();
```

Displaying the Code of a Requested Page

In the beginning of this chapter, you used the WebRequest and the Stream classes to get at a remote page to display the code of the requested page. You used this code to accomplish this task:

```
public Form1()
{
   InitializeComponent();
   System.Net.WebClient Client = new WebClient();
   Stream strm = Client.OpenRead("http://www.reuters.com");
   StreamReader sr = new StreamReader(strm);
   string line;

   while ( (line=sr.ReadLine()) != null )
   {
      listBox1.Items.Add(line);
   }

   strm.Close();
}
```

Now, however, with the introduction of the WebBrowser control, it is quite easy to accomplish the same results. To accomplish this, change the browser application that you have been working on thus far in this chapter. To make this change, simply add a single line to the Document_Completed event, as illustrated here:

```
private void webBrowser1_DocumentCompleted(object sender,
   WebBrowserDocumentCompletedEventArgs e)
{
   buttonStop.Enabled = false;
   textBox2.Text = webBrowser1.DocumentText;
}
```

In the application itself, add another TextBox control below the WebBrowser control. The idea is that when the end user requests a page, you display not only the visual aspect of the page but also the code for the page, in the TextBox control. The code of the page is displayed simply by using the DocumentText property of the WebBrowser control, which will give you the entire page's content as a String. The other option is to get the contents of the page as a Stream using the DocumentStream property. The end result of adding the second TextBox to display the contents of the page as a String is shown in Figure 24-8.

FIGURE 24-8

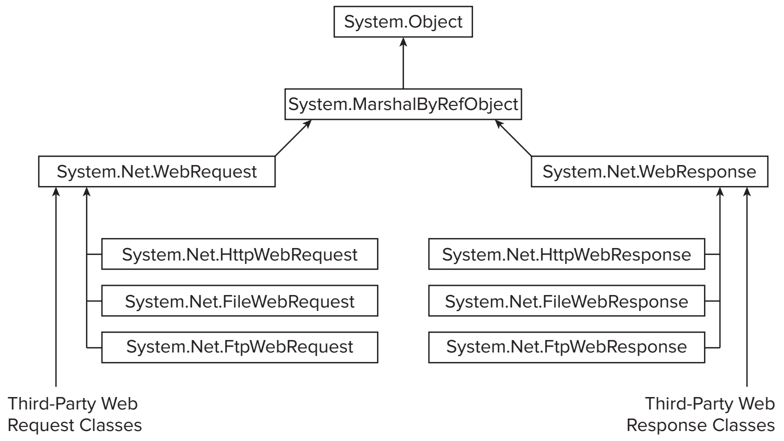
The WebRequest and WebResponse Classes Hierarchy

In this section, you take a closer look at the underlying architecture of the `WebRequest` and `WebResponse` classes.

Figure 24-9 illustrates the inheritance hierarchy of the classes involved.

The hierarchy contains more than just the two classes that you have used in your code. You should also know that the `WebRequest` and `WebResponse` classes are both abstract and cannot be instantiated. These base classes provide general functionality for dealing with web requests and responses independent of the protocol used for a given operation. Requests are made using a particular protocol (HTTP, FTP, SMTP, and so on), and a derived class written for the given protocol will handle the request. Microsoft refers to this scheme as *pluggable protocols*.

Remember in the code that you examined earlier in the "WebRequest and WebResponse Classes" section, your variables are defined as references to the base classes. However, `WebRequest.Create()` actually gives you an `HttpWebRequest` object, and the `GetResponse()` method actually returns an `HttpWebResponse` object. This factory-based mechanism hides many of the details from the client code, allowing support for a wide variety of protocols from the same code base.



System.Object
System.MarshalByRefObject
System.Net.WebRequest
System.Net.WebResponse
System.Net.HttpWebRequest
System.Net.FileWebRequest
System.Net.FtpWebRequest
System.Net.HttpWebResponse
System.Net.FileWebResponse
System.Net.FtpWebResponse
Third-Party Web Request Classes
Third-Party Web Response Classes

FIGURE 24-9

The fact that you need an object specifically capable of dealing with the HTTP protocol is clear from the URI that you supply to `WebRequest.Create()`. `WebRequest.Create()` examines the protocol specifier in the URI to instantiate and return an object of the appropriate class. This keeps your code free from having to know anything about the derived classes or specific protocol used. When you need to access specific features of a protocol, you might need the properties and methods of the derived class, in which case you can cast your `WebRequest` or `WebResponse` reference to the derived class.

With this architecture, you should be able to send requests using any of the common protocols. However, Microsoft currently provides derived classes to cover only the HTTP, HTTPS, FTP, and FILE protocols. The FTP option is the latest option provided by the .NET Framework (ever since the release of the .NET Framework 2.0). If you want to utilize other protocols, for example SMTP, then you need to use the Windows Communication Foundation, revert to using the Windows API, or use the `SmtpClient` object.

UTILITY CLASSES

This section covers a couple of utility classes to make web programming easier when dealing with URIs and IP addresses.

URIs

`Uri` and `UriBuilder` are two classes in the `System` (not `System.Net`) namespace, and they are both intended to represent a URI. `UriBuilder` allows you to build a URI given the strings for the component parts, and the `Uri` class allows you to parse, combine, and compare URIs.

For the `Uri` class, the constructor requires a completed URI string:

```
Uri MSPage = new

Uri("http://www.Microsoft.com/SomeFolder/SomeFile.htm?Order=true");
```

The class exposes a large number of read-only properties. A `Uri` object is not intended to be modified after it has been constructed:

```
string Query = MSPage.Query;                    // ?Order=true;
string AbsolutePath = MSPage.AbsolutePath;      // /SomeFolder/SomeFile.htm
string Scheme = MSPage.Scheme;                  // http
int Port = MSPage.Port;                         // 80 (the default for http)
string Host = MSPage.Host;                      // www.microsoft.com
bool IsDefaultPort = MSPage.IsDefaultPort;      // true since 80 is default
```

UriBuilder, however, implements fewer properties, just enough to allow you to build up a complete URI. These properties are read-write.

You can supply the components to build up a URI to the constructor:

```
UriBuilder MSPage = new
   UriBuilder("http", "www.microsoft.com", 80, "SomeFolder/SomeFile.htm");
```

Or, you can build the components by assigning values to the properties:

```
UriBuilder MSPage = new UriBuilder();
MSPage.Scheme ="http";
MSPage.Host = "www.microsoft.com";
MSPage.Port = 80;
MSPage.Path = "SomeFolder/SomeFile.htm";
```

After you have completed initializing the `UriBuilder`, you can obtain the corresponding `Uri` object with the `Uri` property:

```
Uri CompletedUri = MSPage.Uri;
```

IP Addresses and DNS Names

On the Internet, you identify servers as well as clients by IP address or host name (also referred to as a DNS name). Generally speaking, the host name is the human-friendly name that you type in a web browser window, such as `www.wrox.com` or `www.microsoft.com`. An IP address is the identifier computers use to identify each other. IP addresses are the identifiers used to ensure that web requests and responses reach the appropriate machines. It is even possible for a computer to have more than one IP address.

Today, IP addresses are typically a 32-bit value. An example of a 32-bit IP address is 192.168.1.100. This format of IP address is referred to as Internet Protocol version 4. Because there are now so many computers and other devices vying for a spot on the Internet, a newer type of address was developed — Internet Protocol version 6. IPv6 provides a 64-bit IP address. IPv6 can potentially provide a maximum number of about 3×10^{28} unique addresses. You will find that the .NET Framework allows your applications to work with both IPv4 and IPv6.

For host names to work, you must first send a network request to translate the host name into an IP address, a task carried out by one or more DNS servers.

A DNS server stores a table mapping host names to IP addresses for all the computers it knows about, as well as the IP addresses of other DNS servers to look up the host names it does not know about. Your local computer should always know about at least one DNS server. Network administrators configure this information when a computer is set up.

Before sending out a request, your computer will first ask the DNS server to tell it the IP address corresponding to the host name you have typed in. When it is armed with the correct IP address, the computer can address the request and send it over the network. All this work normally happens behind the scenes while the user is browsing the Web.

.NET Classes for IP Addresses

The .NET Framework supplies a number of classes that are able to assist with the process of looking up IP addresses and finding information about host computers.

IPAddress

`IPAddress` represents an IP address. The address itself is available as the `GetAddressBytes` property and may be converted to a dotted decimal format with the `ToString()` method. `IPAddress` also implements a static `Parse()` method, which effectively performs the reverse conversion of `ToString()` — converting from a dotted decimal string to an `IPAddress`:

```
IPAddress ipAddress = IPAddress.Parse("234.56.78.9");
byte[] address = ipAddress.GetAddressBytes();
string ipString = ipAddress.ToString();
```

In this example, the `byte` integer `address` is assigned a binary representation of the IP address, and the string `ipString` is assigned the text `"234.56.78.9"`.

`IPAddress` also provides a number of constant static fields to return special addresses. For example, the `Loopback` address allows a machine to send messages to itself, whereas the `Broadcast` address allows multicasting to the local network:

```
// The following line will set loopback to "127.0.0.1".
// the loopback address indicates the local host.
string loopback = IPAddress.Loopback.ToString();

// The following line will set broadcast address to "255.255.255.255".
// the broadcast address is used to send a message to all machines on
// the local network.
string broadcast = IPAddress.Broadcast.ToString();
```

IPHostEntry

The `IPHostEntry` class encapsulates information relating to a particular host computer. This class makes the host name available via the `HostName` property (which returns a string), and the `AddressList` property returns an array of `IPAddress` objects. You are going to use the `IPHostEntry` class in the next example: `DNSLookupResolver`.

Dns

The `Dns` class is able to communicate with your default DNS server to retrieve IP addresses. The two important (static) methods are `Resolve()`, which uses the DNS server to obtain the details of a host with a given host name, and `GetHostByAddress()`, which also returns details of the host but this time using the IP address. Both methods return an `IPHostEntry` object:

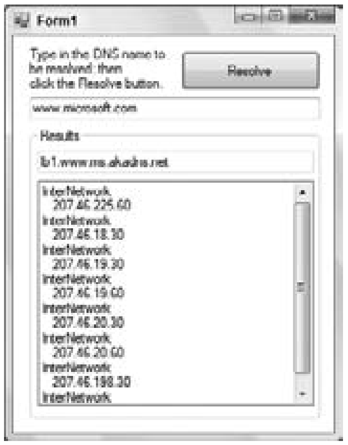
```
IPHostEntry wroxHost = Dns.Resolve("www.wrox.com");
IPHostEntry wroxHostCopy = Dns.GetHostByAddress("208.215.179.178");
```

In this code, both `IPHostEntry` objects will contain details of the Wrox.com servers.

The `Dns` class differs from the `IPAddress` and `IPHostEntry` classes because it has the ability to actually communicate with servers to obtain information. In contrast, `IPAddress` and `IPHostEntry` are more along the lines of simple data structures with convenient properties to allow access to the underlying data.

The DnsLookup Example

The DNS and IP-related classes are illustrated with an example that looks up DNS names: `DnsLookup` (see Figure 24-10).



Form1
Type in the DNS name to be resolved then click the Resolve button.
Resolve
Results

```
www.microsoft.com
lb1.www.ms.akadns.net
InterNetwork
  207.46.225.60
InterNetwork
  207.46.18.30
InterNetwork
  207.46.19.30
InterNetwork
  207.46.19.60
InterNetwork
  207.46.20.30
InterNetwork
  207.46.20.60
InterNetwork
  207.46.198.30
InterNetwork
```

FIGURE 24-10

This sample application simply invites the user to type in a DNS name using the main text box. When the user clicks the Resolve button, the sample uses the `Dns.Resolve()` method to retrieve an `IPHostEntry` reference and display the host name and IP addresses. Note how the host name displayed may be different from the name typed in. This can occur if one DNS name (`www.microsoft.com`) simply acts as a proxy for another DNS name (`lb1.www.ms.akadns.net`).

The `DnsLookup` application is a standard C# Windows application. The controls are added as shown in Figure 24-10, giving them the names `txtBoxInput`, `btnResolve`, `txtBoxHostName`, and `listBoxIPs`, respectively. Then, you simply add the following method to the `Form1` class as the event handler for the `buttonResolve Click` event:

```
void btnResolve_Click (object sender, EventArgs e)
{
   try
   {
      IPHostEntry iphost = Dns.GetHostEntry(txtBoxInput.Text);
```

```
            foreach (IPAddress ip in iphost.AddressList)
            {
               string ipaddress = ip.AddressFamily.ToString();
               listBoxIPs.Items.Add(ipaddress);
               listBoxIPs.Items.Add(" " + ip.ToString());
            }
            txtBoxHostName.Text = iphost.HostName;
         }
         catch(Exception ex)
         {
            MessageBox.Show("Unable to process the request because " +
               "the following problem occurred:\n" +
                ex.Message, "Exception occurred");
         }
      }
```

Notice that in this code you are careful to trap any exceptions. An exception might occur if the user types an invalid DNS name or if the network is down.

After retrieving the `IPHostEntry` instance, you use the `AddressList` property to obtain an array containing the IP addresses, which you then iterate through with a `foreach` loop. For each entry, you display the IP address as an integer and as a string, using the `IPAddress.AddressFamily.ToString()` method.

LOWER-LEVEL PROTOCOLS

This section briefly discusses some of the .NET classes used to communicate at a lower level.

The `System.Net.Sockets` namespace contains the relevant classes. These classes, for example, allow you to directly send out TCP network requests or to listen to TCP network requests on a particular port. The following table explains the main classes:

CLASS	PURPOSE
`Socket`	Deals with managing connections. Classes such as `WebRequest`, `TcpClient`, and `UdpClient` use this class internally.
`NetworkStream`	Derived from Stream. Represents a stream of data from the network.
`SmtpClient`	Enables you to send messages (mail) through the Simple Mail Transfer Protocol.
`TcpClient`	Enables you to create and use TCP connections.
`TcpListener`	Enables you to listen for incoming TCP connection requests.
`UdpClient`	Enables you to create connections for UDP clients. (UDP is an alternative protocol to TCP but is much less widely used, mostly on local networks.)

Network communications work on several different levels. The classes you have seen in this chapter so far work at the highest level — the level at which specific commands are processed. It is probably easiest to understand this concept if you think of file transfer using FTP. Although today's GUI applications hide many of the FTP details, it was not so long ago when you executed FTP from a command-line prompt. In this environment, you explicitly typed commands to send to the server for downloading, uploading, and listing files.

FTP is not the only high-level protocol relying on textual commands. HTTP, SMTP, POP, and other protocols are based on a similar type of behavior. Again, many of the modern graphical tools hide the transmission of commands from the user, so you are generally not aware of them. For example, when you type a URL into a web browser, and the web request goes off to a server, the browser is actually sending a (plain-text) `GET` command to the server, which fulfills a similar purpose as the FTP `get` command. It can also send a `POST` command, which indicates that the browser has attached other data to the request.

These protocols, however, are not sufficient by themselves to achieve communication between computers. Even if both the client and the server understand, for example, the HTTP protocol, it will still not be possible for them to understand each other unless there is also agreement on exactly how to transmit the characters — what binary format will be used? Moreover, getting down to the lowest level, what voltages will be used to represent 0s and 1s in the binary data? Because there are so many items to configure and agree upon, developers and hardware engineers in the networking field often refer to a *protocol stack*. When you list all the various protocols and mechanisms required for communication between two hosts, you create a protocol stack with high-level protocols on the top and low-level protocols on the bottom. This approach results in a modular and layered approach to achieving efficient communication.

Luckily, for most development work, you do not need to go far down the stack or work with voltage levels. If you are writing code that requires efficient communication between computers, then it's not unusual to write code that works directly at the level of sending binary data packets between computers. This is the realm of protocols such as TCP, and Microsoft has supplied a number of classes that allow you to conveniently work with binary data at this level.

Using SmtpClient

The `SmtpClient` object allows you to send mail messages through the Simple Mail Transfer Protocol. A simple sample of using the `SmtpClient` object is illustrated here:

```
SmtpClient sc = new SmtpClient("mail.mySmtpHost.com");
sc.Send("evjen@yahoo.com", "editor@wrox.com",
  "The latest chapter", "Here is the latest.");
```

In its simplest form, you work from an instance of the `SmtpClient` object. In this case, the instantiation also provided the host of the SMTP server that is used to send the mail messages over the Internet. You could have also achieved the same task by using the `Host` property:

```
SmtpClient sc = new SmtpClient();
sc.Host = "mail.mySmtpHost.com";
sc.Send("evjen@yahoo.com", "editor@wrox.com",
  "The latest chapter", "Here is the latest.");
```

When you have the `SmtpClient` in place, it is simply a matter of calling the `Send()` method and providing the From address, the To address, and the Subject, followed by the Body of the mail message.

In many cases, you will have mail messages that are more complex than this. To work with this possibility, you can also pass in a `MailMessage` object into the `Send()` method:

```
SmtpClient sc = new SmtpClient();
sc.Host = "mail.mySmtpHost.com";
MailMessage mm = new MailMessage();
mm.Sender = new MailAddress("evjen@yahoo.com", "Bill Evjen");
mm.To.Add(new MailAddress("editor@wrox.com", "Paul Reese"));
mm.To.Add(new MailAddress("marketing@wrox.com", "Wrox Marketing"));
mm.CC.Add(new MailAddress("publisher@wrox.com", "Barry Pruett"));
mm.Subject = "The latest chapter";
mm.Body = "<b>Here you can put a long message</b>";
mm.IsBodyHtml = true;
mm.Priority = MailPriority.High;
sc.Send(mm);
```

Using `MailMessage` allows you to really fine-tune how you build your mail messages. You are able to send HTML messages, add as many To and CC recipients as you wish, change the message priority, work with the message encodings, and add attachments. The ability to add attachments is defined in the following code snippet:

```
SmtpClient sc = new SmtpClient();
sc.Host = "mail.mySmtpHost.com";
MailMessage mm = new MailMessage();
mm.Sender = new MailAddress("evjen@yahoo.com", "Bill Evjen");
```

```
    mm.To.Add(new MailAddress("editor@wrox.com", "Paul Reese"));
    mm.To.Add(new MailAddress("marketing@wrox.com", "Wrox Marketing"));
    mm.CC.Add(new MailAddress("publisher@wrox.com", "Barry Pruett"));
    mm.Subject = "The latest chapter";
    mm.Body = "<b>Here you can put a long message</b>";
    mm.IsBodyHtml = true;
    mm.Priority = MailPriority.High;
    Attachment att = new Attachment("myExcelResults.zip",
       MediaTypeNames.Application.Zip);
    mm.Attachments.Add(att);
    sc.Send(mm);
```

In this case, an `Attachment` object is created and added using the `Add()` method to the `MailMessage` object before the `Send()` method is called.

Using the TCP Classes

The Transmission Control Protocol (TCP) classes offer simple methods for connecting and sending data between two endpoints. An endpoint is the combination of an IP address and a port number. Existing protocols have well-defined port numbers, for example, HTTP uses port 80, whereas SMTP uses port 25. The Internet Assigned Numbers Authority, IANA, (`www.iana.org`) assigns port numbers to these well-known services. Unless you are implementing a well-known service, you will want to select a port number larger than 1,024.

TCP traffic makes up the majority of traffic on the Internet today. TCP is often the protocol of choice because it offers guaranteed delivery, error correction, and buffering. The `TcpClient` class encapsulates a TCP connection and provides a number of properties to regulate the connection, including buffering, buffer size, and timeouts. Reading and writing is accomplished by requesting a `NetworkStream` object via the `GetStream()` method.

The `TcpListener` class listens for incoming TCP connections with the `Start()` method. When a connection request arrives, you can use the `AcceptSocket()` method to return a socket for communication with the remote machine, or use the `AcceptTcpClient()` method to use a higher-level `TcpClient` object for communication. The easiest way to see how the `TcpListener` and `TcpClient` classes work together is to work through an example.

The TcpSend and TcpReceive Examples

To demonstrate how these classes work, you need to build two applications. Figure 24-11 shows the first application, `TcpSend`. This application opens a TCP connection to a server and sends the C# source code for itself.

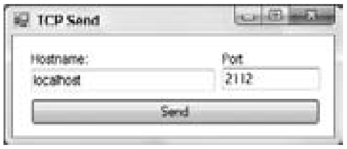


FIGURE 24-11

Once again, you create a C# Windows application. The form consists of two text boxes (`txtHost` and `txtPort`) for the host name and port, respectively, as well as a button (`btnSend`) to click and start a connection. First, you ensure that you include the relevant namespaces:

```
    using System;
    using System.IO;
    using System.Net.Sockets;
    using System.Windows.Forms;
```

The following code shows the event handler for the button's `Click` event:

```
    private void btnSend_Click(object sender, System.EventArgs e)
    {
       TcpClient tcpClient = new TcpClient(txtHost.Text, Int32.Parse(txtPort.Text));
```

```
        NetworkStream ns = tcpClient.GetStream();
        FileStream fs = File.Open("form1.cs", FileMode.Open);

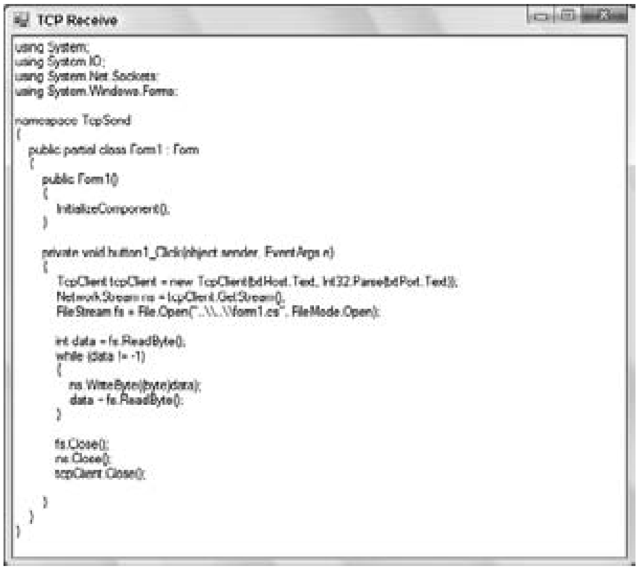
        int data = fs.ReadByte();

        while(data != -1)
        {
           ns.WriteByte((byte)data);
           data = fs.ReadByte();
        }

        fs.Close();
        ns.Close();
        tcpClient.Close();
    }
```

This example creates the `TcpClient` using a host name and a port number. Alternatively, if you have an instance of the `IPEndPoint` class, then you can pass the instance to the `TcpClient` constructor. After retrieving an instance of the `NetworkStream` class, you open the source code file and begin to read bytes. As with many of the binary streams, you need to check for the end of the stream by comparing the return value of the `ReadByte()` method to `-1`. After your loop has read all the bytes and sent them along to the network stream, you must close all the open files, connections, and streams.

On the other side of the connection, the `TcpReceive` application displays the received file after the transmission is finished (see Figure 24-12).



```
using System;
using System.IO;
using System.Net.Sockets;
using System.Windows.Forms;

namespace TcpSend
{
   public partial class Form1 : Form
   {
      public Form1()
      {
         InitializeComponent();
      }

      private void button1_Click(object sender, EventArgs e)
      {
         TcpClient tcpClient = new TcpClient(txtHost.Text, Int32.Parse(txtPort.Text));
         NetworkStream ns = tcpClient.GetStream();
         FileStream fs = File.Open("..\\..\\form1.cs", FileMode.Open);

         int data = fs.ReadByte();
         while (data != -1)
         {
            ns.WriteByte((byte)data);
            data = fs.ReadByte();
         }

         fs.Close();
         ns.Close();
         tcpClient.Close();

      }
   }
}
```

FIGURE 24-12

The form consists of a single `TextBox` control named `txtDisplay`. The `TcpReceive` application uses a `TcpListener` to wait for the incoming connection. To prevent freezing the application interface, you use a background thread to wait for and then read from the connection. Thus, you need to include the `System.Threading` namespace as well these other namespaces:

```
    using System;
    using System.IO;
```

```
using System.Net;
using System.Net.Sockets;
using System.Threading;
using System.Windows.Forms;
```

Inside the form's constructor, you spin up a background thread:

```
public Form1()
{
   InitializeComponent();
   Thread thread = new Thread(new ThreadStart(Listen));
   thread.Start();
}
```

The remaining important code is this:

```
public void Listen()
{
   IPAddress localAddr = IPAddress.Parse("127.0.0.1");
   Int32 port = 2112;
   TcpListener tcpListener = new TcpListener(localAddr, port);
   tcpListener.Start();

   TcpClient tcpClient = tcpListener.AcceptTcpClient();

   NetworkStream ns = tcpClient.GetStream();
   StreamReader sr = new StreamReader(ns);
   string result = sr.ReadToEnd();
   Invoke(new UpdateDisplayDelegate(UpdateDisplay),new object[] {result} );
   tcpClient.Close();
   tcpListener.Stop();
}

public void UpdateDisplay(string text)
{
   txtDisplay.Text= text;
}

protected delegate void UpdateDisplayDelegate(string text);
```

The thread begins execution in the `Listen()` method and allows you to make the blocking call to `AcceptTcpClient()` without halting the interface. Notice that the IP address (`127.0.0.1`) and the port number (`2112`) are hard-coded into the application, so you will need to enter the same port number from the client application.

You use the `TcpClient` object returned by `AcceptTcpClient()` to open a new stream for reading. As with the earlier example, you create a `StreamReader` to convert the incoming network data into a string. Before you close the client and stop the listener, you update the form's text box. You do not want to access the text box directly from your background thread, so you use the form's `Invoke()` method with a delegate and pass the result string as the first element in an array of `object` parameters. `Invoke()` ensures that your call is correctly marshaled into the thread that owns the control handles in the user interface.

TCP Versus UDP

The other protocol covered in this section is UDP (User Datagram Protocol). UDP is a simple protocol with few features and little overhead. Developers often use UDP in applications where the speed and performance requirements outweigh the reliability needs, for example, video streaming. In contrast, TCP offers a number of features to confirm the delivery of data. TCP provides error correction and retransmission in the case of lost or corrupted packets. Last, but hardly least, TCP buffers incoming and outgoing data and also guarantees that a sequence of packets scrambled in transmission is reassembled before delivery to the application. Even with the extra overhead, TCP is the most widely used protocol across the Internet because of its high reliability.

The UDP Class

As you might expect, the UdpClient class features a smaller and simpler interface than TcpClient. This reflects the relatively simpler nature of the protocol. Although both TCP and UDP classes use a socket underneath the covers, the UdpClient class does not contain a method to return a network stream for reading and writing. Instead, the member function Send() accepts an array of bytes as a parameter, and the Receive() function returns an array of bytes. Also, because UDP is a connectionless protocol, you can wait to specify the endpoint for the communication as a parameter to the Send() and Receive() methods, instead of specifying it earlier in a constructor or Connect() method. You can also change the endpoint on each subsequent send or receive.

The following code fragment uses the UdpClient class to send a message to an echo service. A server with an echo service running accepts TCP or UDP connections on port 7. The echo service simply echoes any data sent to the server back to the client. This service is useful for diagnostics and testing, although many system administrators disable echo services for security reasons:

```
using System;
using System.Text;
using System.Net;
using System.Net.Sockets;
namespace Wrox.ProCSharp.InternetAccess.UdpExample
{

   class Class1
   {
      [STAThread]
      static void Main(string[] args)
      {
         UdpClient udpClient = new UdpClient();
         string sendMsg = "Hello Echo Server";
         byte [] sendBytes = Encoding.ASCII.GetBytes(sendMsg);
         udpClient.Send(sendBytes, sendBytes.Length, "SomeEchoServer.net", 7);
         IPEndPoint endPoint = new IPEndPoint(0,0);
         byte [] rcvBytes = udpClient.Receive(ref endPoint);
         string rcvMessage = Encoding.ASCII.GetString(rcvBytes,
                                                      0,
                                                      rcvBytes.Length);
         // should print out "Hello Echo Server"
         Console.WriteLine(rcvMessage);
      }
   }
}
```

You make heavy use of the Encoding.ASCII class to translate strings into arrays of byte and vice versa. Also note that you pass an IPEndPoint by reference into the Receive() method. Because UDP is not a connection-oriented protocol, each call to Receive() might pick up data from a different endpoint, so Receive() populates this parameter with the IP address and port of the sending host.

Both UdpClient and TcpClient offer a layer of abstraction over the lowest of the low-level classes: the Socket.

The Socket Class

The Socket class offers the highest level of control in network programming. One of the easiest ways to demonstrate the class is to rewrite the TcpReceive application with the Socket class. The updated Listen() method is listed in this example:

```
public void Listen()
{
   Socket listener = new Socket(AddressFamily.InterNetwork,
                                 SocketType.Stream,
                                 ProtocolType.Tcp);
        listener.Bind(new IPEndPoint(IPAddress.Any, 2112));
        listener.Listen(0);
        Socket socket = listener.Accept();
        Stream netStream = new NetworkStream(socket);
        StreamReader reader = new StreamReader(netStream);

        string result = reader.ReadToEnd();
        Invoke(new UpdateDisplayDelegate(UpdateDisplay),
               new object[] {result} );
        socket.Close();
        listener.Close();
    }
```

The `Socket` class requires a few more lines of code to complete the same task. For starters, the constructor arguments need to specify an IP addressing scheme for a streaming socket with the TCP protocol. These arguments are just one of the many combinations available to the `Socket` class. The `TcpClient` class can configure these settings for you. You then bind the listener socket to a port and begin to listen for incoming connections. When an incoming request arrives, you can use the `Accept()` method to create a new socket to handle the connection. You ultimately attach a `StreamReader` instance to the socket to read the incoming data, in much the same fashion as before.

The `Socket` class also contains a number of methods for asynchronously accepting, connecting, sending, and receiving. You can use these methods with callback delegates in the same way you used the asynchronous page requests with the `WebRequest` class. If you really need to dig into the internals of the socket, the `GetSocketOption()` and `SetSocketOption()` methods are available. These methods allow you to see and configure options, including timeout, time-to-live, and other low-level options. Next, this chapter looks at another example of using sockets.

Building a Server Console Application

Looking further into the `Socket` class, the next example creates a console application that acts as a server for incoming socket requests. From there, a second example will be created in parallel (another console application), which sends a message to the server console application.

The first application you will build is the console application that acts as a server. This application will open a socket on a specific TCP port and listen for any incoming messages. The code for this console application is presented in its entirety here:

```
using System;
using System.Net;
using System.Net.Sockets;
using System.Text;

namespace SocketConsole
{
    class Program
    {
        static void Main()
        {
            Console.WriteLine("Starting: Creating Socket object");
            Socket listener = new Socket(AddressFamily.InterNetwork,
                                         SocketType.Stream,
                                         ProtocolType.Tcp);
            listener.Bind(new IPEndPoint(IPAddress.Any, 2112));
            listener.Listen(10);

            while (true)
            {
                Console.WriteLine("Waiting for connection on port 2112");
```

```
                    Socket socket = listener.Accept();
                    string receivedValue = string.Empty;

                    while (true)
                    {
                        byte[] receivedBytes = new byte[1024];
                        int numBytes = socket.Receive(receivedBytes);
                        Console.WriteLine("Receiving .");
                        receivedValue += Encoding.ASCII.GetString(receivedBytes,
                                             0, numBytes);
                        if (receivedValue.IndexOf("[FINAL]") > -1)
                        {
                            break;
                        }
                    }

                    Console.WriteLine("Received value: {0}", receivedValue);
                    string replyValue = "Message successfully received.";
                    byte[] replyMessage = Encoding.ASCII.GetBytes(replyValue);
                    socket.Send(replyMessage);
                    socket.Shutdown(SocketShutdown.Both);
                    socket.Close();
                }
                listener.Close();
            }
        }
    }
```

This example sets up a socket using the `Socket` class. The socket created uses the TCP protocol and is set up to receive incoming messages from any IP address using port 2112. Values that come in through the open socket are written to the console screen. This consuming application will continue to receive bytes until the `[FINAL]` string is received. This `[FINAL]` string signifies the end of the incoming message, and the message can then be interpreted.

After the end of the message is received from a client, a reply message is sent to the same client. From there, the socket is closed using the `Close()` method, and the console application will continue to stay up until a new message is received.

Building the Client Application

The next step is to build a client application that will send a message to the first console application. The client will be able to send any message that it wants to the server console application as long as it follows some rules that were established by this application. The first of these rules is that the server console application is listening only on a particular protocol. In the case of this server application, it is listening using the TCP protocol. The other rule is that the server application is listening only on a particular port — in this case, port 2112. The last rule is that in any message that is being sent, the last bits of the message need to end with the string `[FINAL]`.

The following client console application follows all these rules:

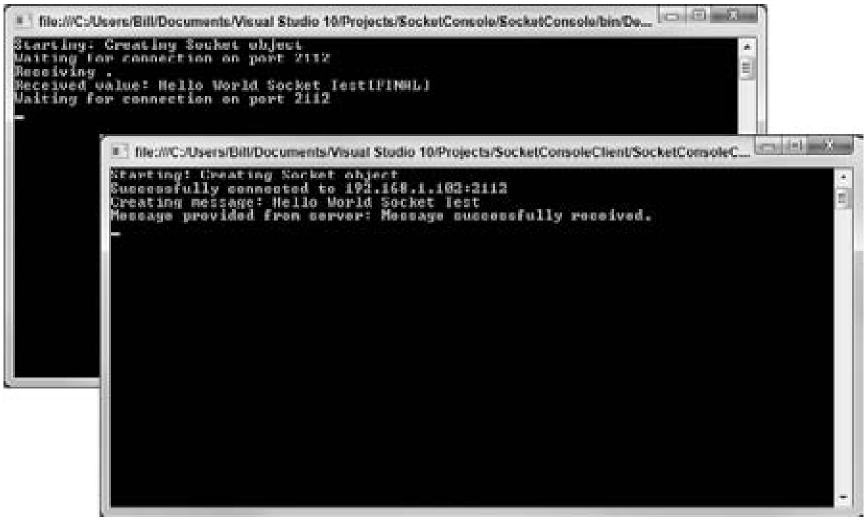
```
using System;
using System.Net;
using System.Net.Sockets;
using System.Text;

namespace SocketConsoleClient
{
    class Program
    {
        static void Main()
        {
                byte[] receivedBytes = new byte[1024];
                IPHostEntry ipHost = Dns.Resolve("127.0.0.1");
                IPAddress ipAddress = ipHost.AddressList[0];
                IPEndPoint ipEndPoint = new IPEndPoint(ipAddress, 2112);
                Console.WriteLine("Starting: Creating Socket object");

                Socket sender = new Socket(AddressFamily.InterNetwork,
                                           SocketType.Stream,
                                           ProtocolType.Tcp);
                sender.Connect(ipEndPoint);
                Console.WriteLine("Successfully connected to {0}",
                       sender.RemoteEndPoint);
                string sendingMessage = "Hello World Socket Test";
                Console.WriteLine("Creating message: Hello World Socket Test");
                byte[] forwardMessage = Encoding.ASCII.GetBytes(sendingMessage
                   + "[FINAL]");
                sender.Send(forwardMessage);
                int totalBytesReceived = sender.Receive(receivedBytes);
                Console.WriteLine("Message provided from server: {0}",
                                  Encoding.ASCII.GetString(receivedBytes,
                                  0, totalBytesReceived));
                sender.Shutdown(SocketShutdown.Both);
                sender.Close();
                Console.ReadLine();
            }
        }
    }
```

In this example, an `IPEndPoint` object is created using the IP address of *localhost* as well as using port 2112 as required by the server console application. In this case, a socket is created and the `Connect()` method is called. After the socket is opened and connected to the server console application socket instance, a string of text is sent to the server application using the `Send()` method. Because the server application is going to return a message, the `Receive()` method is used to grab this message (placing it in a byte array). From there, the byte array is converted into a string and displayed in the console application before the socket is shut down.

Running this application will produce the results presented in Figure 24-13.



file:///C:/Users/Bill/Documents/Visual Studio 10/Projects/SocketConsole/SocketConsole/bin/De...

```
Starting: Creating Socket object
Waiting for connection on port 2112
Receiving .
Received value: Hello World Socket Test[FINAL]
Waiting for connection on port 2112
_
```

file:///C:/Users/Bill/Documents/Visual Studio 10/Projects/SocketConsoleClient/SocketConsoleC...

```
Starting: Creating Socket object
Successfully connected to 192.168.1.102:2112
Creating message: Hello World Socket Test
Message provided from server: Message successfully received.
_
```

FIGURE 24-13

Reviewing the two console applications in the figure, you can see that the server application opens and awaits incoming messages. The incoming message is sent from the client application, and the string sent is then displayed by the server application. The server application waits for other messages to come in, even after the first message is received and displayed. You can see this for yourself by shutting down the client application and re-running the application. You will then see that the server application again displays the message received.

SUMMARY

In this chapter, you reviewed the .NET Framework classes available in the `System.Net` namespace for communication across networks. You have seen some of the .NET base classes that deal with opening client connections on the network and Internet, and how to send requests to and receive responses from servers (the most obvious use of this being to receive HTML pages). By taking advantage of the `WebBrowser` control in .NET 4, you can easily make use of Internet Explorer from your desktop applications.

As a rule of thumb, when programming with classes in the `System.Net` namespace, you should always try to use the most generic class possible. For instance, using the `TcpClient` class instead of the `Socket` class isolates your code from many of the lower-level socket details. Moving one step higher, the `WebRequest` class allows you to take advantage of the pluggable protocol architecture of the .NET Framework. Your code will be ready to take advantage of new application-level protocols as Microsoft and other third-party developers introduce new functionality.

Finally, you learned how to use the asynchronous capabilities in the networking classes, which give a Windows Forms application the professional touch of a responsive user interface.

Now you move on to learning about Windows Services.

25

Windows Services

WHAT'S IN THIS CHAPTER?

- ➤ The architecture of a Windows Service
- ➤ Windows Services installation programs
- ➤ Windows Services control programs
- ➤ Troubleshooting Windows Services

Windows Services are programs that can be started automatically at boot time without the need for anyone to log on to the machine. The following section explains the architecture of Windows Services. The rest of the chapter shows you how to create, monitor, control, and troubleshoot your Windows Services.

WHAT IS A WINDOWS SERVICE?

Windows Services are applications that can be automatically started when the operating system boots. These applications can run without having an interactive user logged on to the system and do some processing in the background.

For example, on a Windows Server, system networking services should be accessible from the client without a user logging on to the server. And on the client system, services allow you to get a new software version from the Internet or to do some file cleanup on the local disk.

You can configure a Windows Service to run from a specially configured user account or from the system user account — a user account that has even more privileges than that of the system administrator.

Here are a few examples of services:

- ➤ Simple TCP/IP Services is a service program that hosts some small TCP/IP servers: echo, daytime, quote, and others.
- ➤ World Wide Web Publishing Service is the service of the Internet Information Server (IIS).
- ➤ Event Log is a service to log messages to the event log system.
- ➤ Windows Search is a service that creates indexes of data on the disk.

You can use the Services administration tool, shown in Figure 25-1, to see all the services on a system. This program can be found with the Administrative Tools.

FIGURE 25-1

WINDOWS SERVICES ARCHITECTURE

Three program types are necessary to operate a Windows Service:

- ➤ A service program
- ➤ A service control program
- ➤ A service configuration program

The *service program* itself provides the actual functionality you are looking for. With a *service control* program, it is possible to send control requests to a service, such as start, stop, pause, and continue. With a *service configuration* program, a service can be installed; it is copied to the file system, written into the registry, and configured as a service. Although .NET components can be installed simply with an xcopy — because they don't need to write information to the registry — installation for services requires registry configuration. A service configuration program can also be used to change the configuration of that service at a later point.

These three ingredients of a Windows Service are discussed in the following subsections.

Service Program

Before looking at the .NET implementation of a service, let's explore, from an independent point of view, what the Windows architecture of services looks like and what the inner functionality of a service is.

The service program implements the functionality of the service. It needs three parts:

- A main function
- A service-main function
- A handler

Before discussing these parts, we need to quickly introduce you to the *Service Control Manager (SCM)*. The SCM plays an important role for services — sending requests to your service to start and to stop it.

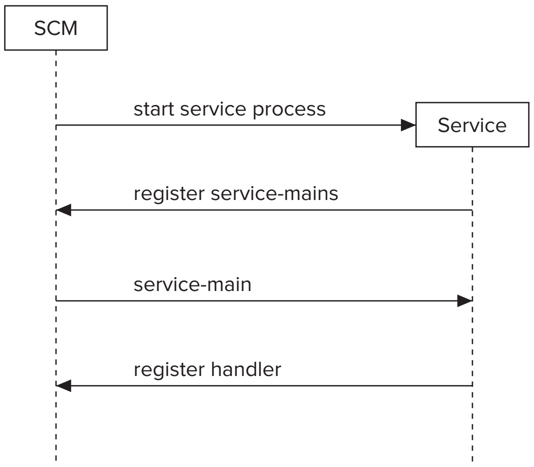

FIGURE 25-2

Service Control Manager

The SCM is the part of the operating system that communicates with the service. Figure 25-2 illustrates how this communication works with a sequence diagram.

At boot time, each process for which a service is set to start automatically is started, and so the main function of this process is called. The service has the responsibility of registering the service-main function for each of its services. The main function is the entry point of the service program, and in this function the entry points for the service-main functions must be registered with the SCM.

Main Function, Service-Main, and Handlers

The main function of the service is the normal entry point of a program, the `Main()` method. The main function of the service might register more than one service-main function. The *service-main* function contains the actual functionality of the service. The service must register a service-main function for each service it provides. A service program can provide a lot of services in a single program; for example, `<windows>\system32\services.exe` is the service program that includes Alerter, Application Management, Computer Browser, and DHCP Client, among other items.

The SCM now calls the service-main function for each service that should be started. One important task of the service-main function is to register a handler with the SCM.

The *handler* function is the third part of a service program. The handler must respond to events from the SCM. Services can be stopped, suspended, and resumed, and the handler must react to these events.

After a handler has been registered with the SCM, the service control program can post requests to the SCM to stop, suspend, and resume the service. The service control program is independent of the SCM and the service itself. The operating system contains many service control programs, for example, the MMC Services snap-in that you saw earlier. You can also write your own service control program; a good example of this is the SQL Server Configuration Manager shown in Figure 25-3.

FIGURE 25-3

Service Control Program

As the name suggests, with a service control program, you can control the service. For stopping, suspending, and resuming the service, you can send control codes to the service, and the handler should react to these events. It is also possible to ask the service about the actual status and to implement a custom handler that responds to custom control codes.

Service Configuration Program

Because services must be configured in the registry, you can't use xcopy installation with services. The registry contains the startup type of the service, which can be set to automatic, manual, or disabled. You also need to configure the user of the service program and dependencies of the service — for example, the services that must be started before this one can start. All these configurations are made within a service configuration program. The installation program can use the service configuration program to configure the service, but this program can also be used at a later time to change service configuration parameters.

Classes for Windows Services

In the .NET Framework, you can find service classes in the `System.ServiceProcess` namespace that implement the three parts of a service:

- ➤ You must inherit from the `ServiceBase` class to implement a service. The `ServiceBase` class is used to register the service and to answer start and stop requests.
- ➤ The `ServiceController` class is used to implement a service control program. With this class, you can send requests to services.
- ➤ The `ServiceProcessInstaller` and `ServiceInstaller` classes are, as their names suggest, classes to install and configure service programs.

Now you are ready to create a new service.

CREATING A WINDOWS SERVICE PROGRAM

The service that you create in this chapter hosts a quote server. With every request that is made from a client, the quote server returns a random quote from a quote file. The first part of the solution uses three assemblies, one for the client and two for the server. Figure 25-4 gives an overview of the solution. The assembly `QuoteServer` holds the actual functionality. The service reads the quote file in a memory cache, and answers requests for quotes with the help of a socket server. The `QuoteClient` is a WPF rich-client application. This application creates a client socket to communicate with the `QuoteServer`. The third assembly is the actual service. The `QuoteService` starts and stops the `QuoteServer`; the service controls the server.

Before creating the service part of your program, create a simple socket server in an extra C# class library that will be used from your service process.

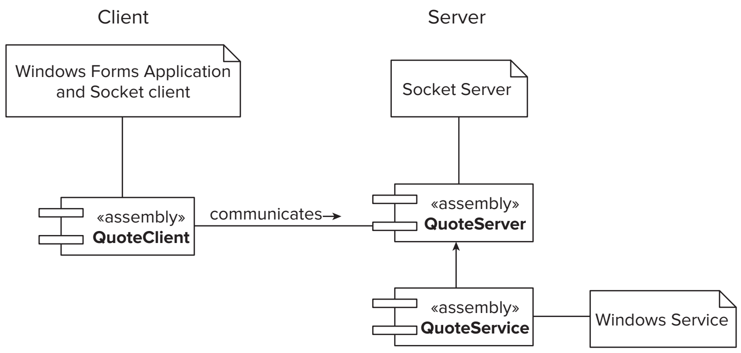

FIGURE 25-4

Creating Core Functionality for the Service

You can build any functionality in a Windows Service, such as scanning for files to do a backup or a virus check or starting a WCF server. However, all service programs share some similarities. The program must be able to start (and to return to the caller), stop, and suspend. This section looks at such an implementation using a socket server.

With Windows 7, the Simple TCP/IP Services can be installed as part of the Windows components. Part of the Simple TCP/IP Services is a "quote of the day," or qotd, TCP/IP server. This simple service listens to port 17 and answers every request with a random message from the file `<windir>\system32\drivers\etc\quotes`. With the sample service, a similar server will be built. The sample server returns a Unicode string, in contrast to the good-old qotd server that returns an ASCII string.

First, create a Class Library called `QuoteServer` and implement the code for the server. The following walks through the source code of your `QuoteServer` class in the file `QuoteServer.cs`:

```
using System;
using System.Collections.Generic;
using System.Diagnostics;
using System.IO;
using System.Linq;
using System.Net;
using System.Net.Sockets;
using System.Text;
using System.Threading;

namespace Wrox.ProCSharp.WinServices
{
   public class QuoteServer
   {
      private TcpListener listener;
      private int port;
      private string filename;
      private List<string> quotes;
      private Random random;
      private Thread listenerThread;
```

code snippet QuoteServer/QuoteServer.cs

The constructor `QuoteServer()` is overloaded so that a filename and a port can be passed to the call. The constructor where just the file name is passed uses the default port 7890 for the server. The default constructor defines the default filename for the quotes as `quotes.txt`:

```
      public QuoteServer()
         : this ("quotes.txt")
      {
      }
      public QuoteServer(string filename)
         : this(filename, 7890)
      {
      }
      public QuoteServer(string filename, int port)
      {
         this.filename = filename;
         this.port = port;
      }
```

`ReadQuotes()` is a helper method that reads all the quotes from a file that was specified in the constructor. All the quotes are added to the `List<string>` quotes. In addition, you are creating an instance of the `Random` class that will be used to return random quotes:

```
protected void ReadQuotes()
{
   quotes = File.ReadAllLines(filename).ToList();
   random = new Random();
}
```

Another helper method is `GetRandomQuoteOfTheDay()`. This method returns a random quote from the quotes collection:

```
protected string GetRandomQuoteOfTheDay()
{
   int index = random.Next(0, quotes.Count);
   return quotes[index];
}
```

In the `Start()` method, the complete file containing the quotes is read in the `List<string>` quotes by using the helper method `ReadQuotes()`. After this, a new thread is started, which immediately calls the `ListenerThread()` method — similarly to the `TcpReceive` example in Chapter 24, "Networking."

Here a thread is used because the `Start()` method cannot block and wait for a client; it must return immediately to the caller (SCM). The SCM would assume that the start failed if the method didn't return to the caller in a timely fashion (30 seconds). The listener thread is set as a background thread so that the application can exit without stopping this thread. The `Name` property of the thread is set because this helps with debugging, as the name will show up in the debugger:

```
public void Start()
{
   ReadQuotes();
   listenerThread = new Thread(ListenerThread);
   listenerThread.IsBackground = true;
   listenerThread.Name = "Listener";
   listenerThread.Start();
}
```

The thread function `ListenerThread()` creates a `TcpListener` instance. The `AcceptSocket()` method waits for a client to connect. As soon as a client connects, `AcceptSocket()` returns with a socket associated with the client. Next, `GetRandomQuoteOfTheDay()` is called to send the returned random quote to the client using `socket.Send()`:

```
protected void ListenerThread()
{
   try
   {
      IPAddress ipAddress = IPAddress.Parse("127.0.0.1");
      listener = new TcpListener(ipAddress, port);
      listener.Start();
      while (true)
      {
         Socket clientSocket = listener.AcceptSocket();
         string message = GetRandomQuoteOfTheDay();
         UnicodeEncoding encoder = new UnicodeEncoding();
         byte[] buffer = encoder.GetBytes(message);
         clientSocket.Send(buffer, buffer.Length, 0);
         clientSocket.Close();
      }
   }
   catch (SocketException ex)
```

```
            {
               Trace.TraceError(String.Format("QuoteServer {0}", ex.Message));
            }
         }
```

In addition to the `Start()` method, the following methods are needed to control the service: `Stop()`, `Suspend()`, and `Resume()`:

```
         public void Stop()
         {
            listener.Stop();
         }
         public void Suspend()
         {
            listener.Stop();
         }
         public void Resume()
         {
            Start();
         }
```

Another method that will be publicly available is `RefreshQuotes()`. If the file containing the quotes changes, the file is re-read with this method:

```
         public void RefreshQuotes()
         {
            ReadQuotes();
         }
      }
   }
```

Before building a service around the server, it is useful to build a test program that creates just an instance of the `QuoteServer` and calls `Start()`. This way, you can test the functionality without the need to handle service-specific issues. This test server must be started manually, and you can easily walk through the code with a debugger.

The test program is a C# console application, `TestQuoteServer`. You need to reference the assembly of the `QuoteServer` class. The file containing the quotes must be copied to the directory `c:\ProCSharp\Services` (or you must change the argument in the constructor to specify where you have copied the file). After calling the constructor, the `Start()` method of the `QuoteServer` instance is called. `Start()` returns immediately after having created a thread, so the console application keeps running until `Return` is pressed:

```
         static void Main()
         {
            var qs = new QuoteServer("quotes.txt", 4567);
            qs.Start();
            Console.WriteLine("Hit return to exit");
            Console.ReadLine();
            qs.Stop();
         }
```

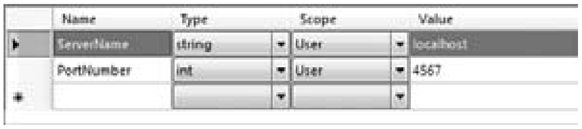
code snippet TestQuoteServer/Program.cs

Note that `QuoteServer` will be running on port 4567 on localhost using this program — you will have to use these settings in the client later.

QuoteClient Example

The client is a simple WPF Windows application in which you can request quotes from the server. This application uses the `TcpClient` class to connect to the running server, and receives the returned message, displaying it in a text box. The user interface just contains a `Button` and a `TextBox`. The `Button` has the `Click` event assigned to the method `OnGetQuote` and the `TextBox` has the `x:Name` property set to `textQuote`.

Server and port information to connect to the server is configured with settings of the application. You can add settings with the Settings tab inside the properties of the project (see Figure 25-5). Here, you can define the `ServerName` and `PortNumber` settings, and define some default values. From here, with the Scope set to User, the settings go into a user-specific configuration file, and every user of the application can have different settings. This Settings feature of Visual Studio also creates a `Settings` class so that the settings can be read and written with a strongly typed class.



Name	Type	Scope	Value
ServerName	string	User	localhost
PortNumber	int	User	4567

FIGURE 25-5

You need to add the following `using` directives to your code:

```
using System;
using System.Net.Sockets;
using System.Text;
using System.Windows;
using System.Windows.Input;
```

code snippet QuoteClient/MainWindow.xaml.cs

The major functionality of the client lies in the handler for the click event of the Get Quote button:

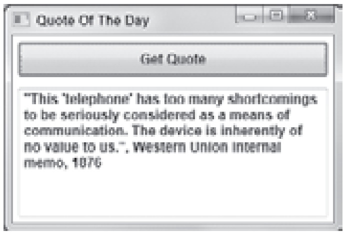
```
protected void OnGetQuote(object sender, RoutedEventArgs e)
{
   const int bufferSize = 1024;
   Cursor currentCursor = this.Cursor;
   this.Cursor = Cursors.Wait;

   string serverName = Properties.Settings.Default.ServerName;
   int port = Properties.Settings.Default.PortNumber;

   var client = new TcpClient();
   NetworkStream stream = null;
   try
   {
      client.Connect(serverName, port);
      stream = client.GetStream();
      byte[] buffer = new byte[bufferSize];
      int received = stream.Read(buffer, 0, bufferSize);
      if (received <= 0)
      {
         return;
      }
      textQuote.Text = Encoding.Unicode.GetString(buffer).Trim('\0');
   }
   catch (SocketException ex)
   {
      MessageBox.Show(ex.Message, "Error Quote of the day",
            MessageBoxButton.OK, MessageBoxImage.Error);
   }
   finally
   {
      if (stream != null)
      {
         stream.Close();
      }
```

```
            if (client.Connected)
            {
               client.Close();
            }
         }
         this.Cursor = currentCursor;
      }
```

After starting the test server and this Windows application client, you can test the functionality. Figure 25-6 shows a successful run of this application.



"This 'telephone' has too many shortcomings to be seriously considered as a means of communication. The device is inherently of no value to us.", Western Union internal memo, 1876

FIGURE 25-6

Next, you implement the service functionality in the server. The program is already running, so what else do you need? Well, the server program should be automatically started at boot time without anyone logged on to the system. You want to control this by using service control programs.

Windows Service Program

Using the new project template for C# Windows Services, you can now start to create a Windows Service program. For the new service, use the name `QuoteService`.

After you click the OK button to create the Windows Service program, you see the Designer surface. However, you can't insert any UI components because the application cannot directly display anything on the screen. The Designer surface is used later in this chapter to add other components, such as installation objects, performance counters, and event logging.

Selecting the properties of this service opens up the Properties editor window, where you can configure the following values:

- ➤ `AutoLog` specifies that events are automatically written to the event log for starting and stopping the service.
- ➤ `CanPauseAndContinue`, `CanShutdown`, and `CanStop` specify pause, continue, shut down, and stop requests.
- ➤ `ServiceName` is the name of the service written to the registry and is used to control the service.
- ➤ `CanHandleSessionChangeEvent` defines whether the service can handle change events from a terminal server session.
- ➤ `CanHandlePowerEvent` is a very useful option for services running on a laptop or mobile devices. If this option is enabled, the service can react to low-power events and change the behavior of the service accordingly. Examples of power events include battery low, power status change (because of a switch from or to A/C power), and change to suspend.

Changing these properties with the Properties editor sets the values of your `ServiceBase`-derived class in the `InitalizeComponent()` method. You already know this method from Windows Forms applications. It is used in a similar way with services.

A wizard generates the code, but change the filename to `QuoteService.cs`, the name of the namespace to `Wrox.ProCSharp.WinServices`, and the class name to `QuoteService`. The code of the service is discussed in detail shortly.

The ServiceBase Class

The `ServiceBase` class is the base class for all Windows Services developed with the .NET Framework. The class `QuoteService` is derived from `ServiceBase`; this class communicates with the SCM using an undocumented helper class, `System.ServiceProcess.NativeMethods`, which is just a wrapper class to the Win32 API calls. The class is internal, so it cannot be used in your code.

The sequence diagram in Figure 25-7 shows the interaction of the SCM, the class `QuoteService`, and the classes from the `System.ServiceProcess` namespace. In the sequence diagram, you can see the lifelines of objects vertically and the communication going on horizontally. The communication is time-ordered from top to bottom.

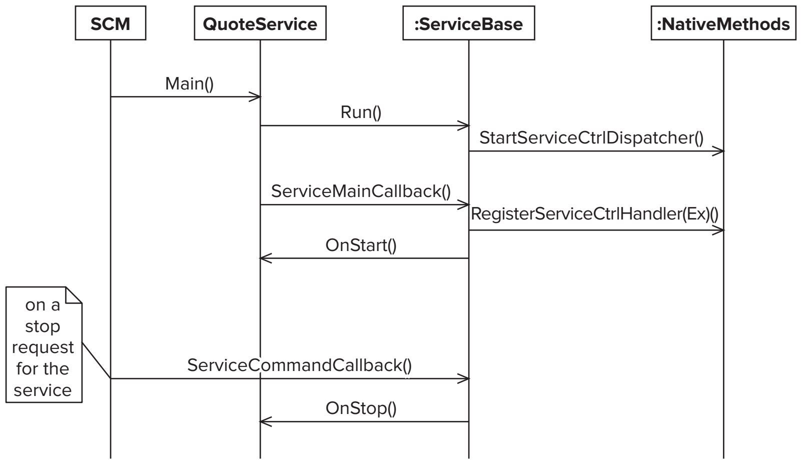


FIGURE 25-7

The SCM starts the process of a service that should be started. At startup, the `Main()` method is called. In the `Main()` method of the sample service, the `Run()` method of the base class `ServiceBase` is called. `Run()` registers the method `ServiceMainCallback()` using `NativeMethods.StartServiceCtrlDispatcher()` in the SCM and writes an entry to the event log.

Next, the SCM calls the registered method `ServiceMainCallback()` in the service program. `ServiceMainCallback()` itself registers the handler in the SCM using `NativeMethods.RegisterServiceCtrlHandler[Ex]()` and sets the status of the service in the SCM. Then the `OnStart()` method is called. In `OnStart()`, you need to implement the startup code. If `OnStart()` is successful, the string "Service started successfully" is written to the event log.

The handler is implemented in the `ServiceCommandCallback()` method. The SCM calls this method when changes are requested from the service. The `ServiceCommandCallback()` method routes the requests further to `OnPause()`, `OnContinue()`, `OnStop()`, `OnCustomCommand()`, and `OnPowerEvent()`.

Main Function

This section looks into the application template–generated main function of the service process. In the main function, an array of `ServiceBase` classes, `ServicesToRun`, is declared. One instance of the `QuoteService` class is created and passed as the first element to the `ServicesToRun` array. If more than one service should run inside this service process, it is necessary to add more instances of the specific service classes to the array. This array is then passed to the static `Run()` method of the `ServiceBase` class. With the `Run()` method of `ServiceBase`, you are giving the SCM references to the entry points of your services. The main thread of your service process is now blocked and waits for the service to terminate.

Here is the automatically generated code:

```
/// <summary>
/// The main entry point for the application.
/// </summary>
static void Main()
{
   ServiceBase[] ServicesToRun;
   ServicesToRun = new ServiceBase[]
   {
      new QuoteService()
   };
   ServiceBase.Run(ServicesToRun);
}
```

code snippet QuoteService/Program.cs

If there is only a single service in the process, the array can be removed; the `Run()` method accepts a single object derived from the class `ServiceBase`, so the `Main()` method can be reduced to this:

```
ServiceBase.Run(new QuoteService());
```

The service program `Services.exe` includes multiple services. If you have a similar service, where more than one service is running in a single process in which you must initialize some shared state for multiple services, the shared initialization must be done before the `Run()` method. With the `Run()` method, the main thread is blocked until the service process is stopped, and any following instructions would not be reached before the end of the service.

The initialization shouldn't take longer than 30 seconds. If the initialization code were to take longer than this, the SCM would assume that the service startup failed. You need to take into account the slowest machines where this service should run within the 30-second limit. If the initialization takes longer, you could start the initialization in a different thread so that the main thread calls `Run()` in time. An event object can then be used to signal that the thread has completed its work.

Service Start

At service start, the `OnStart()` method is called. In this method, you can start the previously created socket server. You must reference the `QuoteServer` assembly for the use of the `QuoteService`. The thread calling `OnStart()` cannot be blocked; this method must return to the caller, which is the `ServiceMainCallback()` method of the `ServiceBase` class. The `ServiceBase` class registers the handler and informs the SCM that the service started successfully after calling `OnStart()`:

```
protected override void OnStart(string[] args)
{
   quoteServer = new QuoteServer(
         Path.Combine(AppDomain.CurrentDomain.BaseDirectory, "quotes.txt"),
         5678);
   quoteServer.Start();
}
```

code snippet QuoteService/QuoteService.cs

The `quoteServer` variable is declared as a private member in the class:

```
namespace Wrox.ProCSharp.WinServices
{
   public partial class QuoteService: ServiceBase
   {
      private QuoteServer quoteServer;
```

Handler Methods

When the service is stopped, the `OnStop()` method is called. You should stop the service functionality in this method:

```
      protected override void OnStop()
      {
         quoteServer.Stop();
      }
```

In addition to `OnStart()` and `OnStop()`, you can override the following handlers in the service class:

- `OnPause()` is called when the service should be paused.
- `OnContinue()` is called when the service should return to normal operation after being paused. To make it possible for the overridden methods `OnPause()` and `OnContinue()` to be called, the `CanPauseAndContinue` property must be set to `true`.
- `OnShutdown()` is called when Windows is undergoing system shutdown. Normally, the behavior of this method should be similar to the `OnStop()` implementation; if more time is needed for a shutdown, you can request additional time. Similarly to `OnPause()` and `OnContinue()`, a property must be set to enable this behavior: `CanShutdown` must be set to `true`.
- `OnPowerEvent()` is called when the power status of the system changes. The information about the change of the power status is in the argument of type `PowerBroadcastStatus`. `PowerBroadcastStatus` is an enumeration with values such as `Battery Low` and `PowerStatusChange`. Here, you will also get information if the system would like to suspend (`QuerySuspend`), where you can approve or deny the suspend. You can read more about power events later in this chapter.
- `OnCustomCommand()` is a handler that can serve custom commands that are sent by a service control program. The method signature of `OnCustomCommand()` has an `int` argument where you get the custom command number. The value can be in the range from 128 to 256; values below 128 are system-reserved values. In your service, you are re-reading the quotes file with the custom command 128:

```
      protected override void OnPause()
      {
         quoteServer.Suspend();
      }

      protected override void OnContinue()
      {
         quoteServer.Resume();
      }

      public const int commandRefresh = 128;
      protected override void OnCustomCommand(int command)
      {
         switch (command)
         {
            case commandRefresh:
               quoteServer.RefreshQuotes();
               break;

            default:
```

```
                        break;
                    }
                }
```

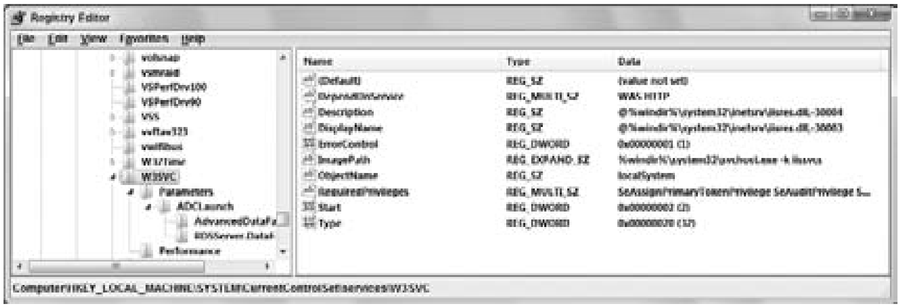
Threading and Services

As stated earlier in this chapter, the SCM assumes that the service failed if the initialization takes too long. To deal with this, you need to create a thread.

The `OnStart()` method in your service class must return in time. If you call a blocking method such as `AcceptSocket()` from the `TcpListener` class, you need to start a thread for doing this. With a networking server that deals with multiple clients, a thread pool is also very useful. `AcceptSocket()` should receive the call and hand the processing off to another thread from the pool. This way, no one waits for the execution of code and the system seems responsive.

Service Installation

A service must be configured in the registry. All services can be found in `HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services`. You can view the registry entries by using `regedit`. The type of the service, display name, path to the executable, startup configuration, and so on, are all found here. Figure 25-8 shows the registry configuration of the W3SVC service.



Name	Type	Data
(Default)	REG_SZ	(value not set)
DependOnService	REG_MULTI_SZ	WAS HTTP
Description	REG_SZ	@%windir%\system32\inetsrv\iisres.dll,-30004
DisplayName	REG_SZ	@%windir%\system32\inetsrv\iisres.dll,-30003
ErrorControl	REG_DWORD	0x00000001 (1)
ImagePath	REG_EXPAND_SZ	%windir%\system32\svchost.exe -k iissvcs
ObjectName	REG_SZ	localSystem
RequiredPrivileges	REG_MULTI_SZ	SeAssignPrimaryTokenPrivilege SeAuditPrivilege S...
Start	REG_DWORD	0x00000002 (2)
Type	REG_DWORD	0x00000020 (32)

Computer\HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\services\W3SVC

FIGURE 25-8

This configuration can be done by using the installer classes from the `System.ServiceProcess` namespace, as discussed in the following section.

Installation Program

You can add an installation program to the service by switching to the design view with Visual Studio and then selecting the Add Installer option from the context menu. With this option, a new `ProjectInstaller` class is created, and a `ServiceInstaller` and a `ServiceProcessInstaller` instance are created.

Figure 25-9 shows the class diagram of the installer classes for services.

With this diagram in mind, let's go through the source code in the file `ProjectInstaller.cs` that was created with the Add Installer option.

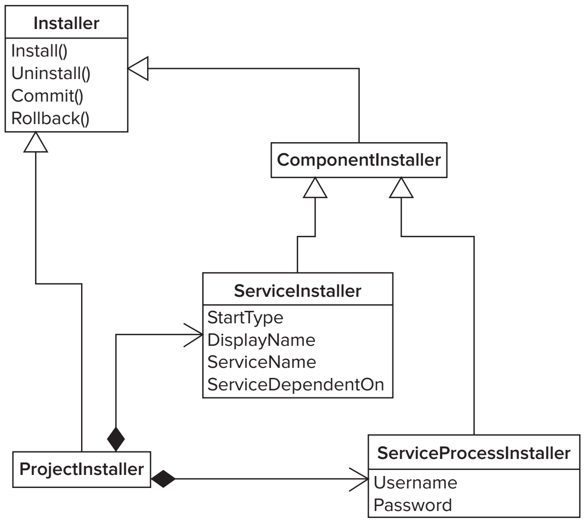


FIGURE 25-9

The Installer Class

The class `ProjectInstaller` is derived from `System.Configuration.Install.Installer`. This is the base class for all custom installers. With the `Installer` class, it is possible to build transaction-based installations. With a transaction-based installation, it is possible to roll back to the previous state if the installation fails, and any changes made by this installation up to that point will be undone. As you can see in Figure 25-9, the `Installer` class has `Install()`, `Uninstall()`, `Commit()`, and `Rollback()` methods, and they are called from installation programs.

The attribute `[RunInstaller(true)]` means that the class `ProjectInstaller` should be invoked when installing an assembly. Custom action installers, as well as `installutil.exe` (which is used later in this chapter), check for this attribute.

`InitializeComponent()` is called inside the constructor of the `ProjectInstaller` class:

```
using System.ComponentModel;
using System.Configuration.Install;

namespace Wrox.ProCSharp.WinServices
{
   [RunInstaller(true)]
   public partial class ProjectInstaller: Installer
   {
      public ProjectInstaller()
      {
         InitializeComponent();
      }
   }
}
```

code snippet QuoteService/ ProjectInstaller.cs

Process Installer and Service Installer

Within the implementation of `InitializeComponent()`, instances of the `ServiceProcessInstaller` class and the `ServiceInstaller` class are created. Both of these classes derive from the `ComponentInstaller` class, which itself derives from `Installer`.

Classes derived from `ComponentInstaller` can be used with an installation process. Remember that a service process can include more than one service. The `ServiceProcessInstaller` class is used for the configuration of the process that defines values for all services in this process, and the `ServiceInstaller` class is for the configuration of the service, so one instance of `ServiceInstaller` is required for each service. If three services are inside the process, you need to add `ServiceInstaller` objects — three `ServiceInstaller` instances are needed in that case:

```
   partial class ProjectInstaller
   {
      /// <summary>
      /// Required designer variable.
      /// </summary>
      private System.ComponentModel.IContainer components = null;

      /// <summary>
      /// Required method for Designer supportdo not modify
      /// the contents of this method with the code editor.
      /// </summary>
      private void InitializeComponent()
      {
         this.serviceProcessInstaller1 =
                     new System.ServiceProcess.ServiceProcessInstaller();
         this.serviceInstaller1 =
                    new System.ServiceProcess.ServiceInstaller();
            //
            // serviceProcessInstaller1
            //
            this.serviceProcessInstaller1.Password = null;
            this.serviceProcessInstaller1.Username = null;
            //
            // serviceInstaller1
            //
            this.serviceInstaller1.ServiceName = "QuoteService";
            //
            // ProjectInstaller
            //
            this.Installers.AddRange(
               new System.Configuration.Install.Installer[]
                  {this.serviceProcessInstaller1,
                   this.serviceInstaller1});
         }

         private System.ServiceProcess.ServiceProcessInstaller
                    serviceProcessInstaller1;
         private System.ServiceProcess.ServiceInstaller serviceInstaller1;

      }
```

code snippet QuoteService/ProjectInstaller.Designer.cs

ServiceProcessInstaller installs an executable that implements the class ServiceBase .ServiceProcessInstaller has properties for the complete process. The following table explains the properties shared by all the services inside the process.

PROPERTY	DESCRIPTION
Username, Password	Indicates the user account under which the service runs if the Account property is set to ServiceAccount.User.
Account	With this property, you can specify the account type of the service.
HelpText	HelpText is a read-only property that returns the help text for setting the username and password.

The process that is used to run the service can be specified with the Account property of the ServiceProcessInstaller class using the ServiceAccount enumeration. The following table explains the different values of the Account property.

VALUE	MEANING
LocalSystem	Setting this value specifies that the service uses a highly privileged user account on the local system, and acts as the computer on the network.
NetworkService	Similarly to LocalSystem, this value specifies that the computer's credentials are passed to remote servers, but unlike LocalSystem, such a service acts as a non-privileged user on the local system. As the name implies, this account should be used only for services that need resources from the network.
LocalService	This account type presents anonymous credentials to any remote server and has the same privileges locally as NetworkService.
User	Setting the Account property to ServiceAccount.User means that you can define the account that should be used from the service.

`ServiceInstaller` is the class needed for every service; it has the following properties for each service inside a process: `StartType`, `DisplayName`, `ServiceName`, and `ServicesDependentOn`, as described in the following table.

PROPERTY	DESCRIPTION
`StartType`	The `StartType` property indicates whether the service is manually or automatically started. Possible values are `ServiceStartMode.Automatic`, `ServiceStartMode.Manual`, and `ServiceStartMode.Disabled`. With `ServiceStartMode.Disabled`, the service cannot be started. This option is useful for services that shouldn't be started on a system. You might want to set the option to `Disabled` if, for example, a required hardware controller is not available.
`DelayedAutoStart`	This property is ignored if the `StartType` is not set to `Automatic`. Here you can specify if the service should not be started immediately when the system boots but afterwards. This feature for Windows Services is new with .NET 4 and supported by the operating system since Windows Vista.
`DisplayName`	`DisplayName` is the friendly name of the service that is displayed to the user. This name is also used by management tools that control and monitor the service.
`ServiceName`	`ServiceName` is the name of the service. This value must be identical to the `ServiceName` property of the `ServiceBase` class in the service program. This name associates the configuration of the `ServiceInstaller` to the required service program.
`ServicesDependentOn`	Specifies an array of services that must be started before this service can be started. When the service is started, all these dependent services are started automatically, and then your service will start.

The ServiceInstallerDialog Class

Another installer class in the `System.ServiceProcess.Design` namespace is `ServiceInstallerDialog`. This class can be used if you want the System Administrator to enter the account that should be used by the service by assigning the username and password during the installation.

If you set the `Account` property of the class `ServiceProcessInstaller` to `ServiceAccount.User` and the `Username` and `Password` properties to `null`, you will see the Set Service Login dialog box at installation time (see Figure 25-10). You can also cancel the installation at this point.

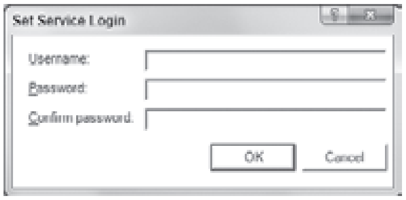

FIGURE 25-10

installutil

After adding the installer classes to the project, you can use the `installutil.exe` utility to install and uninstall the service. This utility can be used to install any assembly that has an `Installer` class. The `installutil.exe` utility calls the method `Install()` of the class that derives from the `Installer` class for installation, and `Uninstall()` for the *uninstallation*.

The command-line inputs for the installation and uninstallation of our service are as follows:

```
installutil quoteservice.exe
installutil /u quoteservice.exe
```

> *If the installation fails, be sure to check the installation log files,* `InstallUtil.InstallLog` *and* `<servicename>.InstallLog`*. Often, you can find very useful information, such as "The specified service already exists."*

Client

After the service has been successfully installed, you can start the service manually from the Services MMC (see the next section for further details), and then you can start the client application.

MONITORING AND CONTROLLING WINDOWS SERVICES

To monitor and control Windows Services, you can use the Services Microsoft Management Console (MMC) snap-in that is part of the Computer Management administration tool. Every Windows system also has a command-line utility, `net.exe`, which allows you to control services. Another Windows command-line utility is `sc.exe`. This utility has much more functionality than `net.exe`. You can also control services directly from the Visual Studio Server Explorer. In this section, you also create a small Windows application that makes use of the `System.ServiceProcess.ServiceController` class to monitor and control services.

MMC Snap-in

Using the Services snap-in to the MMC, you can view the status of all services (see Figure 25-11). It is also possible to send control requests to services to stop, enable, or disable them, as well as to change their configuration. The Services snap-in is a service control program as well as a service configuration program.

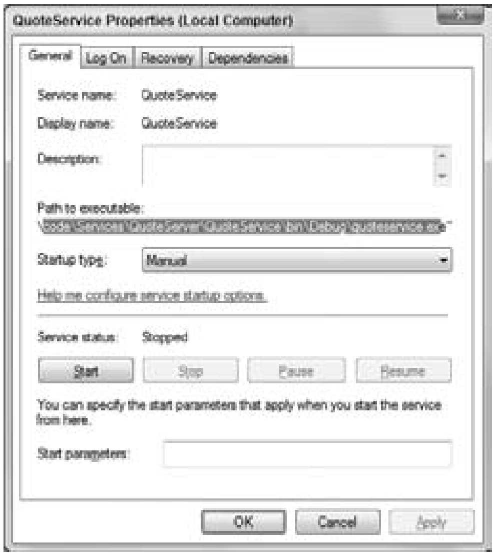
FIGURE 25-11

When you double-click QuoteService, you get the Properties dialog box shown in Figure 25-12. This dialog box enables you to view the service name, the description, the path to the executable, the startup type, and the status. The service is currently started. The account for the service process can be changed with the Log On tab in this dialog box.



QuoteService Properties (Local Computer)

General | Log On | Recovery | Dependencies

Service name: QuoteService

Display name: QuoteService

Description:

Path to executable:
\code\Services\QuoteServer\QuoteService\bin\Debug\quoteservice.exe"

Startup type: Manual

Help me configure service startup options.

Service status: Stopped

Start | Stop | Pause | Resume

You can specify the start parameters that apply when you start the service from here.

Start parameters:

OK | Cancel | Apply

FIGURE 25-12

net.exe Utility

The Services snap-in is easy to use, but the system administrator cannot automate it because it is not usable within an administrative script. Controlling services with a tool that can be automated with a script, you can use the command-line utility `net.exe`. The `net start` command shows all running services, `net start servicename` starts a service, and `net stop servicename` sends a stop request to the service. It is also possible to pause and to continue a service with `net pause` and `net continue` (only if the service allows it, of course).

sc.exe Utility

Another little-known utility delivered as part of the operating system is `sc.exe`. This is a great tool to play with services. Much more can be done with `sc.exe` than with the `net.exe` utility. With `sc.exe`, you can check the actual status of a service, or configure, remove, and add services. This tool also facilitates the deinstallation of the service, if it fails to function correctly.

Visual Studio Server Explorer

You can also control services using the Server Explorer within Visual Studio by selecting Services. The Services item is listed in the tree view with the first element Servers; below that you can find the name of your computer, and below that there's the Services item. By selecting a service and opening the context menu, you can start or stop a service. This context menu can also be used to add a `ServiceController` class to the project.

To control a specific service in your application, drag and drop a service from the Server Explorer to the Designer: a `ServiceController` instance is added to the application. The properties of this object are automatically set to access the selected service, and the assembly `System.ServiceProcess` is referenced. You can use this instance to control a service in the same way you can with the application that you develop in the next section.

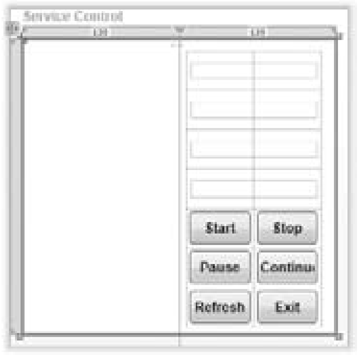


FIGURE 25-13

Writing a Custom Service Controller

In this section, you create a small Windows application that uses the `ServiceController` class to monitor and control Windows Services.

Create a WPF application with a user interface as shown in Figure 25-13. The main window of this application has a list box to show all services, four text boxes to display the display name, status, type, and name of the service, and six buttons. Four buttons are used to send control events, one button for a refresh of the list, and one button to exit the application.

You can read more about WPF in Chapter 35, "Core WPF."

Monitoring the Service

With the `ServiceController` class, you can get the information about each service. The following table shows the properties of the `ServiceController` class.

PROPERTY	DESCRIPTION
`CanPauseAndContinue`	Returns `true` if pause and continue requests can be sent to the service.
`CanShutdown`	Returns `true` if the service has a handler for a system shutdown.
`CanStop`	Returns `true` if the service is stoppable.
`DependentServices`	Returns a collection of dependent services. If the service is stopped, then all dependent services are stopped beforehand.
`ServicesDependentOn`	Returns a collection of the services that this service depends on.
`DisplayName`	Specifies the name that should be displayed for this service.
`MachineName`	Specifies the name of the machine that the service runs on.
`ServiceName`	Specifies the name of the service.
`ServiceType`	Specifies the type of the service. The service can be run inside a shared process where more than one service uses the same process (`Win32ShareProcess`), or run in such a way that there is just one service in a process (`Win32OwnProcess`). If the service can interact with the desktop, the type is `InteractiveProcess`.
`Status`	Specifies the status of the service. The status can be running, stopped, paused, or in some intermediate mode such as start pending, stop pending, and so on. The status values are defined in the enumeration `ServiceControllerStatus`.

In the sample application, the properties `DisplayName`, `ServiceName`, `ServiceType`, and `Status` are used to display the service information. Also, `CanPauseAndContinue` and `CanStop` are used to enable or disable the Pause, Continue, and Stop buttons.

To get all the needed information for the user interface, the class `ServiceControllerInfo` is created. This class can be used for data binding and offers status information, the name of the service, the service type, and the information about which buttons to control the service should be enabled or disabled.

`ServiceControllerInfo` contains an embedded `ServiceController` that is set with the constructor of the `ServiceControllerInfo` class. There is also a read-only property `Controller` to access the embedded `ServiceController`:

```
public class ServiceControllerInfo
{
   private readonly ServiceController controller;

   public ServiceControllerInfo(ServiceController controller)
   {
      this.controller = controller;
   }

   public ServiceController Controller
   {
      get { return controller; }
   }
```

code snippet ServiceControl/ServiceControllerInfo.cs

To display current information about the service, the `ServiceControllerInfo` class has the read-only properties `DisplayName`, `ServiceName`, `ServiceTypeName`, and `ServiceStatusName`. The implementation of the properties `DisplayName` and `ServiceName` just accesses the properties `DisplayName` and `ServiceName` of the underlying `ServiceController` class. With the implementation of the properties `ServiceTypeName` and `ServiceStatusName`, more work is done — the status and type of the service cannot be returned that easily because a string should be displayed instead of a number, which is what the `ServiceController` class returns. The property `ServiceTypeName` returns a string that represents the type of the service. The `ServiceType` you get from the property `ServiceController.ServiceType` represents a set of flags that can be combined by using the bitwise `OR` operator. The `InteractiveProcess` bit can be set together with `Win32OwnProcess` and `Win32ShareProcess`. So, first it is checked if the `InteractiveProcess` bit is set before continuing to check for the other values. With services, the string returned will be "`Win32 Service Process`" or `"Win32 Shared Process"`:

```
   public string ServiceTypeName
   {
      get
      {
         ServiceType type = controller.ServiceType;
         string serviceTypeName = "";
         if ((type & ServiceType.InteractiveProcess) != 0)
         {
            serviceTypeName = "Interactive ";
            type -= ServiceType.InteractiveProcess;
         }
         switch (type)
         {
            case ServiceType.Adapter:
               serviceTypeName += "Adapter";
               break;

            case ServiceType.FileSystemDriver:
            case ServiceType.KernelDriver:
            case ServiceType.RecognizerDriver:
               serviceTypeName += "Driver";
               break;

            case ServiceType.Win32OwnProcess:
               serviceTypeName += "Win32 Service Process";
               break;

            case ServiceType.Win32ShareProcess:
                serviceTypeName += "Win32 Shared Process";
                break;

            default:
                serviceTypeName += "unknown type " + type.ToString();
                break;
        }
        return serviceTypeName;
    }
}

public string ServiceStatusName
{
    get
    {
        switch (controller.Status)
        {
            case ServiceControllerStatus.ContinuePending:
                return "Continue Pending";
            case ServiceControllerStatus.Paused:
                return "Paused";
            case ServiceControllerStatus.PausePending:
                return "Pause Pending";
            case ServiceControllerStatus.StartPending:
                return "Start Pending";
            case ServiceControllerStatus.Running:
                return "Running";
            case ServiceControllerStatus.Stopped:
                return "Stopped";
            case ServiceControllerStatus.StopPending:
                return "Stop Pending";
            default:
                return "Unknown status";
        }
    }
}

public string DisplayName
{
    get { return controller.DisplayName; }
}

public string ServiceName
{
    get { return controller.ServiceName; }
}
```

The `ServiceControllerInfo` class has some more properties to enable the Start, Stop, Pause, and Continue buttons: `EnableStart`, `EnableStop`, `EnablePause`, and `EnableContinue`. These properties return a Boolean value according to the current status of the service:

```
public bool EnableStart
{
    get
    {
        return controller.Status == ServiceControllerStatus.Stopped;
    }
}

public bool EnableStop
{
    get
    {
            return controller.Status == ServiceControllerStatus.Running;
         }
      }

      public bool EnablePause
      {
         get
         {
            return controller.Status == ServiceControllerStatus.Running &&
                  controller.CanPauseAndContinue;
         }
      }

      public bool EnableContinue
      {
         get
         {
            return controller.Status == ServiceControllerStatus.Paused;
         }
       }
    }
```

In the `ServiceControlWindow` class, the method `RefreshServiceList()` gets all the services using `ServiceController.GetServices()` for display in the list box. The `GetServices()` method returns an array of `ServiceController` instances representing all Windows Services installed on the operating system. The `ServiceController` class also has the static method `GetDevices()` that returns a `ServiceController` array representing all device drivers. The returned array is sorted with the help of the generic `Array.Sort()` method. The sort is done by the `DisplayName` as is defined with the Lambda expression that is passed to the `Sort()` method. Using `Array.ConvertAll()`, the `ServiceController` instances are converted to the type `ServiceControllerInfo`. Here, a Lambda expression is passed that invokes the `ServiceControllerInfo` constructor for every `ServiceController` object. Last, the `ServiceControllerInfo` array is assigned to the `DataContext` property of the window for data binding:

```
      protected void RefreshServiceList()
      {
         ServiceController[] services = ServiceController.GetServices();

         Array.Sort(services, (s1, s2) =>
                    s1.DisplayName.CompareTo(s2.DisplayName));

         this.DataContext =
            Array.ConvertAll(services, controller =>
               new ServicesControllerInfo(controller));
      }
```

code snippet ServiceControl/ServiceControlWindow.xaml.cs

The method `RefreshServiceList()` to get all the services in the list box is called within the constructor of the class `ServiceControlWindow`. The constructor also defines the event handler for the `Click` event of the buttons:

```
      public ServiceControlWindow()
      {
         InitializeComponent();

         RefreshServiceList();
      }
```

Now, you can define the XAML code to bind the information to the controls.

First, a `DataTemplate` is defined for the information that is shown inside the `ListBox`. The `ListBox` will contain a `Label` where the `Content` is bound to the `DisplayName` property of the data source. As you bind an array of `ServiceControllerInfo` objects, the property `DisplayName` is defined with the `ServiceControllerInfo` class:

```
<Window.Resources>
  <DataTemplate x:Key="listTemplate">
    <Label Content="{Binding Path=DisplayName}"/>
  </DataTemplate>
</Window.Resources>
```

code snippet ServiceControl/ServiceControlWindow.xaml

The `ListBox` that is placed in the left side of the Window sets the `ItemsSource` property to `{Binding}`. This way, the data that is shown in the list is received from the `DataContext` property that was set in the `RefreshServiceList()` method. The `ItemTemplate` property references the resource `listTemplate` that is defined with the `DataTemplate` shown earlier. The property `IsSynchronizedWithCurrentItem` is set to `True` so that the `TextBox` and `Button` controls that are inside the same Window are bound to the current item that is selected with the `ListBox`:

```
<ListBox Grid.Row="0" Grid.Column="0" HorizontalAlignment="Left"
      Name="listBoxServices" VerticalAlignment="Top"
      ItemsSource="{Binding}"
      ItemTemplate="{StaticResource listTemplate}"
      IsSynchronizedWithCurrentItem="True">
</ListBox>
```

With the `TextBlock` controls, the `Text` property is bound to the corresponding property of the `ServiceControllerInfo` instance. Whether the `Button` controls are enabled or disabled is also defined from the data binding by binding the `IsEnabled` property to the corresponding properties of the `ServiceControllerInfo` instance that return a Boolean value:

```
<TextBlock Grid.Row="0" Grid.ColumnSpan="2" Name="textDisplayName"
    Text="{Binding Path=DisplayName, Mode=OneTime}" />
<TextBlock Grid.Row="1" Grid.ColumnSpan="2" Name="textStatus"
    Text="{Binding Path=ServiceStatusName, Mode=OneTime}" />
<TextBlock Grid.Row="2" Grid.ColumnSpan="2" Name="textType"
    Text="{Binding Path=ServiceTypeName, Mode=OneTime}" />
<TextBlock Grid.Row="3" Grid.ColumnSpan="2" Name="textName"
    Text="{Binding Path=ServiceName, Mode=OneTime}" />
<Button Grid.Row="4" Grid.Column="0" Name="buttonStart" Content="Start"
    IsEnabled="{Binding Path=EnableStart, Mode=OneTime}"
    Click="OnServiceCommand" />
<Button Grid.Row="4" Grid.Column="1" Name="buttonStop" Content="Stop"
    IsEnabled="{Binding Path=EnableStop, Mode=OneTime}"
    Click="OnServiceCommand" />
<Button Grid.Row="5" Grid.Column="0" Name="buttonPause" Content="Pause"
    IsEnabled="{Binding Path=EnablePause, Mode=OneTime}"
    Click="OnServiceCommand" />
<Button Grid.Row="5" Grid.Column="1" Name="buttonContinue"
    Content="Continue" IsEnabled="{Binding Path=EnableContinue,
    Mode=OneTime}" Click="OnServiceCommand" />
<Button Grid.Row="6" Grid.Column="0" Name="buttonRefresh" Content="Refresh"
    Click="OnRefresh" />
<Button Grid.Row="6" Grid.Column="1" Name="buttonExit"
    Content="Exit" Click="OnExit" />
```

Controlling the Service

With the `ServiceController` class, you can also send control requests to the service. The following table explains the methods that can be applied.

METHOD	DESCRIPTION
`Start()`	`Start()` tells the SCM that the service should be started. In the example service program, `OnStart()` is called.
`Stop()`	`Stop()` calls `OnStop()` in the example service program with the help of the SCM if the property `CanStop` is `true` in the service class.
`Pause()`	`Pause()` calls `OnPause()` if the property `CanPauseAndContinue` is `true`.
`Continue()`	`Continue()` calls `OnContinue()` if the property `CanPauseAndContinue` is `true`.
`ExecuteCommand()`	With `ExecuteCommand()`, it is possible to send a custom command to the service.

The following code controls the services. Because the code for starting, stopping, suspending, and pausing is similar, only one handler is used for the four buttons:

```
protected void OnServiceCommand(object sender, RoutedEventArgs e)
{
   Cursor oldCursor = this.Cursor;
   try
   {
      this.Cursor = Cursors.Wait;
      ServiceControllerInfo si =
            (ServiceControllerInfo)listBoxServices.SelectedItem;
      if (sender == this.buttonStart)
      {
         si.Controller.Start();
         si.Controller.WaitForStatus(ServiceControllerStatus.Running,
               TimeSpan.FromSeconds(10));
      }
      else if (sender == this.buttonStop)
      {
         si.Controller.Stop();
         si.Controller.WaitForStatus(ServiceControllerStatus.Stopped,
               TimeSpan.FromSeconds(10));
      }
      else if (sender == this.buttonPause)
      {
         si.Controller.Pause();
         si.Controller.WaitForStatus(ServiceControllerStatus.Paused,
               TimeSpan.FromSeconds(10));
      }
      else if (sender == this.buttonContinue)
      {
         si.Controller.Continue();
         si.Controller.WaitForStatus(ServiceControllerStatus.Running,
               TimeSpan.FromSeconds(10));
      }
      int index = listBoxServices.SelectedIndex;
      RefreshServiceList();
      listBoxServices.SelectedIndex = index;
   }
   catch (System.ServiceProcess.TimeoutException ex)
```

```
        {
           MessageBox.Show(ex.Message, "Timout Service Controller",
                 MessageBoxButton.OK, MessageBoxImage.Error);
        }
        catch (InvalidOperationException ex)
        {
           MessageBox.Show(String.Format("{0} {1}", ex.Message,
                 ex.InnerException != null ? ex.InnerException.Message :
                                             String.Empty),
                 MessageBoxButton.OK, MessageBoxImage.Error);
        }
        finally
        {
           this.Cursor = oldCursor;
        }
     }

     protected void OnExit(object sender, RoutedEventArgs e)
     {
        Application.Current.Shutdown();
     }

     protected void OnRefresh_Click(object sender, RoutedEventArgs e)
     {
        RefreshServiceList();
     }
```

code snippet ServiceControl/ServiceControlWindow.xaml.cs

Because the action of controlling the services can take some time, the cursor is switched to the wait cursor in the first statement. Then a `ServiceController` method is called depending on the pressed button. With the `WaitForStatus()` method, you are waiting to check that the service changes the status to the requested value, but you only wait 10 seconds maximum. After this time, the information in the `ListBox` is refreshed, and the same service as before is selected. The new status of this service is then displayed.

Because the application requires administrative privileges, as most services require that for starting and stopping, an application manifest with the `requestedExecutionLevel` set to `requireAdministrator` is added to the project:

```
<?xml version="1.0" encoding="utf-8"?>
<asmv1:assembly manifestVersion="1.0"
    xmlns="urn:schemas-microsoft-com:asm.v1"
    xmlns:asmv1="urn:schemas-microsoft-com:asm.v1"
    xmlns:asmv2="urn:schemas-microsoft-com:asm.v2"
    xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance">
  <assemblyIdentity version="1.0.0.0" name="MyApplication.app"/>
  <trustInfo xmlns="urn:schemas-microsoft-com:asm.v2">
    <security>
      <requestedPrivileges xmlns="urn:schemas-microsoft-com:asm.v3">
        <requestedExecutionLevel level="requireAdministrator" uiAccess="false" />
      </requestedPrivileges>
    </security>
  </trustInfo>
</asmv1:assembly>
```

code snippet ServiceControl/app.manifest

TROUBLESHOOTING AND EVENT LOGGING

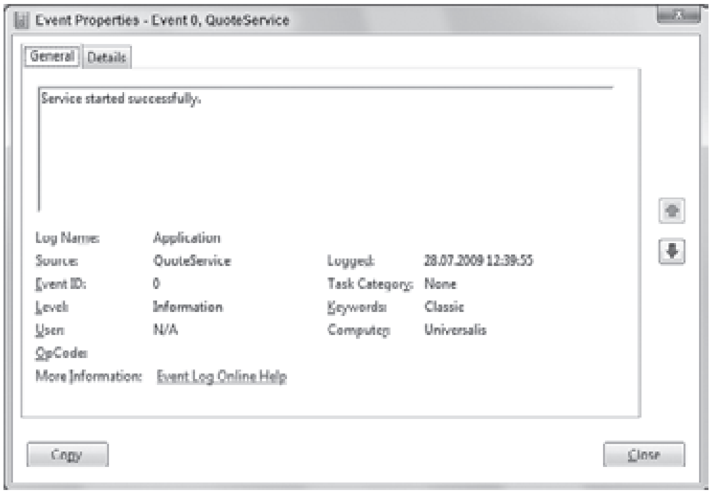
Troubleshooting services is different from troubleshooting normal applications. This section touches on some service issues, problems specific to interactive services, and event logging.

The best way to start building a service is to create an assembly with the functionality you want and a test client, before the service is actually created. Here, you can do normal debugging and error handling. As soon as the application is running, you can build a service by using this assembly. Of course, there might still be problems with the service:

- Don't display errors in a message box from the service (except for interactive services that are running on the client system). Instead, use the event logging service to write errors to the event log. Of course, in the client application that uses the service, you can display a message box to inform the user about errors.
- The service cannot be started from within a debugger, but a debugger can be attached to the running service process. Open the solution with the source code of the service and set breakpoints. From the Visual Studio Debug menu, select Processes and attach the running process of the service.
- The Performance Monitor can be used to monitor the activity of services. You can add your own performance objects to the service. This can add some useful information for debugging. For example, with the Quote service, you could set up an object to give the total number of quotes returned, the time it takes to initialize, and so on.

Services can report errors and other information by adding events to the event log. A service class derived from `ServiceBase` automatically logs events when the `AutoLog` property is set to `true`. The `ServiceBase` class checks this property and writes a log entry at start, stop, pause, and continue requests.

Figure 25-15 shows an example of a log entry from a service.



Service started successfully.

FIGURE 25-15

You can read more about event logging and how to write custom events in Chapter 19, "Instrumentation."

SUMMARY

In this chapter, you have seen the architecture of Windows Services and how you can create them with the .NET Framework. Applications can start automatically at boot time with Windows Services, and you can use a privileged system account as the user of the service. Windows Services are built from a main function, a service-main function, and a handler, and you've seen other relevant programs in regard to Windows Services, such as a service control program and a service installation program.

The .NET Framework has great support for Windows Services. All the plumbing code that is necessary for building, controlling, and installing services is built into the .NET Framework classes in the `System.ServiceProcess` namespace. By deriving a class from `ServiceBase`, you can override methods that are invoked when the service is paused, resumed, or stopped. For installation of services, the classes `ServiceProcessInstaller` and `ServiceInstaller` deal with all registry configurations needed for services. You can also control and monitor services by using `ServiceController`.

The next chapter gives you information about interop with native code. Behind the scenes, many .NET classes make use of native code. For example, the `ServiceBase` class wraps the Windows API `CreateService()`. With the next chapter, you learn how to use native methods and COM objects from your own classes.

26

Interop

WHAT'S IN THIS CHAPTER?

- COM and .NET technologies
- Using COM objects from within .NET applications
- Using .NET components from within COM clients
- Platform invoke for invoking native methods

If you have Windows programs written prior to .NET, you probably don't have the time and resources to rewrite everything for .NET. Sometimes rewriting code is useful for refactoring or rethinking the application architecture. A rewrite can also help with productivity in the long term, when adding new features is easier to do with the new technology. However, there is no reason to rewrite old code just because a new technology is available. You might have thousands of lines of existing, running code, which would require too much effort to rewrite just to move it into the managed environment.

The same applies to Microsoft. With the namespace `System.DirectoryServices`, Microsoft hasn't rewritten the COM objects accessing the hierarchical data store; the classes inside this namespace are wrappers accessing the ADSI COM objects instead. The same thing happens with `System.Data.OleDb`, where the OLE DB providers that are used by classes from this namespace do have quite complex COM interfaces.

The same issue may apply to your own solutions. If you have existing COM objects that should be used from .NET applications, or the other way around, if you want to write .NET components that should be used in old COM clients, this chapter is a starter for using COM interoperability (or *interop*).

If you don't have existing COM components you want to integrate with your application, or old COM clients that should use some .NET components, you can skip this chapter.

Like all other chapters, you can download the sample code for this chapter from the Wrox web site at `www.wrox.com`.

.NET AND COM

COM is the predecessor technology to .NET. COM defines a component model where components can be written in different programming languages. A component written with C++ can be used from a Visual Basic client. Components can also be used locally inside a process, across processes, or across the network. Does this sound familiar? Of course, .NET has similar goals. However, the way in which these goals are achieved is different. The COM concepts became more and more complex to use and turned out not to be extensible enough. .NET fulfills goals similar to those of COM but introduces new concepts to make your job easier.

Even today, when using COM interop the prerequisite is to know COM. It doesn't matter if .NET components are used by COM clients or if COM components are used by .NET applications — you must know COM. So, this section compares COM and .NET functionality.

If you already have a good grasp of COM technologies, this section may refresh your COM knowledge. Otherwise, it introduces you to the concepts of COM — that now, using .NET, you happily don't have to deal with anymore in your daily work. However, all the problems that came with COM still apply when COM technology is integrated into .NET applications.

COM and .NET do have many similar concepts, with very different approaches to using them, including:

- ➤ Metadata
- ➤ Freeing memory
- ➤ Interfaces
- ➤ Method binding
- ➤ Data types
- ➤ Registration
- ➤ Threading
- ➤ Error handling
- ➤ Event handling

These concepts, plus the marshaling mechanism, are covered in the following sections.

Metadata

With COM, all information about the component is stored inside the type library. The type library includes information such as names and IDs of interfaces, methods, and arguments. With .NET, all this information can be found inside the assembly itself, as you saw in Chapter 14, "Reflection," and Chapter 18, "Assemblies." The problem with COM is that the type library is not extensible. With C++, IDL (Interface Definition Language) files have been used to describe the interfaces and methods. Some of the IDL modifiers cannot be found inside the type library, because Visual Basic (and the Visual Basic team was responsible for the type library) couldn't use these IDL modifiers. With .NET, this problem doesn't exist because the .NET metadata is extensible using custom attributes.

As a result of this behavior, some COM components have a type library and others don't. When no type library is available, a C++ header file can be used that describes the interfaces and methods. With .NET, it is easier to use COM components that do have a type library, but it is also possible to use COM components without a type library. In that case, it is necessary to redefine the COM interface by using C# code.

Freeing Memory

With .NET, memory is released by the garbage collector. This is completely different with COM. COM relies on reference counts.

The interface `IUnknown`, which is the interface that is required to be implemented by every COM object, offers three methods. Two of these methods are related to reference counts. The method `AddRef()` must be called by the client if another interface pointer is needed; this method increments the reference count. The method `Release()` decrements the reference count, and if the resulting reference count is 0, the object destroys itself to free the memory.

Interfaces

Interfaces are the heart of COM. They distinguish between a contract used between the client and the object, and the implementation. The interface (the contract) defines the methods that are offered by the component and that can be used by the client. With .NET, interfaces play an important part, too.

COM distinguishes among three interface types: *custom*, *dispatch*, and *dual* interfaces.

Custom Interfaces

Custom interfaces derive from the interface `IUnknown`. A custom interface defines the order of the methods in a *virtual table* (*vtable*), so that the client can access the methods of the interface directly. This also means that the client needs to know the vtable during development time, because binding to the methods happens by using memory addresses. As a result, custom interfaces cannot be used by scripting clients. Figure 26-1 shows the vtable of the custom interface `IMath`, which provides the methods `Add()` and `Sub()` in addition to the methods of the `IUnknown` interface.

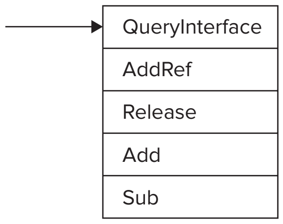

FIGURE 26-1

Dispatch Interfaces

Because a scripting client (and earlier Visual Basic clients) doesn't support custom interfaces, a different interface type is needed. With dispatch interfaces, the interface available for the client is always the `IDispatch` interface. `IDispatch` derives from `IUnknown` and offers four methods in addition to the `IUnknown` methods. The two most important methods are `GetIDsOfNames()` and `Invoke()`. As shown in Figure 26-2, with a dispatch interface two tables are needed. The first one maps the method or property name to a dispatch ID; the second one maps the dispatch ID to the implementation of the method or property.

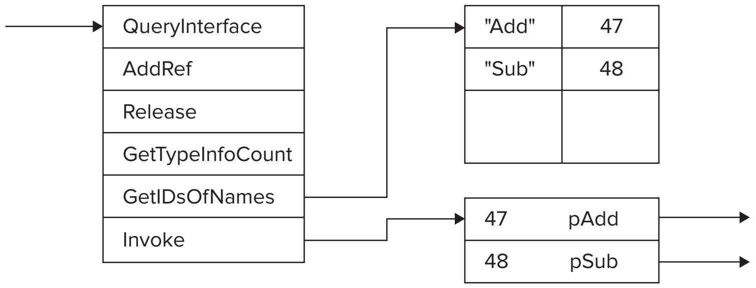

FIGURE 26-2

When the client invokes a method in the component, it first calls the method `GetIDsOfNames()`, passing the name of the method it wants to call. `GetIDsOfNames()` makes a lookup into the name-to-ID table to return the dispatch ID. This ID is used by the client to call the `Invoke()` method.

Dual Interfaces

As you can imagine, on one hand, dispatch interfaces are a lot slower than custom interfaces. On the other hand, custom interfaces cannot be used by scripting clients. A dual interface can solve this dilemma. As you can see in Figure 26-3, a dual interface is derived from `IDispatch` but provides the additional methods of the interface directly in the vtable. Scripting clients can use the `IDispatch` interface to invoke the Add and Sub methods, whereas clients aware of the vtable can call the Add and Sub methods directly.

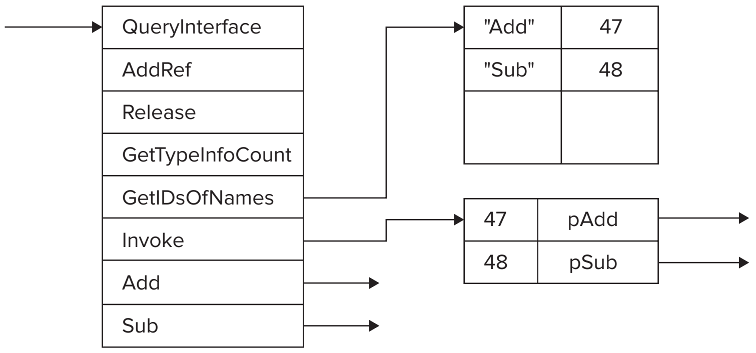

FIGURE 26-3

Casting and QueryInterface

If a .NET class implements multiple interfaces, casts can be done to get one interface or another. With COM, the interface `IUnknown` offers a similar mechanism with the method `QueryInterface()`. As discussed in the previous section, the interface `IUnknown` is the base interface of every interface, so `QueryInterface()` is available anyway.

Method Binding

How a client maps to a method is defined with the terms *early* and *late binding*. Late binding means that the method to invoke is looked for during runtime. .NET uses the `System.Reflection` namespace to make this possible (see Chapter 14).

COM uses the `IDispatch` interface discussed earlier for late binding. Late binding is possible with dispatch and dual interfaces.

With COM, early binding has two different options. One way of early binding, also known as vtable binding, is to use the vtable directly — this is possible with custom and dual interfaces. The second option for early binding is also known as ID binding. Here the dispatch ID is stored inside the client code, so during runtime only a call to `Invoke()` is necessary. `GetIdsOfNames()` is called during design time. With such clients, it is important to remember that the dispatch ID must not be changed.

Data Types

For dual and dispatch interfaces, the data types that can be used with COM are restricted to a list of automation-compatible data types. The `Invoke()` method of the `IDispatch` interface accepts an array of `VARIANT` data types. The `VARIANT` is a union of many different data types, such as `BYTE`, `SHORT`, `LONG`, `FLOAT`, `DOUBLE`, `BSTR`, `IUnknown*`, `IDispatch*`, and so on. `VARIANT`s have been easy to use from Visual Basic, but it was complex to use them from C++. .NET has the `Object` class instead of `VARIANT`s.

With custom interfaces, all data types available with C++ can be used with COM. However, this also restricts the clients that can use this component to certain programming languages.

Registration

.NET distinguishes between private and shared assemblies, as discussed in Chapter 18. With COM, all components are globally available through a registry configuration.

All COM objects have a unique identifier that consists of a 128-bit number and is also known as class ID (CLSID). The COM API call to create COM objects, `CoCreateInstance()`, just looks into the registry to find the CLSID and the path to the DLL or EXE to load the DLL or launch the EXE and instantiate the component.

Because such a 128-bit number cannot be easily remembered, many COM objects also have a ProgID. The ProgID is an easy-to-remember name, such as `Excel.Application`, that just maps to the CLSID.

In addition to the CLSID, COM objects also have a unique identifier for each interface (IID) and for the type library (typelib ID).

Information in the registry is discussed in more detail later in the chapter.

Threading

COM uses apartment models to relieve the programmer of having to deal with threading issues. However, this also adds some more complexity. Different apartment types have been added with different releases of the operating system. This section discusses the single-threaded apartment and the multithreaded apartment.

Single-Threaded Apartment

The *single-threaded apartment (STA)* was introduced with Windows NT 3.51. With an STA, only one thread (the thread that created the instance) is allowed to access the component. However, it is legal to have multiple STAs inside one process, as shown in Figure 26-4.

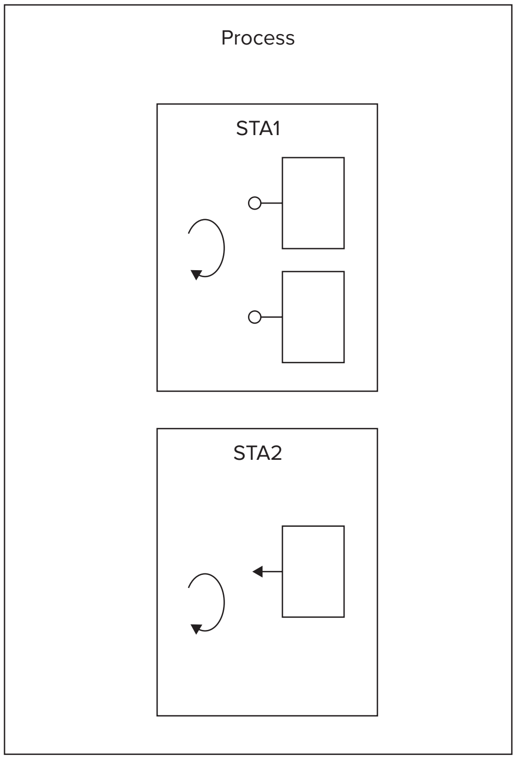

FIGURE 26-4

In this figure, the inner rectangles with the lollipop represent COM components. Components and threads (curved arrows) are surrounded by apartments. The outer rectangle represents a process.

With STAs, there's no need to protect instance variables from multiple-thread access, because this protection is provided by a COM facility, and only one thread accesses the component.

A COM object that is not programmed with thread safety marks the requirements for an STA in the registry with the registry key `ThreadingModel` set to `Apartment`.

Multithreaded Apartment

Windows NT 4.0 introduced the concept of a *multithreaded apartment* (*MTA*). With an MTA, multiple threads can access the component simultaneously. Figure 26-5 shows a process with one MTA and two STAs.

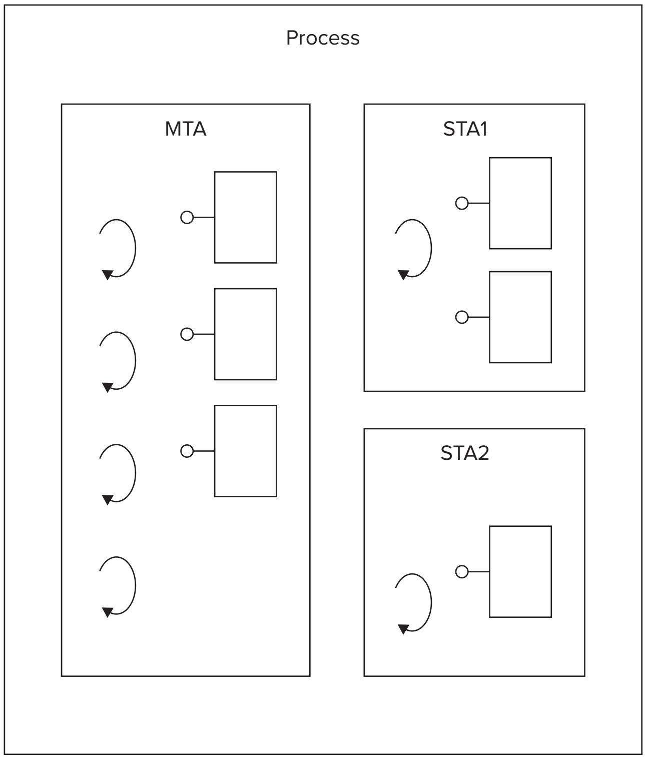

FIGURE 26-5

A COM object programmed with thread safety in mind marks the requirement for an MTA in the registry with the key `ThreadingModel` set to `Free`. The value `Both` is used for thread-safe COM objects that don't mind the apartment type.

Error Handling

With .NET, errors are generated by throwing exceptions. With the older COM technology, errors are defined by returning `HRESULT` values with the methods. An `HRESULT` value of `S_OK` means that the method was successful.

If a more detailed error message is offered by the COM component, the COM component implements the interface `ISupportErrorInfo`, where not only an error message but also a link to a help file and the source of the error are returned with an error information object on the return of the method. Objects that implement `ISupportErrorInfo` are automatically mapped to more detailed error information with an exception in .NET.

Events

.NET offers a callback mechanism with the C# keywords `event` and `delegate` (see Chapter 8, “Delegates, Lambdas, and Events”).

Figure 26-6 shows the COM event-handling architecture. With COM events, the component has to implement the interface `IConnectionPointContainer` and one or more connection point objects (CPOs) that implement the interface `IConnectionPoint`. The component also defines an outgoing interface — `ICompletedEvents` in Figure 26-6 — that is invoked by the CPO. The client must implement this outgoing interface in the sink object, which itself is a COM object. During runtime, the client queries the server for the interface `IConnectionPointContainer`. With the help of this interface, the client asks for a CPO with the method `FindConnectionPoint()` to get a pointer to `IConnectionPoint` returned. This interface pointer is used by the client to call the `Advise()` method, where a pointer to the sink object is passed to the server. In turn, the component can invoke methods inside the sink object of the client.

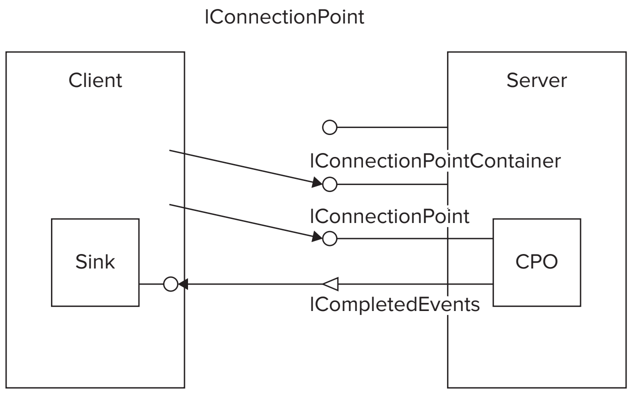

FIGURE 26-6

Later in this chapter, you learn how the .NET events and the COM events can be mapped so that COM events can be handled by a .NET client and vice versa.

Marshaling

Data passed from .NET to the COM component and the other way around must be converted to the corresponding representation. This mechanism is also known as *marshaling*. What happens here depends on the data type of the data that is passed: You have to differentiate between blittable and nonblittable data types.

Blittable data types have a common representation with both .NET and COM, and no conversion is needed. Simple data types such as `byte`, `short`, `int`, `long`, and classes and arrays that only contain these simple data types belong to the blittable data types. Arrays must be one-dimensional to be blittable.

A conversion is needed with *nonblittable* data types. The following table lists some of the nonblittable COM data types with their .NET-related data types. Nonblittable types have a higher overhead because of the conversion.

COM DATA TYPE	.NET DATA TYPE
`SAFEARRAY`	`Array`
`VARIANT`	`Object`
`BSTR`	`String`
`IUnknown*, IDispatch*`	`Object`

USING A COM COMPONENT FROM A .NET CLIENT

To see how a .NET application can use a COM component, you first have to create a COM component. Creating COM components is not possible with C# or Visual Basic 2010; you need either Visual Basic 6.0 or C++ (or any other language that supports COM). This chapter uses the Active Template Library (ATL) and C++ with Visual Studio 2010.

Here we will start creating a simple COM component and use this from a runtime callable wrapper (RCW). We will also use the component with the new C# 4 dynamic language extensions. Threading issues are discussed, and finally COM connection points are mapped to .NET events.

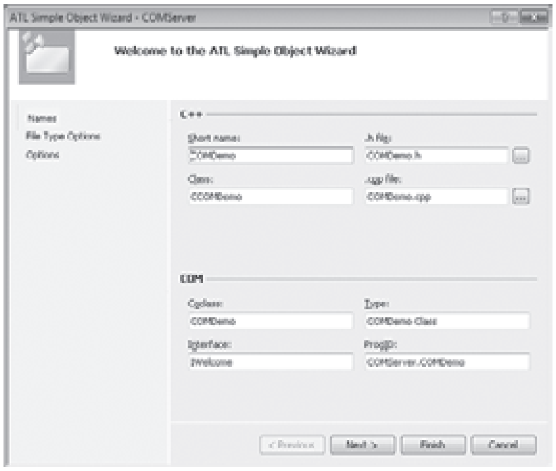
A short note about building COM components with Visual Basic 9.0 and C#: With Visual Basic 10.0 and C# it is possible to build .NET components that can be used as COM objects by using a wrapper that is the real COM component. It would make no sense for a .NET component that is wrapped from a COM component to be used by a .NET client with COM interop.

Because this is not a COM book, it does not discuss all aspects of the code but only what you need to build the sample.

Creating a COM Component

To create a COM component with ATL and C++, create a new ATL Project. You can find the ATL Project Wizard within the Visual C++ Projects group when you select File New Project. Set the name to COMServer. With the Application Settings, select Dynamic Link Library and click Finish.

The ATL Project Wizard just creates the foundation for the server. A COM object is still needed. Add a class in Solution Explorer and select ATL Simple Object. In the dialog that starts up, enter COMDemo in the Short name field. The other fields will be filled in automatically, but change the interface name to `IWelcome` and the ProgID to `COMServer.COMDemo` (see Figure 26-7). Click Finish to create the stub code for the class and the interface.



ATL Simple Object Wizard - COMServer

Welcome to the ATL Simple Object Wizard

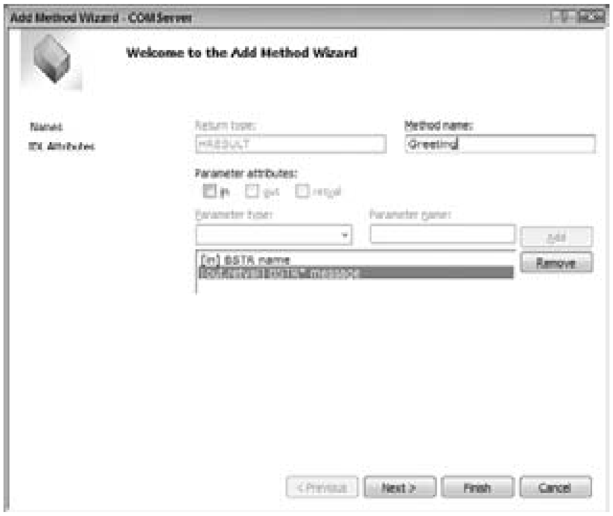
C++
Short name: COMDemo
.h file: COMDemo.h
Class: CCOMDemo
.cpp file: COMDemo.cpp

COM
Coclass: COMDemo
Type: COMDemo Class
Interface: IWelcome
ProgID: COMServer.COMDemo

FIGURE 26-7

The COM component offers two interfaces, so that you can see how `QueryInterface()` is mapped from .NET, and just three simple methods, so that you can see how the interaction takes place. In class view, select the interface `IWelcome` and add the method `Greeting()` (see Figure 26-8) with these parameters:

```
HRESULT Greeting([in] BSTR name, [out, retval] BSTR* message);
```



Return type: HRESULT

Method name: Greeting

[in] BSTR name
[out,retval] BSTR* message

FIGURE 26-8

The IDL file `COMServer.idl` defines the interface for COM. Your wizard-generated code from the file `COMServer.idl` should look similar to the following code. The unique identifiers (`uuid`s) will differ. The interface `IWelcome` defines the `Greeting()` method. The brackets before the keyword `interface` define some attributes for the interface. `uuid` defines the interface ID and `dual` marks the type of the interface:

```
[
    object,
    uuid(EB1E5898-4DAB-4184-92E2-BBD8F9341AFD),
    dual,
    nonextensible,
    pointer_default(unique)
]
interface IWelcome : IDispatch{
    [id(1)] HRESULT Greeting([in] BSTR name, [out,retval] BSTR* message);
};
```

code snippet COMServer/COMServer.idl

The IDL file also defines the content of the type library, which is the COM object (`coclass`) that implements the interface `IWelcome`:

```
[
    uuid(8C123EAE-F567-421F-ACBE-E11F89909160),
    version(1.0),
]
library COMServerLib
{
    importlib("stdole2.tlb");
    [
        uuid(ACB04E72-EB08-4D4A-91D3-34A5DB55D4B4)
    ]
    coclass COMDemo
    {
        [default] interface IWelcome;
    };
};
```

Add the custom attribute with the same identifier and the name `Wrox.ProCSharp.Interop.Server.IWelcome` to the header section of the `IWelcome` interface. Add the same attribute with a corresponding name to the coclass `COMDemo`:

```
    [
       object,
       uuid(EB1E5898-4DAB-4184-92E2-BBD8F9341AFD),
       dual,
       nonextensible,
       helpstring("IWelcome Interface"),
       pointer_default(unique),
       custom(0F21F359-AB84-41e8-9A78-36D110E6D2F9,
       "Wrox.ProCSharp.Interop.Server.IWelcome")
    ]
    interface IWelcome : IDispatch{
       [id(1)] HRESULT Greeting([in] BSTR name, [out,retval] BSTR* message);
    };
    [
       uuid(8C123EAE-F567-421F-ACBE-E11F89909160),
       version(1.0),
    ]
    library COMServerLib
    {
       importlib("stdole2.tlb");
       [
          uuid(ACB04E72-EB08-4D4A-91D3-34A5DB55D4B4),
          helpstring("COMDemo Class"),
          custom(0F21F359-AB84-41e8-9A78-36D110E6D2F9,
          "Wrox.ProCSharp.Interop.Server.COMDemo")
       ]
       coclass COMDemo
       {
          [default] interface IWelcome;
       };
    };
```

Now add a second interface to the file `COMServer.idl`. You can copy the header section of the `IWelcome` interface to the header section of the new `IMath` interface, but be sure to change the unique identifier that is defined with the `uuid` keyword. You can generate such an ID with the `guidgen` utility. The interface `IMath` offers the methods `Add()` and `Sub()`:

```
    // IMath
    [
       object,
       uuid(2158751B-896E-461d-9012-EF1680BE0628),
       dual,
       nonextensible,
       helpstring("IMath Interface"),
       pointer_default(unique),
       custom(0F21F359-AB84-41e8-9A78-36D110E6D2F9,
       "Wrox.ProCSharp.Interop.Server.IMath")
    ]
    interface IMath: IDispatch
    {
        [id(1)] HRESULT Add([in] LONG val1, [in] LONG val2,
                            [out, retval] LONG* result);
        [id(2)] HRESULT Sub([in] LONG val1, [in] LONG val2,
                            [out, retval] LONG* result);
    };
```

The coclass `COMDemo` must also be changed so that it implements both the interfaces `IWelcome` and `Math`. The `IWelcome` interface is the default interface:

```
        importlib("stdole2.tlb");
        [
            uuid(ACB04E72-EB08-4D4A-91D3-34A5DB55D4B4),
            helpstring("COMDemo Class"),
            custom(0F21F359-AB84-41e8-9A78-36D110E6D2F9,
            "Wrox.ProCSharp.Interop.Server.COMDemo")
        ]
        coclass COMDemo
        {
            [default] interface IWelcome;
            interface IMath;
        };
```

Now, you can set the focus away from the IDL file toward the C++ code. In the file `COMDemo.h`, you can find the class definition of the COM object. The class `CCOMDemo` uses multiple inheritances to derive from the template classes `CComObjectRootEx`, `CComCoClass`, and `IDisplatchImpl`. The `CComObjectRootEx` class offers an implementation of the `IUnknown` interface functionality such as implementation of the `AddRef()` and `Release()` methods. The `CComCoClass` class creates a factory that instantiates objects of the template argument, which here is `CComDemo`. `IDispatchImpl` offers an implementation of the methods from the `IDispatch` interface.

With the macros that are surrounded by `BEGIN_COM_MAP` and `END_COM_MAP`, a map is created to define all the COM interfaces that are implemented by the COM class. This map is used by the implementation of the `QueryInterface` method.

```
    class ATL_NO_VTABLE CCOMDemo:
       public CComObjectRootEx<CComSingleThreadModel>,
       public CComCoClass<CCOMDemo, &CLSID_COMDemo>,
       public IDispatchImpl<IWelcome, &IID_IWelcome, &LIBID_COMServerLib,
          /*wMajor =*/ 1, /*wMinor =*/ 0>
    {
    public:
       CCOMDemo()
       {
       }

    DECLARE_REGISTRY_RESOURCEID(IDR_COMDEMO)

    BEGIN_COM_MAP(CCOMDemo)
       COM_INTERFACE_ENTRY(IWelcome)
       COM_INTERFACE_ENTRY(IDispatch)
    END_COM_MAP()

       DECLARE_PROTECT_FINAL_CONSTRUCT()

       HRESULT FinalConstruct()
       {
          return S_OK;
       }

       void FinalRelease()
       {
   }

public:
   STDMETHOD(Greeting)(BSTR name, BSTR* message);
};

OBJECT_ENTRY_AUTO(__uuidof(COMDemo), CCOMDemo)
```

code snippet *COMServer/COMDemo.h*

With this class definition, you have to add the second interface, `IMath`, as well as the methods that are defined with the `IMath` interface:

```
class ATL_NO_VTABLE CCOMDemo:
   public CComObjectRootEx<CComSingleThreadModel>,
   public CComCoClass<CCOMDemo, &CLSID_COMDemo>,
   public IDispatchImpl<IWelcome, &IID_IWelcome, &LIBID_COMServerLib,
      /*wMajor =*/ 1, /*wMinor =*/ 0>
 public IDispatchImpl<IMath, &IID_IMath, &LIBID_COMServerLib, 1, 0>
{
public:
   CCOMDemo()
   {
   }

DECLARE_REGISTRY_RESOURCEID(IDR_COMDEMO)

BEGIN_COM_MAP(CCOMDemo)
   COM_INTERFACE_ENTRY(IWelcome)
   COM_INTERFACE_ENTRY(IMath)
   COM_INTERFACE_ENTRY2(IDispatch, IWelcome)
END_COM_MAP()

   DECLARE_PROTECT_FINAL_CONSTRUCT()

   HRESULT FinalConstruct()
   {
      return S_OK;
   }

   void FinalRelease()
   {
   }

public:
   STDMETHOD(Greeting)(BSTR name, BSTR* message);
   STDMETHOD(Add)(long val1, long val2, long* result);
   STDMETHOD(Sub)(long val1, long val2, long* result);
};

OBJECT_ENTRY_AUTO(__uuidof(COMDemo), CCOMDemo)
```

Now, you can implement the three methods in the file `COMDemo.cpp` with the following code. The `CComBSTR` is an ATL class that makes it easier to deal with `BSTR`s. In the `Greeting()` method, only a welcome message is returned, which adds the name passed in the first argument to the message that is returned. The `Add()` method just does a simple addition of two values, and the `Sub()` method does a subtraction and returns the result:

```
STDMETHODIMP CCOMDemo::Greeting(BSTR name, BSTR* message)
{
   CComBSTR tmp("Welcome, ");
   tmp.Append(name);
```

```
        *message = tmp;
        return S_OK;
    }

    STDMETHODIMP CCOMDemo::Add(LONG val1, LONG val2, LONG* result)
    {
        *result = val1 + val2;
        return S_OK;
    }

    STDMETHODIMP CCOMDemo::Sub(LONG val1, LONG val2, LONG* result)
    {
        *result = val1 - val2;
        return S_OK;
    }
```

code snippet COMServer/COMDemo.cpp

Now, you can build the component. The build process also configures the component in the registry.

Creating a Runtime Callable Wrapper

You can now use the COM component from within .NET. To make this possible, you must create a runtime callable wrapper (RCW). Using the RCW, the .NET client sees a .NET object instead of the COM component; there is no need to deal with the COM characteristics because this is done by the wrapper. An RCW hides the `IUnknown` and `IDispatch` interfaces (see Figure 26-9) and deals itself with the reference counts of the COM object.

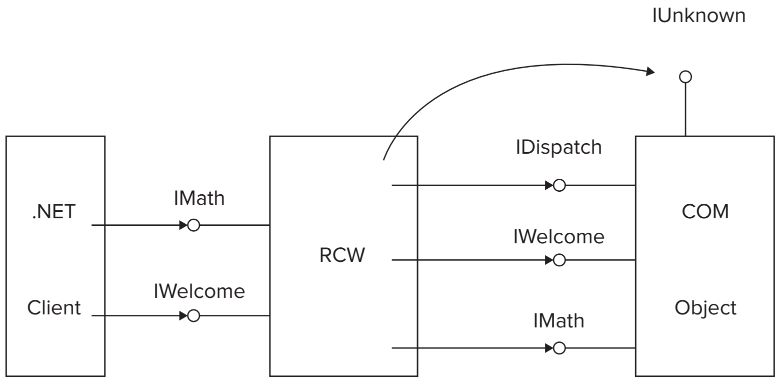


FIGURE 26-9

The RCW can be created by using the command-line utility `tlbimp` or by using Visual Studio. Starting the command

```
tlbimp COMServer.dll /out:Interop.COMServer.dll
```

creates the file `Interop.COMServer.dll`, which contains a .NET assembly with the wrapper class. In this generated assembly, you can find the namespace `COMWrapper` with the class `CCOMDemoClass` and the interfaces `CCOMDemo`, `IMath`, and `IWelcome`. The name of the namespace can be changed by using options of the `tlbimp` utility. The option `/namespace` allows you to specify a different namespace, and with `/asmversion` you can define the version number of the assembly.

Another important option of this command-line utility is `/keyfile`*, which is used for assigning a strong name to the generated assembly. Strong names are discussed in Chapter 18.*

An RCW can also be created by using Visual Studio. To create a simple sample application, create a C# console project. In Solution Explorer, add a reference to the COM server by selecting the COM tab in the Add Reference dialog, and scroll down to the entry `COMServer 1.0 Type Library`. Here are listed all COM objects that are configured in the registry. Selecting a COM component from the list creates an RCW class. With Visual Studio 2010, this wrapper class can be created in the main assembly of the project by setting the property `Embed Interop Types` to `true`, which is the default. Setting it to `false` creates a separate interop assembly that needs to be deployed with the application.

Using the RCW

After creating the wrapper class, you can write the code for the application to instantiate and access the component. Because of the custom attributes in the C++ file, the generated namespace of the RCW class is `Wrox.ProCSharp.COMInterop.Server`. Add this namespace, as well as the namespace `System.Runtime.InteropServices`, to the declarations. From the namespace `System.Runtime.InteropServices`, the `Marshal` class will be used to release the COM object:

```
using System;
using System.Runtime.InteropServices;
using Wrox.ProCSharp.Interop.Server

namespace Wrox.ProCSharp.Interop.Client
{
   class Program
   {
      [STAThread]
      static void Main()
      {
```

code snippet DotnetClient/Program.cs

Now, the COM component can be used similarly to a .NET class. `obj` is a variable of type `COMDemo`. `COMDemo` is a .NET interface that offers the methods of both the `IWelcome` and `IMath` interfaces. However, it is also possible to cast to a specific interface such as `IWelcome`. With a variable that is declared as type `IWelcome`, the method `Greeting()` can be called.

```
         var obj = new COMDemo();
         IWelcome welcome = obj;
         Console.WriteLine(welcome.Greeting("Stephanie"));
```

If the object — as in this case — offers multiple interfaces, a variable of the other interface can be declared, and by using a simple assignment with the cast operator, the wrapper class does a `QueryInterface()` with the COM object to return the second interface pointer. With the I `Math` variable, the methods of the `IMath` interface can be called.

```
         IMath math;
         math = (IMath)welcome;
         int x = math.Add(4, 5);
         Console.WriteLine(x);
```

If the COM object should be released before the garbage collector cleans up the object, the static method `Marshal.ReleaseComObject()` invokes the `Release()` method of the component, so that the component can destroy itself and free up memory:

```
         Marshal.ReleaseComObject(math);
      }
   }
}
```

Earlier you learned that the COM object is released as soon as the reference count is 0. `Marshal.ReleaseComObject()` *decrements the reference count by 1 by invoking the* `Release()` *method. Because the RCW does just one call to* `AddRef()` *to increment the reference count, a single call to* `Marshal.ReleaseComObject()` *is enough to release the object no matter how many references to the RCW you keep.*

After releasing the COM object using `Marshal.ReleaseComObject()`, you may not use any variable that references the object. In the example, the COM object is released by using the variable `math`. The variable `welcome`, which references the same object, cannot be used after releasing the object. Otherwise, you will get an exception of type `InvalidComObjectException`.

Releasing COM objects when they are no longer needed is extremely important. COM objects make use of the native memory heap, whereas .NET objects make use of the managed memory heap. The garbage collector only deals with managed memory.

As you can see, with a runtime callable wrapper, a COM component can be used similarly to a .NET object.

Using the COM Server with Dynamic Language Extensions

C# 4 includes an extension for using dynamic languages from C#. This is also an advantage for using COM servers that offer the `IDispatch` interface. As you read earlier in the “Dispatch Interfaces” section, this interface is resolved at runtime with the methods `GetIdsOfNames()` and `Invoke()`. With the `dynamic` keyword and the help of a COM binder that is used behind the scenes, the COM component can be called without creating an RCW object.

Declaring a variable of type `dynamic` and assigning a `COM` object to it uses the COM binder, and you can invoke the methods of the default interface as shown. Creating an instance of the `COM` object without using an RCW can be done by getting the `Type` object using `Type.GetTypeFromProgID()`, and instantiating the `COM` object with the `Activator.CreateInstance()` method. You just don’t get IntelliSense with the dynamic keyword, but can use the optional parameters that are very common with COM:

```
using System;

namespace Wrox.ProCSharp.Interop
{
    class Program
    {
        static void Main()
        {
            Type t = Type.GetTypeFromProgID("COMServer.COMDemo");
            dynamic o = Activator.CreateInstance(t);
            Console.WriteLine(o.Greeting("Angela"));
        }
    }
}
```

code snippet DynamicDotnetClient/Program.cs

The dynamic language extensions of C# are explained in Chapter 12, “Dynamic Language Extensions.”

Threading Issues

As discussed earlier in this chapter, a COM component marks the apartment (STA or MTA) it wants to live in, based on whether or not it is implemented as thread-safe. However, the thread has to join an apartment. What apartment the thread should join can be defined with the `[STAThread]` and `[MTAThread]` attributes, which can be applied to the `Main()` method of an application. The attribute `[STAThread]` means that the thread joins an STA, whereas the attribute `[MTAThread]` means that the thread joins an MTA. Joining an MTA is the default if no attribute is applied.

It is also possible to set the apartment state programmatically with the `ApartmentState` property of the `Thread` class. The `ApartmentState` property allows you to set a value from the `ApartmentState` enumeration. `ApartmentState` has the possible values `STA` and `MTA` (and `Unknown` if it wasn't set). Be aware that the apartment state of a thread can be set only once. If it is set a second time, the second setting is ignored.

Adding Connection Points

To see how COM events can be handled in a .NET application, the COM component must be extended. First, you have to add another interface to the interface definition file `COMDemo.idl`. The interface `_ICompletedEvents` is implemented by the client, which is the .NET application, and called by the component. In this example, the method `Completed()` is called by the component when the calculation is ready. Such an interface is also known as an outgoing interface. An outgoing interface must be either a dispatch or a custom interface. Dispatch interfaces are supported by all clients. The custom attribute with the `ID 0F21F359-AB84-41e8-9A78-36D110E6D2F9` defines the name of the interface that will be created in the RCW. The outgoing interface must also be written to the interfaces supported by the component inside the `coclass` section, and marked as a `source` interface:

```
library COMServerLib
{
   importlib("stdole2.tlb");

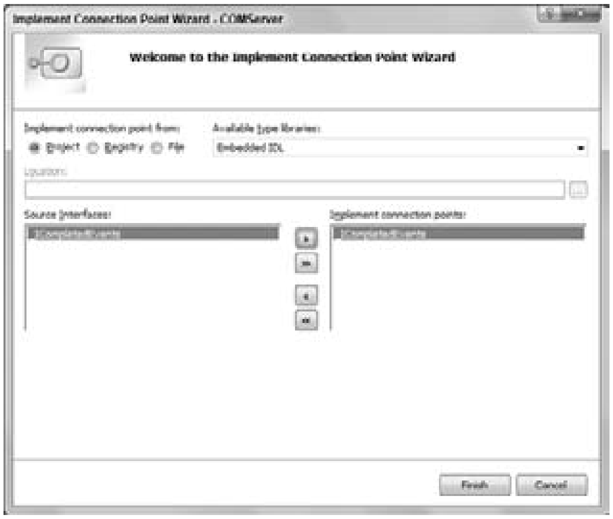
    [
       uuid(5CFF102B-0961-4EC6-8BB4-759A3AB6EF48),
       helpstring("_ICompletedEvents Interface"),
       custom(0F21F359-AB84-41e8-9A78-36D110E6D2F9,
         "Wrox.ProCSharp.COMInterop.Server.ICompletedEvents"),
    ]
    dispinterface _ICompletedEvents
    {
       properties:
       methods:
          [id(1)] void Completed(void);
    };

    [
      uuid(ACB04E72-EB08-4D4A-91D3-34A5DB55D4B4),
      helpstring("COMDemo Class")
      custom(0F21F359-AB84-41e8-9A78-36D110E6D2F9,
         "Wrox.ProCSharp.COMInterop.Server.COMDemo"),
    ]
```

```
coclass COMDemo
{
   [default] interface IWelcome;
   interface IMath;
   [default, source] dispinterface _ICompletedEvents;
};
```

code snippet COMServer/COMServer.idl

You can use a wizard to create an implementation that fires the event back to the client. Open the class view, select the class `CComDemo`, open the context menu, and select Add ➪ Add Connection Point . . . to start the Implement Connection Point Wizard (see Figure 26-10). Select the source interface `ICompletedEvents` for implementation with the connection point.



Implement Connection Point Wizard - COMServer

Welcome to the Implement Connection Point Wizard

Implement connection point from: [✓ Project] Registry File

Available type libraries: Embedded IDL

Location:

Source interfaces: [illegible]

Implement connection points: [illegible]

FIGURE 26-10

The wizard creates the proxy class `CProxy_ICompletedEvents` to fire the events to the client. Also, the class `CCOMDemo` is changed. The class now inherits from `IConnectionPointContainerImpl` and the proxy class. The interface `IConnectionPointContainer` is added to the interface map, and a connection point map is added to the source interface `_ICompletedEvents`.

```
class ATL_NO_VTABLE CCOMDemo:
   public CComObjectRootEx<CComSingleThreadModel>,
   public CComCoClass<CCOMDemo, &CLSID_COMDemo>,
   public IDispatchImpl<IWelcome, &IID_IWelcome, &LIBID_COMServerLib,
      /*wMajor =*/ 1, /*wMinor =*/ 0>,
   public IDispatchImpl<IMath, &IID_IMath, &LIBID_COMServerLib, 1, 0>,
   public IConnectionPointContainerImpl<CCOMDemo>,
   public CProxy_ICompletedEvents<CCOMDemo>
{
public:

//.

BEGIN_COM_MAP(CCOMDemo)
   COM_INTERFACE_ENTRY(IWelcome)
   COM_INTERFACE_ENTRY(IMath)
   COM_INTERFACE_ENTRY2(IDispatch, IWelcome)
   COM_INTERFACE_ENTRY(IConnectionPointContainer)
END_COM_MAP()
//.

public:
   BEGIN_CONNECTION_POINT_MAP(CCOMDemo)
      CONNECTION_POINT_ENTRY(__uuidof(_ICompletedEvents))
   END_CONNECTION_POINT_MAP()
};
```

code snippet COMServer/COMDemo.h

Finally, the method `Fire_Completed()` from the proxy class can be called inside the methods `Add()` and `Sub()` in the file `COMDemo.cpp`:

```
STDMETHODIMP CCOMDemo::Add(LONG val1, LONG val2, LONG* result)
{
   *result = val1 + val2;
   Fire_Completed();
   return S_OK;
}

STDMETHODIMP CCOMDemo::Sub(LONG val1, LONG val2, LONG* result)
{
   *result = val1 - val2;
   Fire_Completed();
   return S_OK;
}
```

code snippet COMServer/COMDemo.cpp

After rebuilding the COM DLL, you can change the .NET client to use these COM events just like a normal .NET event:

```
      static void Main()
      {
         COMDemo obj = new COMDemo();

         IWelcome welcome = obj;
         Console.WriteLine(welcome.Greeting("Stephanie"));

         obj.Completed += () => Console.WriteLine("Calculation completed");

         IMath math = (IMath)welcome;
         int result = math.Add(3, 5);
         Console.WriteLine(result);

         Marshal.ReleaseComObject(math);
   }
```

code snippet DotnetClient/Program.cs

As you can see, the RCW offers automatic mapping from COM events to .NET events. COM events can be used similarly to .NET events in a .NET client.

USING A .NET COMPONENT FROM A COM CLIENT

So far, you have seen how to access a COM component from a .NET client. Equally interesting is to find a solution for accessing .NET components on an old COM client that is using Visual Basic 6.0, or C++ with MFC (Microsoft Foundation Classes), or ATL.

In this section, a COM object is defined with .NET code that is used by a COM client with the help of a COM callable wrapper (CCW). By using the object from a COM client, you will see how to create a type library from the .NET assembly, use different .NET attributes to specify COM interop behaviors, and register the .NET assembly as a COM component. Then, a COM client with C++ is created to use the CCW. Finally, the .NET component is expanded to offer COM connection points.

COM Callable Wrapper

If you want to access a COM component with a .NET client, you have to work with an RCW. To access a .NET component from a COM client application, you must use a CCW. Figure 26-11 shows the CCW that wraps a .NET class, and offers COM interfaces that a COM client expects to use. The CCW offers interfaces such as `IUnknown`, `IDispatch`, and others. It also offers interfaces such as `IConnectionPointContainer` and `IConnectionPoint` for events. Of course, the CCW also offers the custom interfaces that are defined by the .NET class such as `IWelcome` and `IMath`. A COM client gets what it expects from a COM object — although a .NET component operates behind the scenes. The wrapper deals with methods such as `AddRef()`, `Release()`, and `QueryInterface()` from the `IUnknown` interface, whereas in the .NET object you can count on the garbage collector without the need to deal with reference counts.

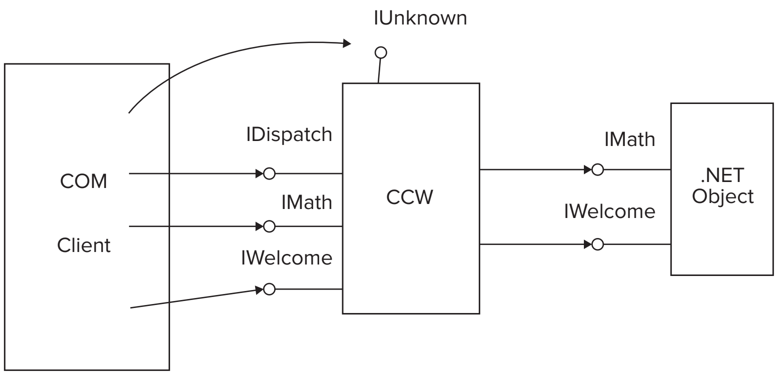


FIGURE 26-11

Creating a .NET Component

In the following example, you build the same functionality into a .NET class that you have previously built into a COM component. Start by creating a C# class library, and name it `DotNetServer`. Then add the interfaces `IWelcome` and `IMath`, and the class `DotNetComponent` that implements these interfaces. The attribute `ComVisible(true)` makes the class and interfaces available for COM:

```
using System;
using System.Runtime.InteropServices;

namespace Wrox.ProCSharp.Interop.Server
{
   [ComVisible(true)]
   public interface IWelcome
   {
      string Greeting(string name);
   }

   [ComVisible(true)]
   public interface IMath
   {
      int Add(int val1, int val2);
      int Sub(int val1, int val2);
```

```
    }

    [ComVisible(true)]
    public class DotnetComponent: IWelcome, IMath
    {
       public DotnetComponent()
       {
       }

       public string Greeting(string name)
       {
          return "Hello " + name;
       }

       public int Add(int val1, int val2)
       {
          return val1 + val2;
       }

       public int Sub(int val1, int val2)
       {
          return val1 - val2;
       }
    }
}
```

code snippet DotnetServer/DotnetServer.cs

After building the project, you can create a type library.

Creating a Type Library

A type library can be created by using the command-line utility `tlbexp`. The command

```
tlbexp DotnetServer.dll
```

creates the type library `DotnetServer.tlb`. You can view the type library with the utility *OLE/COM Object Viewer* `oleview32.exe`. This tool is part of the Microsoft SDK, and you can start it from the Visual Studio 2010 Command Prompt. Select File ➪ View TypeLib to open the type library. Now you can see the interface definition that is very similar to the interfaces created with the COM server earlier.

The name of the type library is created from the name of the assembly. The header of the type library also defines the full name of the assembly in a custom attribute, and all the interfaces are forward-declared before they are defined.

```
// Generated .IDL file (by the OLE/COM Object Viewer)
//
// typelib filename: DotnetServer.tlb

[
  uuid(14F7A17A-B97D-41DA-B3E1-B6025F188FAD),
  version(1.0),
  custom(90883F05-3D28-11D2-8F17-00A0C9A6186D, "DotnetServer, Version=1.0.0.0,
         Culture=neutral, PublicKeyToken=null")
]
library DotnetServer
{
    // TLib :     // TLib : mscorlib.dll : {BED7F4EA-1A96-11D2-8F08-00A0C9A6186D}
    importlib("mscorlib.tlb");
    // TLib : OLE Automation : {00020430-0000-0000-c260-000000000046}
    importlib("stdole2.tlb");

    // Forward declare all types defined in this typelib
    interface IWelcome;
    interface IMath;
    interface _DotnetComponent;
```

In the following generated code, you can see that the interfaces `IWelcome` and `IMath` are defined as COM dual interfaces. You can see all methods that have been declared in the C# code are listed here in the type library definition. The parameters changed; the .NET types are mapped to COM types (for example, from the `String` class to the `BSTR` type), and the signature is changed, so that a `HRESULT` is returned. Because the interfaces are dual, dispatch IDs are also generated:

```
   [
     odl,
     uuid(6AE7CB9C-7471-3B6A-9E13-51C2294266F0),
     version(1.0),
     dual,
     oleautomation,
     custom(0F21F359-AB84-41E8-9A78-36D110E6D2F9,
            "Wrox.ProCSharp.Interop.Server.IWelcome")
    ]
    interface IWelcome : IDispatch {
        [id(0x60020000)]
        HRESULT Greeting(
                        [in] BSTR name,
                        [out, retval] BSTR* pRetVal);
    };

    [
     odl,
     uuid(AED00E6F-3A60-3EB8-B974-1556096350CB),
     version(1.0),
     dual,
     oleautomation,
     custom(0F21F359-AB84-41E8-9A78-36D110E6D2F9,
            "Wrox.ProCSharp.Interop.Server.IMath")

    ]
    interface IMath : IDispatch {
        [id(0x60020000)]
        HRESULT Add(
                        [in] long val1,
                        [in] long val2,
                        [out, retval] long* pRetVal);
        [id(0x60020001)]
        HRESULT Sub(
                        [in] long val1,
                        [in] long val2,
                        [out, retval] long* pRetVal);
    };
```

The `coclass` section marks the COM object itself. The `uuid` in the header is the CLSID used to instantiate the object. The class `DotnetComponent` supports the interfaces `_DotnetComponent`, `_Object`, `IWelcome`, and `IMath`. `_Object` is defined in the file `mscorlib.tlb` included in an earlier code section and offers the methods of the base class `Object`. The default interface of the component is `_DotnetComponent`, which is defined after the `coclass` section as a dispatch interface. In the interface declaration, it is marked as dual, but because no methods are included, it is a dispatch interface. With this interface, it is possible to access all methods of the component using late binding:

```
    [
     uuid(2F1E78D4-1147-33AC-9233-C0F51121DAAA),
     version(1.0),
     custom(0F21F359-AB84-41E8-9A78-36D110E6D2F9,
            "Wrox.ProCSharp.Interop.Server.DotnetComponent")
```

```
        ]
        coclass DotnetComponent {
            [default] interface _DotnetComponent;
            interface _Object;
            interface IWelcome;
            interface IMath;
        };

        [
          odl,
          uuid(2B36C1BF-61F7-3E84-87B2-EAB52144046D),
          hidden,
          dual,
          oleautomation,
          custom(0F21F359-AB84-41E8-9A78-36D110E6D2F9,
                 "Wrox.ProCSharp.Interop.Server.DotnetComponent")

        ]
        interface _DotnetComponent : IDispatch {
        };
    };
```

There are quite a few defaults for generating the type library. However, often it is advantageous to change some of the default .NET to COM mappings. This can be done with several attributes in the `System.Runtime.InteropServices` namespaces.

COM Interop Attributes

Applying attributes from the namespace `System.Runtime.InteropServices` to classes, interfaces, or methods allows you to change the implementation of the CCW. The following table lists these attributes and their descriptions.

ATTRIBUTE	DESCRIPTION
`Guid`	This attribute can be assigned to the assembly, interfaces, and classes. Using the `Guid` as an assembly attribute defines the type-library ID, applying it to interfaces defines the interface ID (IID), and setting the attribute to a class defines the class ID (CLSID). The unique IDs that must be defined with this attribute can be created with the utility `guidgen`. The CLSID and type-library IDs are changed automatically with every build. If you don't want to change them with every build, you can fix this by using this attribute. The IID is changed only if the signature of the interface changes; for example, if a method is added or removed, or some parameters are changed. Because with COM the IID should change with every new version of this interface, this is a very good default behavior, and usually there's no need to apply the IID with the `Guid` attribute. The only time you want to apply a fixed IID for an interface is when the .NET interface is an exact representation of an existing COM interface, and the COM client already expects this identifier.
`ProgId`	This attribute can be applied to a class to specify what name should be used when the object is configured in the registry.
`ComVisible`	With the Assembly Information settings of the Project properties you can configure if all the types of the assembly should be visible by COM. By default this setting is false which is a good default that makes it necessary to explicitly mark the classes, interfaces, and delegates with the `ComVisible` attribute to create a COM representation. In case the default setting is changed to make all types visible by COM, you can set that `ComVisible` attribute to `false` for the types where a COM representation should not be created.

ATTRIBUTE	DESCRIPTION
`InterfaceType`	This attribute, if set to a `ComInterfaceType enumeration value`, enables you to modify the default dual interface type that is created for .NET interfaces. `ComInterfaceType` has the values `InterfaceIsDual`, `InterfaceIsIDispatch`, and `InterfaceIsIUnknown`. If you want to apply a custom interface type to a .NET interface, set the attribute like this: `InterfaceType(ComInterfaceType .InterfaceIsIUnknown)`.
`ClassInterface`	This attribute enables you to modify the default dispatch interface that is created for a class. `ClassInterface` accepts an argument of a `ClassInterfaceType` enumeration. The possible values are `AutoDispatch`, `AutoDual`, and `None`. In the previous example, you have seen that the default is `AutoDispatch`, because a dispatch interface is created. If the class should only be accessible by the defined interfaces, apply the attribute `ClassInterface(ClassInterfaceType.None)` to the class.
`DispId`	This attribute can be used with dual and dispatch interfaces to define the `DispId` of methods and properties.
`In Out`	COM allows the specification of attributes for parameter types if the parameter should be sent to the component `In`, from the component to the client `Out`, or in both directions `In, Out`.
`Optional`	Parameters of COM methods may be optional. Parameters that should be optional can be marked with the `Optional` attribute.

Now, you can change the C# code to specify a dual interface type for the `IWelcome` interface and a custom interface type for the `IMath` interface. With the class `DotnetComponent`, the attribute `ClassInterface` with the argument `ClassInterfaceType.None` specifies that no separate COM interface will be generated. The attributes `ProgId` and `Guid` specify a ProgID and a GUID:

```
[InterfaceType(ComInterfaceType.InterfaceIsDual)]
[ComVisible(true)]
public interface IWelcome
{
   [DispId(60040)]
   string Greeting(string name);
}

[InterfaceType(ComInterfaceType.InterfaceIsIUnknown)]
[ComVisible(true)]
public interface IMath
{
 int Add(int val1, int val2);
 int Sub(int val1, int val2);
}

[ClassInterface(ClassInterfaceType.None)]
[ProgId("Wrox.DotnetComponent")]
[Guid("77839717-40DD-4876-8297-35B98A8402C7")]
[ComVisible(true)]
public class DotnetComponent: IWelcome, IMath
{
  public DotnetComponent()
  {
  }
```

code snippet DotnetServer/DotnetServer.cs

Rebuilding the class library and the type library changes the interface definition. You can verify this with `OleView.exe`. `IWelcome` is now a dual interface, `IMath` a custom interface that derives from `IUnknown` instead of `IDispatch`, and the `coclass` section no longer has a `_DotnetComponent` interface.

COM Registration

Before the .NET component can be used as a COM object, it is necessary to configure it in the registry. Also, if you don't want to copy the assembly into the same directory as the client application, it is necessary to install the assembly in the global assembly cache. The global assembly cache itself is discussed in Chapter 18.

To install the assembly in the global assembly cache, you must sign it with a strong name (using Visual Studio 2010, you can define a strong name in properties of the solution). Then you can register the assembly in the global assembly cache:

```
gacutil -i DotnetServer.dll
```

Now, you can use the `regasm` utility to configure the component inside the registry. The option `/tlb` extracts the type library and also configures the type library in the registry:

```
regasm DotnetServer.dll /tlb
```

The information for the .NET component that is written to the registry is as follows. The `All COM` configuration is in the hive `HKEY_CLASSES_ROOT (HKCR)`. The key of the ProgID (in this example, it is `Wrox.DotnetComponent`) is written directly to this hive, along with the CLSID.

The key `HKCR\CLSID\{CLSID}\InProcServer32` has the following entries:

- `mscoree.dll` — `mscoree.dll` represents the CCW. This is a real COM object that is responsible for hosting the .NET component. This COM object accesses the .NET component to offer COM behavior for the client. The file `mscoree.dll` is loaded and instantiated from the client via the normal COM instantiation mechanism.
- `ThreadingModel=Both` — This is an attribute of the `mscoree.dll` COM object. This component is programmed in a way that offers support both for STA and MTA.
- `Assembly=DotnetServer, Version=1.0.0.0, Culture=neutral, PublicKeyToken=5cd57c93b4d9c41a` — The value of the `Assembly` stores the assembly full name, including the version number and the public key token, so that the assembly can be uniquely identified. The assembly registered here will be loaded by `mscoree.dll`.
- `Class=Wrox.ProCSharp.Interop.Server.DotnetComponent` — The name of the class will also be used by `mscoree.dll`. This is the class that will be instantiated.
- `RuntimeVersion=v4.0.20826` — The registry entry `RuntimeVersion` specifies the version of the .NET runtime that will be used to host the .NET assembly.

In addition to the configurations shown here, all the interfaces and the type library are configured with their identifiers, too.

Creating a COM Client Application

Now, it's time to create a COM client. Start by creating a simple C++ Win32 Console application project, and name it `COMClient`. You can leave the default options selected and click Finish in the Project Wizard.

At the beginning of the file `COMClient.cpp`, add a preprocessor command to include the `<iostream>` header file and to import the type library that you created for the .NET component. The import statement creates a "smart pointer" class that makes it easier to deal with COM objects. During a build process, the import statement creates `.tlh` and `.tli` files that you can find in the debug directory of your project, which includes the smart pointer class. Then add `using namespace` directives to open the namespace `std` that will be used for writing output messages to the console, and the namespace `DotnetComponent` that is created inside the smart pointer class:

```
// COMClient.cpp: Defines the entry point for the console application.
//

#include "stdafx.h"
#include <iostream>
```

```
#import "./DotNetComponent/bin/debug/DotnetServer.tlb" named_guids

using namespace std;
using namespace DotnetComponent;
```

code snippet COMClient/COMClient.cpp

In the `_tmain()` method, the first thing to do before any other COM call is the initialization of COM with the API call `CoInitialize()`. `CoInitialize()` creates and enters an STA for the thread. The variable `spWelcome` is of type `IWelcomePtr`, which is a smart pointer. The smart pointer method `CreateInstance()` accepts the ProgID as an argument to create the COM object by using the COM API `CoCreateInstance()`. The operator `->` is overridden with the smart pointer, so that you can invoke the methods of the COM object such as `Greeting()`:

```
int _tmain(int argc, _TCHAR* argv[])
{
  HRESULT hr;
  hr = CoInitialize(NULL);

  try
  {
    IWelcomePtr spWelcome;

    // CoCreateInstance()
    hr = spWelcome.CreateInstance("Wrox.DotnetComponent");

    cout << spWelcome->Greeting("Bill") << endl;
```

The second interface supported by your .NET component is `IMath`, and there is also a smart pointer that wraps the COM interface: `IMathPtr`. You can directly assign one smart pointer to another as in `spMath = spWelcome;`. In the implementation of the smart pointer (the = operator is overridden), the `QueryInterface()` method is called. With a reference to the `IMath` interface, you can call the `Add()` method.

```
    IMathPtr spMath;
    spMath = spWelcome;   // QueryInterface()

    long result = spMath->Add(4, 5);
    cout << "result:" << result << endl;
  }
```

If an `HRESULT` error value is returned by the COM object (this is done by the CCW that returns `HRESULT` errors if the .NET component generates exceptions), the smart pointer wraps the `HRESULT` errors and generates `_com_error` exceptions instead. Errors are handled in the `catch` block. At the end of the program, the COM DLLs are closed and unloaded using `CoUninitialize()`:

```
  catch (_com_error& e)
  {
    cout << e.ErrorMessage() << endl;
  }

  CoUninitialize();
  return 0;
}
```

Now you can run the application, and you will get outputs from the `Greeting()` and the `Add()` methods to the console. You can also try to debug into the smart pointer class, where you can see the COM API calls directly.

If you get an exception stating that the component cannot be found, check if the same version of the assembly that is configured in the registry is installed in the global assembly cache.

Adding Connection Points

Adding support for COM events to the .NET components requires some changes to the implementation of your .NET class. Offering COM events is not a simple matter of using the `event` and `delegate` keywords; it is necessary to add some more COM interop attributes.

First, you have to add an interface to the .NET project: `IMathEvents`. This interface is the source or outgoing interface for the component, and will be implemented by the `sink` object in the client. A source interface must be either a dispatch or a custom interface. A scripting client supports only dispatch interfaces. Dispatch interfaces are usually preferred as source interfaces:

```
[InterfaceType(ComInterfaceType.InterfaceIsIDispatch)]
[ComVisible(true)]
public interface IMathEvents
{
   [DispId(46200)]
   void CalculationCompleted();
}
```

code snippet DotnetServer/DotnetServer.cs

With the class `DotnetComponent`, a source interface must be specified. This can be done with the attribute `[ComSourceInterfaces]`. Add the attribute `[ComSourceInterfaces]`, and specify the outgoing interface declared earlier. You can add more than one source interface with different constructors of the attribute class; however, the only client language that supports more than one source interface is C++. Visual Basic 6.0 clients support only one source interface.

```
[ClassInterface(ClassInterfaceType.None)]
[ProgId("Wrox.DotnetComponent")]
[Guid("77839717-40DD-4876-8297-35B98A8402C7")]
[ComSourceInterfaces(typeof(IMathEvents))]
[ComVisible(true)]
public class DotnetComponent : IWelcome, IMath
{
    public DotnetComponent()
    {
    }
```

Inside the class `DotnetComponent`, you have to declare an event for every method of the source interface. The type of the method must be the name of the delegate, and the name of the event must be exactly the same as the name of the method inside the source interface. You can add the event calls to the `Add()` and `Sub()` methods. This step is the normal .NET way to invoke events, as discussed in Chapter 8.

```
    public event Action CalculationCompleted;

    public int Add(int val1, int val2)
    {
       int result = val1 + val2;
       if (CalculationCompleted != null)
          CalculationCompleted();
       return result;
    }

    public int Sub(int val1, int val2)
    {
       int result = val1 - val2;
       if (CalculationCompleted != null)
          CalculationCompleted();
       return result;
    }
}
```

The name of the event must be the same as the name of the method inside the source interface. Otherwise, the events cannot be mapped for COM clients.

Creating a Client with a Sink Object

After you've built and registered the .NET assembly and installed it into the global assembly cache, you can build a client application by using the event sources. Implementing a callback or sink object that implements the `IDispatch` interface was — using Visual Basic 6.0 — just a matter of adding the `With Events` keyword, very similar to how Visual Basic deals with .NET events today. It's more work with C++, but here the Active Template Library helps.

Open the C++ Console application created in the section "Creating a COM Client Application" and add the following includes to the file `stdafx.h`:

```
#include <atlbase.h>
extern CComModule _Module;
#include <atlcom.h>
```

***code snippet** COMClient/stdafx.h*

The file `stdafx.cpp` requires an include of the ATL implementation file `atlimpl.cpp`:

```
#include <atlimpl.cpp>
```

***code snippet** COMClient/stdafx.cpp*

Add the new class `CEventHandler` to the file `COMClient.cpp`. This class contains the implementation of the `IDispatch` interface to be called by the component. The implementation of the `IDispatch` interface is done by the base class `IDispEventImpl`. This class reads the type library to match the dispatch IDs of the methods and the parameters to the methods of the class. The template parameters of the class `IDispatchEventImpl` requires an ID of the sink object (here the ID 4 is used), the class that implements the callback methods (`CEventHandler`), the interface ID of the callback interface (`DIID_IMathEvents`), the ID of the type library (`LIBID_DotnetComponent`), and the version number of the type library. You can find the named IDs `DIID_IMathEvents` and `LIBID_DotnetComponent` in the file `dotnetcomponent.tlh` that was created from the `#import` statement.

The sink map that is surrounded by `BEGIN_SINK_MAP` and `END_SINK_MAP` defines the methods that are implemented by the sink object. `SINK_ENTRY_EX` maps the method `OnCalcCompleted` to the dispatch ID 46200. This dispatch ID was defined with the method `CalculationCompleted` of the `IMathEvents` interface in the .NET component.

```
class CEventHandler: public IDispEventImpl<4, CEventHandler,
      &DIID_IMathEvents, &LIBID_DotnetComponent, 1, 0>
{
public:
   BEGIN_SINK_MAP(CEventHandler)
      SINK_ENTRY_EX(4, DIID_IMathEvents, 46200, OnCalcCompleted)
   END_SINK_MAP()

   HRESULT __stdcall OnCalcCompleted()
   {
      cout << "calculation completed" << endl;
      return S_OK;
   }
};
```

***code snippet** COMClient/COMClient.cpp*

The main method now needs a change to advise the component of the existence of the event sink object, so that the component can call back into the sink. This can be done with the method `DispEventAdvise()` of the `CEventHandler` class by passing an `IUnknown` interface pointer. The method `DispEventUnadvise()` unregisters the sink object again.

```
int _tmain(int argc, _TCHAR* argv[])
{
   HRESULT hr;
   hr = CoInitialize(NULL);

   try
   {
      IWelcomePtr spWelcome;
      hr = spWelcome.CreateInstance("Wrox.DotnetComponent");

      IUnknownPtr spUnknown = spWelcome;

      cout << spWelcome->Greeting("Bill") << endl;

      CEventHandler* eventHandler = new CEventHandler();
      hr = eventHandler->DispEventAdvise(spUnknown);

      IMathPtr spMath;
      spMath = spWelcome;   // QueryInterface()

      long result = spMath->Add(4, 5);
      cout << "result:" << result << endl;

      eventHandler->DispEventUnadvise(spWelcome.GetInterfacePtr());
      delete eventHandler;
   }
   catch (_com_error& e)
   {
      cout << e.ErrorMessage() << endl;
   }

   CoUninitialize();
   return 0;
}
```

PLATFORM INVOKE

Not all the features of Windows API calls are available from the .NET Framework. This is not only true for old Windows API calls but also for very new features from Windows 7 or Windows Server 2008 R2. Maybe you've written some DLLs that export unmanaged methods, and you would like to use them from C# as well.

To reuse an unmanaged library that doesn't contain COM objects, just exported functions, platform invoke (p/invoke) can be used. With p/invoke, the CLR loads the DLL that includes the function that should be called and marshals the parameters.

To use the unmanaged function, first you have to find out the name of the function as it is exported. You can do this by using the `dumpbin` tool with the `/exports` option.

For example, the command

```
dumpbin /exports c:\windows\system32\kernel32.dll | more
```

lists all exported functions from the DLL `kernel32.dll`. In the example, you use the `CreateHardLink()` Windows API function to create a hard link to an existing file. With this API call, you can have several filenames that reference the same file as long as the filenames are on just one hard disk. This API call is not available from .NET Framework 4, so platform invoke must be used.

To call a native function, you have to define a C# external method with the same number of arguments, and the argument types that are defined with the unmanaged method must have mapped types with managed code.

The Windows API call `CreateHardLink()` has this definition in C++:

```
BOOL CreateHardLink(
   LPCTSTR lpFileName,
   LPCTSTR lpExistingFileName,
   LPSECURITY_ATTRIBUTES lpSecurityAttributes);
```

Now, this definition must be mapped to .NET data types. The return type is a `BOOL` with unmanaged code; this simply maps to the `bool` data type. `LPCTSTR` defines a `long` pointer to a `const` string. The Windows API uses the Hungarian naming convention for the data type. `LP` is a `long` pointer, `C` a const, and `STR` is a null-terminated string. The `T` marks the type as a generic type, and the type is either resolved to `LPCSTR` (an ANSI string) or `LPWSTR` (a wide Unicode string), depending on the compiler's settings. C strings map to the .NET type `String`. `LPSECURITY_ATTRIBUTES`, which is a long pointer to a struct of type `SECURITY_ATTRIBUTES`. Because you can pass `NULL` to this argument, mapping this type to `IntPtr` is okay. The C# declaration of this method must be marked with the `extern` modifier, because there's no implementation of this method within the C# code. Instead, the implementation of this method is found in the DLL `kernel32.dll`, which is referenced with the attribute `[DllImport]`. Because the return type of the .NET declaration `CreateHardLink()` is of type `bool`, and the native method `CreateHardLink()` returns a `BOOL`, some additional clarification is useful. Because there are different Boolean data types with C++ (for example the native `bool` and the Windows-defined `BOOL`, which have different values), the attribute `[MarshalAs]` specifies to what native type the .NET type `bool` should map.

```
[DllImport("kernel32.dll", SetLastError="true",
           EntryPoint="CreateHardLink", CharSet=CharSet.Unicode)]
[return: MarshalAs(UnmanagedType.Bool)]
public static extern bool CreateHardLink(string newFileName,
                                         string existingFilename,
                                         IntPtr securityAttributes);
```

The web site `http://www.pinvoke.net` *and the tool P/Invoke Interop Assistant, which can be downloaded from* `http://www.codeplex.com`*, are very helpful with the conversion from native to managed code.*

The settings that you can specify with the attribute `[DllImport]` are listed in the following table.

DLLIMPORT PROPERTY OR FIELD	DESCRIPTION
`EntryPoint`	You can give the C# declaration of the function a different name than it has with the unmanaged library. The name of the method in the unmanaged library is defined in the field `EntryPoint`.
`CallingConvention`	Depending on the compiler or compiler settings that were used to compile the unmanaged function, different calling conventions can be used. The calling convention defines how the parameters are dealt with and where to put them on the stack. You can define the calling convention by setting an enumerable value. The Windows API usually uses the `StdCall` calling convention on the Windows operating system, and it uses the `Cdecl` calling convention on Windows CE. Setting the value to `CallingConvention.Winapi` works for the Windows API in both the Windows and the Windows CE environments.
`CharSet`	String parameters can be either ANSI or Unicode. With the `CharSet` setting, you can define how strings are managed. Possible values that are defined with the `CharSet` enumeration are `Ansi`, `Unicode`, and `Auto`. `CharSet.Auto` uses Unicode on the Windows NT platform, and ANSI on Windows 98 and Windows ME.
`SetLastError`	If the unmanaged function sets an error by using the Windows API `SetLastError`, you can set the `SetLastError` field to `true`. This way, you can read the error number afterward by using `Marshal.GetLastWin32Error()`.

To make the `CreateHardLink()` method easier to use from a .NET environment, you should follow these guidelines:

- Create an internal class named `NativeMethods` that wraps the platform invoke method calls.
- Create a public class to offer the native method functionality to .NET applications.
- Use security attributes to mark the required security.

In the sample code, the public method `CreateHardLink()` in the class `FileUtility` is the method that can be used by .NET applications. This method has the filename arguments reversed compared to the native Windows API method `CreateHardLink()`. The first argument is the name of the existing file, and the second argument is the name of the new file. This is similar to other classes in the Framework; for example, `File.Copy()`. Because the third argument used to pass the security attributes for the new filename is not used with this implementation, the public method has just two parameters. The return type is changed as well. Instead of returning an error by returning the value `false`, an exception is thrown. In case of an error, the unmanaged method `CreateHardLink()` sets the error number with the unmanaged API `SetLastError()`. To read this value from .NET, the `[DllImport]` field `SetLastError` is set to `true`. Within the managed method `CreateHardLink()`, the error number is read by calling `Marshal.GetLastWin32Error()`. To create an error message from this number, the `Win32Exception` class from the namespace `System.ComponentModel` is used. This class accepts an error number with the constructor, and returns a localized error message. In case of an error, an exception of type `IOException` is thrown, which has an inner exception of type `Win32Exception`. The public method `CreateHardLink()` has the `FileIOPermission` attribute applied to check if the caller has the necessary permission. You can read more about .NET security in Chapter 21, "Security."

```
using System;
using System.ComponentModel;
using System.IO;
using System.Runtime.InteropServices;
using System.Security;
using System.Security.Permissions;
```

```
namespace Wrox.ProCSharp.Interop
{
    [SecurityCritical]
    internal static class NativeMethods
    {
        [DllImport("kernel32.dll", SetLastError = true,
           EntryPoint = "CreateHardLinkW", CharSet = CharSet.Unicode)]
        [return: MarshalAs(UnmanagedType.Bool)]
        private static extern bool CreateHardLink(
              [In, MarshalAs(UnmanagedType.LPWStr)] string newFileName,
              [In, MarshalAs(UnmanagedType.LPWStr)] string existingFileName,
              IntPtr securityAttributes);

        internal static void CreateHardLink(string oldFileName,
                                            string newFileName)
        {
            if (!CreateHardLink(newFileName, oldFileName, IntPtr.Zero))
            {
                var ex = new Win32Exception(Marshal.GetLastWin32Error());
                throw new IOException(ex.Message, ex);
            }
        }
    }

    public static class FileUtility
    {
        [FileIOPermission(SecurityAction.LinkDemand, Unrestricted = true)]
        public static void CreateHardLink(string oldFileName,
                                          string newFileName)
        {
            NativeMethods.CreateHardLink(oldFileName, newFileName);
        }
    }
}
```

code snippet PInvokeSample/NativeMethods.cs

This class can now be used to create hard links very easily. If the file passed with the first argument of the program does not exist, you will get an exception with the message "The system cannot find the file specified." If the file exists, you get a new filename referencing the original file. You can easily verify this by changing text in one file; it will show up in the other file as well.

```
using System;
using System.IO;

namespace Wrox.ProCSharp.Interop
{
    class Program
    {
        static void Main(string[] args)
        {
            if (args.Length != 2)
            {
                Console.WriteLine("usage: PInvokeSample " +
                              "existingfilename newfilename");
                return;
            }
            try
            {
                FileUtility.CreateHardLink(args[0], args[1]);
            }
            catch (IOException ex)
            {
                Console.WriteLine(ex.Message);
            }

        }
    }
}
```

With native method calls, often you have to use Window handles. A Window handle is a 32-bit value where, depending on the handle types, some values are not allowed. With .NET 1.0 for handles, usually the `IntPtr` structure was used because you can set every possible 32-bit value with this structure. However, with some handle types, this led to security problems and possible threading race conditions and leaked handles with the finalization phase. That's why .NET 2.0 introduced the `SafeHandle` class. The class `SafeHandle` is an abstract base class for every Windows handle. Derived classes inside the `Microsoft.Win32.SafeHandles` namespace are `SafeHandleZeroOrMinusOneIsInvalid` and `SafeHandleMinusOneIsInvalid`. As the name indicates, these classes do not accept invalid 0 or –1 values. Further derived handle types are `SafeFileHandle`, `SafeWaitHandle`, `SafeNCryptHandle`, and `SafePipeHandle`, which can be used by the specific Windows API calls.

For example, to map the Windows API `CreateFile()`, you can use this declaration to return a `SafeFileHandle`. Of course, usually you could use the .NET classes `File` and `FileInfo` instead.

```
[DllImport("Kernel32.dll", SetLastError = true,
            CharSet = CharSet.Unicode)]
internal static extern SafeFileHandle CreateFile(
   string fileName,
   [MarshalAs(UnmanagedType.U4)] FileAccess fileAccess,
   [MarshalAs(UnmanagedType.U4)] FileShare fileShare,
   IntPtr securityAttributes,
   [MarshalAs(UnmanagedType.U4)] FileMode creationDisposition,
   int flags,
   SafeFileHandle template);
```

SUMMARY

In this chapter, you have seen how the different generations of COM and .NET applications can interact. Instead of rewriting applications and components, a COM component can be used from a .NET application just like a .NET class. The tool that makes this possible is `tlbimp`, which creates a runtime callable wrapper (RCW) that hides the COM object behind a .NET façade.

Likewise, `tlbexp` creates a type library from a .NET component that is used by the COM callable wrapper (CCW). The CCW hides the .NET component behind a COM façade. Using .NET classes as COM components makes it necessary to use some attributes from the namespace `System.Runtime.InteropServices` to define specific COM characteristics that are needed by the COM client.

With platform invoke, you've seen how native methods can be invoked using C#. Platform invoke requires redefining the native method with C# and .NET data types. After defining the mapping, you can invoke the native method as if it were a C# method. Another option for doing interop would be to use the technology It Just Works (IJW) with C++/CLI. You can read information about C++/CLI in Chapter 53, "C#, Visual Basic, C++/CLI, and F#."

27

Core XAML

WHAT'S IN THIS CHAPTER?

- XAML syntax
- Dependency properties
- Markup extensions
- Loading XAML dynamically

When writing a .NET application, usually C# is not the only syntax you need to know. If you write Windows Presentation Foundation (WPF) applications, use Windows Workflow Foundation (WF), create XPS documents, or write Silverlight applications, you also need XAML. XAML (eXtensible Application Markup Language) is a declarative XML syntax that's usually needed with these applications.

This chapter gives you more information on the syntax of XAML and extensibility mechanisms that are available with this markup language.

OVERVIEW

XAML code is declared using textual XML. You can use designers to create XAML code or write XAML code by hand. Visual Studio contains designers to write XAML code for WPF, Silverlight, or WF. Other tools are also available to create XAML such as Microsoft Expression Design and Microsoft Expression Blend.

XAML is used with several technologies, but there are differences among the various technologies. With the XML namespace `http://schemas.microsoft.com/winfx/2006/xaml/presentation`, which is mapped as the default with WPF applications, WPF extensions to XAML are defined. WPF makes use of dependency properties, attached properties, and several WPF-specific markup extensions. WF 4 uses the XML namespace `http://schemas.microsoft.com/netfx/2009/xaml/activities` for the definition of the Workflow activities. The XML namespace `http://schemas.microsoft.com/winfx/2006/xaml` usually is mapped to the `x` prefix and defines features that are common to all XAML vocabularies.

A XAML element usually maps to a .NET class. That's not a strict requirement, but that's usually the case. With Silverlight 1.0, .NET was not available with the plugin and the XAML code was interpreted and could be accessed programmatically just with JavaScript. This changed since Silverlight 2.0, where a smaller version of the .NET Framework is part of the Silverlight plugin. With WPF, every XAML element has a class behind it. That's also the case with Windows Workflow Foundation, for example, the `DoWhile` XAML element is a looping activity backed by the `DoWhile` class in the namespace `System.Activities.Statements`. The `Button` XAML element is the same as the `Button` class in the `System.Windows.Controls` namespace.

It's also possible to use custom .NET classes within XML by mapping the .NET namespace to an XML alias, which is explained later. With .NET 4, XAML gets syntax enhancements, and this version is known as XAML 2009. The first version of XAML is XAML 2006, which is defined in the XML namespace `http://schemas.microsoft.com/winfx/2006/xaml/presentation`. The new version of XAML supports enhancements, like generics within XAML code. However, the WPF and WF designers available with the release of Visual Studio 2010 are still based on XAML 2006. You can use XAML 2009 by using it directly from within your applications to load XAML. This chapter gives you the information on changes of XAML 2009.

What happens with XAML code on a build process? To compile a WPF project, MSBuild tasks are defined in the assembly `PresentationBuildTasks`, named `MarkupCompilePass1` and `MarkupCompilePass2`. These MSBuild tasks create a binary representation of the markup code named BAML (Binary Application Markup Language) that is added to the .NET resources of an assembly. During runtime the binary representation is used.

Reading and writing XAML and BAML can be done with readers and writers. In the namespace `System.Xaml`, classes for core XAML features, such as abstract `XamlReader` and `XamlWriter` classes, and concrete implementations to read and write objects and XAML XML formats are available. The namespace `System.Windows.Markup` also contains some features that are available for all technologies using XAML from the assembly `System.Xaml`. Classes from this namespace that are found in the assembly `PresentationFramework` are WPF-specific extensions. For example, there you can find other `XamlReader` and `XamlWriter` classes that are optimized for WPF features.

Let's get into the syntax of XAML next.

Elements Map to .NET Objects

As mentioned in the last section, usually a XAML element maps to a .NET class. Let's start with creating a `Button` object inside a `Window` programmatically with a C# console project. To compile the following code where a `Button` object is instantiated with the `Content` property set to a string, a `Window` is defined with `Title` and `Content` properties set, and the assemblies `PresentationFramework`, `PresentationCore`, `WindowsBase` and `System.Xaml` need to be referenced.

```
using System;
using System.Windows;
using System.Windows.Controls;

namespace Wrox.ProCSharp.XAML
{
    class Program
    {
        [STAThread]
        static void Main()
        {
            var b = new Button
            {
                Content = "Click Me!"
            };
            var w = new Window
            {
                Title = "Code Demo",
                Content = b
            };
            var app = new Application();
            app.Run(w);
        }
    }
}
```

code snippet CodeIntro/Program.cs

A similar UI can be created by using XAML code. As before, a `Window` element is created that contains a `Button` element. The `Window` element has the `Title` attribute set in addition to its content.

```
<Window x:Class="Wrox.ProCSharp.XAML.MainWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        Title="XAML Demo" Height="350" Width="525">
    <Button Content="Click Me!" />
</Window>
```

code snippet XAMLIntro/MainWindow.xaml

Of course, the `Application` instance from before is missing. This can be defined with XAML as well. In the `Application` element, the `StartupUri` attribute is set, which links to the XAML file that contains the main window.

```
<Application x:Class="Wrox.ProCSharp.XAML.App"
             xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
             xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
             StartupUri="MainWindow.xaml">
   <Application.Resources>
   </Application.Resources>
</Application>
```

code snippet XAMLIntro/App.xaml

Using Custom .NET Classes

To use custom .NET classes within XAML code, only the .NET namespace needs to be declared within XAML, and an XML alias must be defined. To demonstrate this, a simple `Person` class with the `FirstName` and `LastName` properties is defined as shown.

```
namespace Wrox.ProCSharp.XAML
{
    public class Person
    {
        public string FirstName { get; set; }
        public string LastName { get; set; }

        public override string ToString()
        {
            return string.Format("{0} {1}", FirstName, LastName);
        }
    }
}
```

code snippet DemoLib/Person.cs

In XAML, an XML namespace alias named `local` is defined that maps to the .NET namespace `Wrox.ProCSharp.XAML`. Now it's possible to use all classes from this namespace with the alias. In the XAML code a `ListBox` is added that contains items of type Person. Using XAML attributes, the values of the properties `FirstName` and `LastName` are set. When you run the application, the output of the `ToString()` method is shown inside the `ListBox`.

```
<Window x:Class="Wrox.ProCSharp.XAML.MainWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        xmlns:local="clr-namespace:Wrox.ProCSharp.XAML"
        Title="XAML Demo" Height="350" Width="525">
    <StackPanel>
        <Button Content="Click Me!" />
        <ListBox>
            <local:Person FirstName="Stephanie" LastName="Nagel" />
            <local:Person FirstName="Angela" LastName="Schoeberl" />
        </ListBox>
    </StackPanel>
</Window>
```

code snippet XAMLIntro/MainWindow.xaml

If the .NET namespace is not in the same assembly as the XAML code, the assembly name must also be included with the XML namespace alias, for example, `xmlns:local="clr-namespace:Wrox.ProCSharp.XAML;assembly=XAMLIntro"`.

To map a .NET namespace to an XML namespace, you can use the assembly attribute `XmlnsDefinition`. One argument of this attribute defines the XML namespace, the other the .NET namespace. Using this attribute, it is also possible to map multiple .NET namespaces to a single XML namespace.

```
[assembly: XmlnsDefinition("http://www.wrox.covm/Schemas/2010",
"Wrox.ProCSharp.XAML")]
```

code snippet DemoLib/AssemblyInfo.cs

With this attribute in place, the namespace declaration in the XAML code can be changed to map to the XML namespace.

```
<Window x:Class="Wrox.ProCSharp.XAML.MainWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        xmlns:local="http://www.wrox.com/Schemas/2010"
        Title="XAML Demo" Height="350" Width="525">
    <StackPanel>
        <Button Content="Click Me!" />
        <ListBox>
            <local:Person FirstName="Stephanie" LastName="Nagel" />
            <local:Person FirstName="Angela" LastName="Schoeberl" />
        </ListBox>
    </StackPanel>
</Window>
```

Properties as Attributes

Properties can be set as attributes as long as the property type can be represented as a string or there is a conversion from a string to the property type. The following code snippet sets the `Content` and `Background` property of the `Button` element with attributes. The `Content` property is of type `object` and thus also accepts a string. The `Background` property is of type `Brush`. The `Brush` type defines the `BrushConverter` class as a converter type with the attribute `TypeConverter` with which the class is annotated. `BrushConverter` uses a list of colors to return a `SolidColorBrush` from the `ConvertFromString()` method.

```
        <Button Content="Click Me!" Background="LightGoldenrodYellow" />
```

code snippet XAMLSyntax/MainWindow.xaml

A type converter derives from the base class TypeConverter *in the* System.ComponentModel *namespace. The type of the class that needs conversion defines the type converter with the* TypeConverter *attribute. WPF uses many type converters to convert XML attributes to a specific type.* ColorConverter, FontFamilyConverter, PathFigureCollectionConverter, ThicknessConverter, GeometryConverter *are just a few of a large number of type converters.*

Properties as Elements

It's always also possible to use the element syntax to supply the value for properties. The `Background` property of the `Button` class can be set with the child element `Button.Background`. This way more complex brushes can be applied to this property, for example, a `LinearGradientBrush`, as shown in the example.

When setting the content in the sample, neither the `Content` attribute nor a `Button.Content` element is used to write the content; instead, the content is written directly as a child value to the `Button` element. That's possible because with a base class of the `Button` class (`ContentControl`), the `ContentProperty` attribute is applied, which marks the `Content` property as a `ContentProperty`: `[ContentProperty ("Content")]`. With such a marked property, the value of the property can be written as child element.

```
<Button>
    Click Me!
    <Button.Background>
        <LinearGradientBrush StartPoint="0.5,0.0" EndPoint="0.5, 1.0">
            <GradientStop Offset="0" Color="Yellow" />
            <GradientStop Offset="0.3" Color="Orange" />
            <GradientStop Offset="0.7" Color="Red" />
            <GradientStop Offset="1" Color="DarkRed" />
        </LinearGradientBrush>
    </Button.Background>
</Button>
```

code snippet XAMLSyntax/MainWindow.xaml

Essential .NET Types

In XAML 2006, core .NET types need to be referenced from an XML namespace like all other .NET classes, for example, the `String` with the `sys` alias, as shown here:

```
<sys:String xmlns:sys="clr-namespace:System;assembly=mscorlib>Simple String</sys:String>
```

XAML 2009 defines types such as `String`, `Boolean`, `Object`, `Decimal`, `Double`, `Int32` and others with the `x` alias.

```
<x:String>Simple String</x:String>
```

Collections

In the `ListBox` that contains `Person` elements, you've already seen a collection within XAML. In the `ListBox`, the items have been directly defined as child elements. Also, the `LinearGradientBrush` contained a collection of `GradientStop` elements. This is possible because the base class `ItemsControl` has the attribute `ContentProperty` set to the `Items` property of the class, and the `GradientBrush` base class sets the attribute `ContentProperty` to `GradientStops`.

A longer version that defines the background by directly setting the `GradientStops` property and defining the `GradientStopCollection` element as its child is shown here:

```
        <Button Click="OnButtonClick">
              Click Me!
              <Button.Background>
                  <LinearGradientBrush StartPoint="0.5,0.0" EndPoint="0.5, 1.0">
                      <LinearGradientBrush.GradientStops>
                          <GradientStopCollection>
                              <GradientStop Offset="0" Color="Yellow" />
                              <GradientStop Offset="0.3" Color="Orange" />
                              <GradientStop Offset="0.7" Color="Red" />
                              <GradientStop Offset="1" Color="DarkRed" />
                          </GradientStopCollection>
                      </LinearGradientBrush.GradientStops>
                  </LinearGradientBrush>
              </Button.Background>
          </Button>
```

code snippet XAMLSyntax/MainWindow.xaml

To define an array, the `x:Array` extension can be used. The `x:Array` extension has a `Type` property where you can specify the type of the items of the array.

```
<x:Array Type="local:Person">
    <local:Person FirstName="Stephanie" LastName="Nagel" />
    <local:Person FirstName="Angela" LastName="Schoeberl" />
</x:Array>
```

XAML 2006 does not support generics, so to use a generic collection class from XAML you need to define a non-generic class that derives from the generic class and use the non-generic class instead. In XAML 2009, generics are directly supported in XAML with the `x:TypeArguments` to define the generic type, as shown here with `ObservableCollection<T>`.

```
<ObservableCollection x:TypeArguments="local:Person">
    <local:Person FirstName="Stephanie" LastName="Nagel" />
    <local:Person FirstName="Angela" LastName="Schoeberl" />
</ObservableCollection>
```

Constructors

If a class doesn't have a default constructor, it cannot be used with XAML 2006. With XAML 2009, you can use `x:Arguments` to invoke a constructor with parameters. Here is the `Person` class instantiated with a constructor that requires two `String` arguments.

```
<local:Person>
    <x:Arguments>
        <x:String>Stephanie</x:String>
        <x:String>Nagel</x:String>
    </x:Arguments>
</local:Person>
```

DEPENDENCY PROPERTIES

WPF uses dependency properties for data binding, animations, property change notification, styling, and so forth. For data binding, the property of the UI element that is bound to the source of a .NET property must be a dependency property.

From the outside, a dependency property looks like a normal .NET property. However, with a normal .NET property you usually also define the data member that is accessed by the `get` and `set` accessors of the property.

```
        private int val;
        public int Value
        {
            get
            {
                return val;
            }
            set
            {
                val = value;
            }
        }
```

That's not the case with dependency properties. A dependency property usually has a `get` and `set` accessor of a property as well. With the implementation of the `get` and `set` accessors, the methods `GetValue()` and `SetValue()` are invoked. `GetValue()` and `SetValue()` are members of the base class `DependencyObject`, which also gives you a requirement for dependency objects — that they must be implemented in a class that derives from `DependencyObject`.

With a dependency property, the data member is kept inside an internal collection that is managed by the base class and only allocates data if the value is changed. With unchanged values, the data can be shared between different instances or also base classes. The `GetValue` and `SetValue` methods require a `DependencyProperty` argument. This argument is defined by a static member of the class that has the same name as the property appended to the term `Property`. With the property `Value`, the static member has the name `ValueProperty`. `DependencyProperty.Register()` is a helper method that registers the property in the dependency property system. In this code snippet the `Register` method is used with three arguments to define the name of the property, the type of the property, and the type of the owner that is the class `MyDependencyObject`.

```
        public int Value
        {
            get { return (int)GetValue(ValueProperty); }
            set { SetValue(ValueProperty, value); }
        }

        public static readonly DependencyProperty ValueProperty =
            DependencyProperty.Register("Value", typeof(int), typeof(MyDependencyObject));
```

code snippet DependencyObjectDemo/MyDependencyObject.cs

Creating a Dependency Property

Let's look at a sample that defines not one but three dependency properties. The class `MyDependencyObject` defines the dependency properties `Value`, `Minimum`, and `Maximum`. All of these properties are dependency properties that are registered with the method `DependencyProperty.Register()`. The methods `GetValue()` and `SetValue()` are members of the base class `DependencyObject`. For the `Minimum` and `Maximum` properties, default values are defined that can be set with the `DependencyProperty.Register()` method and a fourth argument to set the `PropertyMetadata`. Using a constructor with one parameter, `PropertyMetadata`, the `Minimum` property is set to `0`, and the `Maximum` property is set to `100`.

```
using System;
using System.Windows;

namespace Wrox.ProCSharp.XAML
{
    class MyDependencyObject : DependencyObject
    {
        public int Value
        {
            get { return (int)GetValue(ValueProperty); }
            set { SetValue(ValueProperty, value); }
        }

        public static readonly DependencyProperty ValueProperty =
            DependencyProperty.Register("Value", typeof(int), typeof(MyDependencyObject));

        public int Minimum
        {
            get { return (int)GetValue(MinimumProperty); }
            set { SetValue(MinimumProperty, value); }
        }

        public static readonly DependencyProperty MinimumProperty =
            DependencyProperty.Register("Minimum", typeof(int), typeof(MyDependencyObject),
                                        new PropertyMetadata(0));

        public int Maximum
        {
            get { return (int)GetValue(MaximumProperty); }
            set { SetValue(MaximumProperty, value); }
        }

        public static readonly DependencyProperty MaximumProperty =
            DependencyProperty.Register("Maximum", typeof(int), typeof(MyDependencyObject),
                                        new PropertyMetadata(100));
    }
}
```

code snippet DependencyObjectDemo/MyDependencyObject.cs

Within the `get` and `set` property accessors you may not do more than just calling the `GetValue()` and `SetValue()` methods. Using the dependency properties, the property values can be accessed from the outside with the `GetValue()` and `SetValue()` methods, which is also done from WPF, and thus, the strongly-typed property accessors might not be invoked at all. They are just here for convenience for custom code.

Coerce Value Callback

Dependency properties support coercion. With coercion, the value of the property can be checked to see if it is valid, for example, that it falls within a valid range. That's why the `Minimum` and `Maximum` properties are included in the sample. Now the registration of the `Value` property is changed to pass the event handler method `CoerceValue()` to the constructor of `PropertyMetadata`, which is passed as an argument to the `DependencyProperty.Register()` method. The `CoerceValue()` method is now invoked with every change of the property value from the implementation of the `SetValue()` method. Within `CoerceValue()`, the `set` value is checked to see if it falls within the range between the minimum and maximum, and the value is set accordingly if this is not the case.

```
using System;
using System.Windows;

namespace Wrox.ProCSharp.XAML
{
    class MyDependencyObject : DependencyObject
    {
        public int Value
        {
            get { return (int)GetValue(ValueProperty); }
```

```
                set { SetValue(ValueProperty, value); }
            }

            public static readonly DependencyProperty ValueProperty =DependencyProperty.
               Register("Value", typeof(int), typeof(MyDependencyObject));new PropertyMetadata
               (0, null, CoerceValue));

            public int Minimum
            {
                get { return (int)GetValue(MinimumProperty); }
                set { SetValue(MinimumProperty, value); }
            }

            public static readonly DependencyProperty MinimumProperty =
                DependencyProperty.Register("Minimum", typeof(int), typeof(MyDependencyObject),
                                            new PropertyMetadata(0));

            public int Maximum
            {
                get { return (int)GetValue(MaximumProperty); }
                set { SetValue(MaximumProperty, value); }
            }

            public static readonly DependencyProperty MaximumProperty =
                DependencyProperty.Register("Maximum", typeof(int), typeof(MyDependencyObject),
                                            new PropertyMetadata(100));

            private static object CoerceValue(DependencyObject element, object value)
            {
                int newValue = (int)value;
                MyDependencyObject control = (MyDependencyObject)element;

                newValue = Math.Max(control.Minimum, Math.Min(control.Maximum, newValue));
                return newValue;
            }
        }
    }
```

code snippet DependencyObjectDemo/MyDependencyObject.cs

Value Changed Callbacks and Events

To get some information on value changes, dependency properties also support value change callbacks. You can add a `DependencyPropertyChanged` event handler to the `DependencyProperty.Register()` method that is invoked when the property value changes. In the sample code, the handler method `OnValueChanged()` is assigned to the `PropertyChangedCallback` to the `PropertyMetadata` object. In the `OnValueChanged` method, you can access the old and new values of the property with the `DependencyPropertyChangedEventArgs()` argument.

```
    using System;
    using System.Windows;

    namespace Wrox.ProCSharp.XAML
    {
        class MyDependencyObject : DependencyObject
        {
            public int Value
            {
                get { return (int)GetValue(ValueProperty); }
                set { SetValue(ValueProperty, value); }
            }
            public static readonly DependencyProperty ValueProperty =
                DependencyProperty.Register("Value", typeof(int), typeof(MyDependencyObject),
                new PropertyMetadata(0, OnValueChanged, CoerceValue));

            //...

            private static void OnValueChanged(DependencyObject obj,
                                               DependencyPropertyChangedEventArgs args)
            {
                int oldValue = (int)args.OldValue;
                int newValue = (int)args.NewValue;
                //...
            }
        }
    }
```

code snippet DependencyObjectDemo/MyDependencyObject.cs

BUBBLING AND TUNNELING EVENTS

Elements can be contained in elements. With XAML and WPF, you can define that a `Button` contains a `ListBox`; the `ListBox` contains items that are `Button` controls again. When you click on an inner control, the event should go all the way to the outside. WPF supports bubbling and tunneling events. Often these events are used in pairs. The `PreviewMouseMove` event is a tunneling event that tunnels from the outside to the inside. `MouseMove` follows the `PreviewMouseMove` event and is a bubbling event that bubbles from the inside to the outside.

Core information about .NET events is explained in Chapter 8, "Delegates, Lambdas, and Events."

To demonstrate bubbling, the following XAML code contains four `Button` controls where the surrounding `StackPanel` defines an event handler for the `Button.Click` event named `OnOuterButtonClick()`. `button2` contains a `ListBox` that has two `Button` controls as its children and the `Click` event handler `OnButton2()`. Both of the inner buttons also have an event handler associated with the `Click` event.

```
<Window x:Class=" Wrox.ProCSharp.XAML.MainWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        Title="MainWindow" Height="350" Width="525">
    <StackPanel x:Name="stackPanel1" Button.Click="OnOuterButtonClick">
        <Button x:Name="button1" Content="Button 1" Margin="5" />
        <Button x:Name="button2" Margin="5" Click="OnButton2" >
            <ListBox x:Name="listBox1">
                <Button x:Name="innerButton1" Content="Inner Button 1" Margin="4"
                        Padding="4" Click="OnInner1" />
                <Button x:Name="innerButton2" Content="Inner Button 2" Margin="4"
                        Padding="4" Click="OnInner2" />
            </ListBox>
        </Button>
        <ListBox ItemsSource="{Binding}" />
    </StackPanel>
</Window>
```

code snippet BubbleDemo/MainWindow.xaml

The event handler methods are implemented in the code-behind. The second argument of the handler methods is of type RoutedEventArgs, which provides information about the Source of the event and the OriginalSource. When you click button1, the handler method OnOuterButtonClick() is invoked, although there's no Click event directly associated with this button; the event is bubbled to the container element. Source and OriginalSource is button1 in that case. If you click on button2 first, the event handler OnButton2() is invoked, followed by OnOuterButtonClick(). The handler OnButton2() changes the Source property, so with OnOuterButtonClick() you can see a different Source than in the handler before. The Source property of an event can be changed, but the OriginalSource is readonly. Clicking the button innerButton1 invokes the OnInner1() event handler followed by OnButton2() and by OnOuterButtonClick(). The event bubbles. When you click innerButton2 only the handler OnInner2() is invoked because the Handled property there is set to true. Bubbling stops here.

```
using System;
using System.Collections.ObjectModel;
using System.Windows;

namespace BubbleDemo
{
    public partial class MainWindow : Window
    {
        private ObservableCollection<string> messages = new ObservableCollection<string>();
        public MainWindow()
        {
            InitializeComponent();
            this.DataContext = messages;
        }

        private void AddMessage(string message, object sender, RoutedEventArgs e)
        {
            messages.Add(String.Format("{0}, sender: {1}; source: {2}; original source: {3}",
                message, (sender as FrameworkElement).Name,
                (e.Source as FrameworkElement).Name,
                (e.OriginalSource as FrameworkElement).Name));
        }

        private void OnOuterButtonClick(object sender, RoutedEventArgs e)
        {
            AddMessage("outer event", sender, e);
        }

        private void OnInner1(object sender, RoutedEventArgs e)
        {
            AddMessage("inner1", sender, e);
        }

        private void OnInner2(object sender, RoutedEventArgs e)
        {
            AddMessage("inner2", sender, e);
            e.Handled = true;
        }

        private void OnButton2(object sender, RoutedEventArgs e)
        {
            AddMessage("button2", sender, e);
            e.Source = sender;
        }
    }
}
```

code snippet BubbleDemo/MainWindow.xaml.cs

Changing the source and also changing the event type is very common. For example, the `Button` *class reacts to the mouse down and up events, handles these, and creates a button click event instead.*

How can you define bubbling and tunneling events in custom classes? The `MyDependencyObject` is changed to support an event on a value change. For bubbling and tunneling event support, the class must now derive from `UIElement` instead of `DependencyObject` because this class defines `AddHandler()` and `RemoveHandler()` methods for events.

To let the caller of the `MyDependencyObject` receive information on value changes, the class defines the `ValueChanged` event. The event is declared with explicit `add` and `remove` handlers, where the `AddHandler()` and `RemoveHandler()` methods of the base class are invoked. The `AddHandler()` and `RemoveHandler()` methods require a type `RoutedEvent` and the delegate as parameters. The routed event named `ValueChangedEvent` is declared very similarly to a dependency property. It is declared as a static member and registered by calling the method `EventManager.RegisterRoutedEvent()`. This method requires the name of the event, the routing strategy (which can be `Bubble`, `Tunnel`, and `Direct`), the type of the handler, and the type of the owner class. The `EventManager` class also gives you the capability to register static events and get information about the events registered.

```
using System;
using System.Windows;

namespace Wrox.ProCSharp.XAML
{
    class MyDependencyObject : UIElement
    {
        public int Value
        {
            get { return (int)GetValue(ValueProperty); }
            set { SetValue(ValueProperty, value); }
        }

        public static readonly DependencyProperty ValueProperty =
            DependencyProperty.Register("Value", typeof(int), typeof(MyDependencyObject),
            new PropertyMetadata(0, OnValueChanged, CoerceValue));

        //...

        private static void OnValueChanged(DependencyObject obj,
                                           DependencyPropertyChangedEventArgs args)
        {
            MyDependencyObject control = (MyDependencyObject)obj;

            RoutedPropertyChangedEventArgs<int> e = new RoutedPropertyChangedEventArgs<int>(
                    (int)args.OldValue, (int)args.NewValue, ValueChangedEvent);
            control.OnValueChanged(e);
        }

        public static readonly RoutedEvent ValueChangedEvent =
            EventManager.RegisterRoutedEvent("ValueChanged", RoutingStrategy.Bubble,
                typeof(RoutedPropertyChangedEventHandler<int>), typeof(MyDependencyObject));
        public event RoutedPropertyChangedEventHandler<int> ValueChanged
        {
            add
            {
                AddHandler(ValueChangedEvent, value);
            }
            remove
            {
                RemoveHandler(ValueChangedEvent, value);
            }
        }

        protected virtual void OnValueChanged(RoutedPropertyChangedEventArgs<int> args)
        {
            RaiseEvent(args);
        }
    }
}
```

code snippet DependencyObjectDemo/MyDependencyObject.cs

Now you can use this with bubbling functionality in the same way that you've seen it used before with the button click event.

ATTACHED PROPERTIES

Dependency properties are properties available with a specific type. With an attached property, you can define properties for other types. Some container controls define attached properties for their children; for example, if the `DockPanel` control is used, a `Dock` property is available for its children. The `Grid` control defines `Row` and `Column` properties.

The code snippet below demonstrates how this looks in XAML. The `Button` class doesn't have the property `Dock`, but it's attached from the `DockPanel`.

```
<DockPanel>
    <Button Content="Top" DockPanel.Dock="Top" Background="Yellow" />
    <Button Content="Left" DockPanel.Dock="Left" Background="Blue" />
</DockPanel>
```

Attached properties can be defined very similarly to dependency properties, as you can see in the next sample. The class that defines the attached properties must derive from the base class `DependencyObject` and defines a normal property, where the `get` and `set` accessors invoke the methods `GetValue()` and `SetValue()` of the base class. This is where the similarities end. Instead of invoking the method `Register()` with the `DependencyProperty` class, now `RegisterAttached()` is invoked. `RegisterAttached()` registers an attached property that is now available with every element.

```
using System.Windows;

namespace Wrox.ProCSharp.XAML
{
    class MyAttachedPropertyProvider : DependencyObject
    {
        public int MyProperty
        {
            get { return (int)GetValue(MyPropertyProperty); }
            set { SetValue(MyPropertyProperty, value); }
        }

        public static readonly DependencyProperty MyPropertyProperty =
            DependencyProperty.RegisterAttached("MyProperty", typeof(int),
                typeof(MyAttachedPropertyProvider));
        public static void SetMyProperty(UIElement element, int value)
        {
            element.SetValue(MyPropertyProperty, value);
        }

        public static int GetMyProperty(UIElement element)
        {
            return (int)element.GetValue(MyPropertyProperty);
        }
    }
}
```

code snippet AttachedPropertyDemo/MyAttachedPropertyProvider.cs

In the XAML code, the attached property can now be attached to any elements. The second `Button` control, named `button2`, has the property `MyAttachedPropertyProvider.MyProperty` attached to it and the value 5 assigned.

```
<Window x:Class="Wrox.ProCSharp.XAML.MainWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        xmlns:local="clr-namespace:Wrox.ProCSharp.XAML"
        Title="MainWindow" Height="350" Width="525">
    <Grid x:Name="grid1">
        <Grid.RowDefinitions>
            <RowDefinition Height="Auto" />
            <RowDefinition Height="Auto" />
            <RowDefinition Height="*" />
        </Grid.RowDefinitions>

        <Button Grid.Row="0" x:Name="button1" Content="Button 1" />
        <Button Grid.Row="1" x:Name="button2" Content="Button 2"
                local:MyAttachedPropertyProvider.MyProperty="5" />

        <ListBox Grid.Row="2" x:Name="list1" />
    </Grid>
</Window>
```

code snippet AttachedPropertyDemo/MainWindow.xaml

Doing the same in code-behind it is necessary to invoke the static method `SetMyProperty()` of the class `MyAttachedPropertyProvider`. It's not possible to extend the class `Button` with a property. The method `SetProperty()` gets a `UIElement` instance that should be extended by the property and the value. In the code snippet, the property is attached to `button1` and the value is set to 44.

The `foreach` loop that follows the property setting retrieves the values from the attached properties from all child elements of the `Grid` element `grid1`. Retrieving the values is done with the `GetProperty()` method of the class `MyAttachedPropertyProvider`. This is done from the `DockPanel` and the `Grid` control to retrieve the settings from its children to arrange them.

```
using System;
using System.Windows;

namespace Wrox.ProCSharp.XAML
```

```
{
    public partial class MainWindow : Window
    {
        public MainWindow()
        {
            InitializeComponent();

            MyAttachedPropertyProvider.SetMyProperty(button1, 44);

            foreach (object item in LogicalTreeHelper.GetChildren(grid1))
            {
                FrameworkElement e = item as FrameworkElement;
                if (e != null)
                    list1.Items.Add(String.Format("{0}: {1}", e.Name,
                        MyAttachedPropertyProvider.GetMyProperty(e)));
            }
        }
    }
}
```

code snippet AttachedPropertyDemo/MainWindow.xaml.cs

There are some mechanisms available to extend classes at a later time. Extension methods can be used to extend any class with methods. Extension methods only support extending classes with methods, not properties. Extension methods are explained in Chapter 3, "Objects and Types." The `ExpandoObject` *class allows the extension of types with methods and properties. To use this feature, the class must derive from* `ExpandoObject`. `ExpandoObject` *and dynamic types are explained in Chapter 12, "Dynamic Language Extensions."*

Chapters 35 and 36 show many different attached properties in action, for example attached properties from container controls such as `Canvas`, `DockPanel`, `Grid`, *but also the* `ErrorTemplate` *property from the* `Validation` *class.*

MARKUP EXTENSIONS

With markup extensions you can extend XAML, with either element or attribute syntax. If an XML attribute contains curly brackets, that's a sign of a markup extension. Often markup extensions with attributes are used as shorthand notation instead of using elements.

One example of such a markup extension is `StaticResourceExtension`, which finds resources. Here's a resource of a linear gradient brush with the key `gradientBrush1`.

```
<Window.Resources>
    <LinearGradientBrush x:Key="gradientBrush1" StartPoint="0.5,0.0" EndPoint="0.5, 1.0">
        <GradientStop Offset="0" Color="Yellow" />
        <GradientStop Offset="0.3" Color="Orange" />
        <GradientStop Offset="0.7" Color="Red" />
        <GradientStop Offset="1" Color="DarkRed" />
    </LinearGradientBrush>
</Window.Resources>
```

code snippet MarkupExtensionDemo/MainWindow.xaml

This resource can be referenced by using the `StaticResourceExtension` with attribute syntax to set the `Background` property of a `TextBlock`. Attribute syntax is defined by curly brackets and the name of the extension class without the `Extension` postfix.

```
<TextBlock Text="Test" Background="{StaticResource gradientBrush1}" />
```

The longer form of the attribute shorthand notation uses element syntax, as the next code snippet demonstrates. `StaticResourceExtension` is defined as a child element of the `TextBlock.Background` element. The property `ResourceKey` is set with an attribute to `gradientBrush1`. In the previous example, the resource key is not set with the property `ResourceKey` (which would be possible as well) but with a constructor overload where the resource key can be set.

```
<TextBlock Text="Test">
    <TextBlock.Background>
        <StaticResourceExtension ResourceKey="gradientBrush1" />
    </TextBlock.Background>
</TextBlock>
```

Creating Custom Markup Extensions

A markup extension is created by defining a class that derives from the base class `MarkupExtension`. Most markup extensions have the `Extension` postfix (this naming convention is similar to the `Attribute` postfix with attributes, which you can read about in Chapter 14, "Reflection"). With a custom markup extension, you only need to override the method `ProvideValue()`, which returns the value from the extension. The type that is returned is annotated to the class with the attribute `MarkupExtensionReturnType`. With the method `ProvideValue`, an `IServiceProvider` object is passed. With this interface you can query for different services, such as `IProvideValueTarget` or `IXamlTypeResolver`. `IProvideValueTarget` can be used to access the control and property where the markup extension is applied to with the `TargetObject` and `TargetProperty` properties. `IXamlTypeResolver` can be used to resolve XAML element names to CLR objects. The custom markup extension class `CalculatorExtension` defines the properties `X` and `Y` of type `double` and an `Operation` property that is defined by an enumeration. Depending on the value of the `Operation` property, different calculations are done on the `X` and `Y` input properties, and a string is returned.

```
using System;
using System.Windows;
using System.Windows.Markup;

namespace Wrox.ProCSharp.XAML
{
    public enum Operation
    {
        Add,
        Subtract,
        Multiply,
        Divide
    }

    [MarkupExtensionReturnType(typeof(string))]
    public class CalculatorExtension : MarkupExtension
    {
        public CalculatorExtension()
        {

        }

        public double X { get; set; }
        public double Y { get; set; }

        public Operation Operation { get; set; }
        public override object ProvideValue(IServiceProvider serviceProvider)
        {
            IProvideValueTarget provideValue =
                  serviceProvider.GetService(typeof(IProvideValueTarget))
                                           as IProvideValueTarget;
            if (provideValue != null)
            {
                var host = provideValue.TargetObject as FrameworkElement;
                var prop = provideValue.TargetProperty as DependencyProperty;
             }

            double result = 0;
            switch (Operation)
            {
                case Operation.Add:
                    result = X + Y;
                    break;
                case Operation.Subtract:
                    result = X - Y;
                    break;
                case Operation.Multiply:
                    result = X * Y;
                    break;
                case Operation.Divide:
                    result = X / Y;
                    break;
                default:
                    throw new ArgumentException("invalid operation");
            }

            return result.ToString();
        }
    }
}
```

code snippet MarkupExtensionDemo/CalculatorExtension.cs

The markup extension can now be used with an attribute syntax in the first `TextBlock` to add the values 3 and 4, or with the element syntax with the second `TextBlock`.

```
<Window x:Class="Wrox.ProCSharp.XAML.MainWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        xmlns:local="clr-namespace:Wrox.ProCSharp.XAML"
        Title="MainWindow" Height="350" Width="525">
    <StackPanel>
        <TextBlock Text="{local:Calculator Operation=Add, X=3, Y=4}" />
        <TextBlock>
            <TextBlock.Text>
                <local:CalculatorExtension>
                    <local:CalculatorExtension.Operation>
                        <local:Operation>Multiply</local:Operation>
                     </local:CalculatorExtension.Operation>
                    <local:CalculatorExtension.X>7</local:CalculatorExtension.X>
                    <local:CalculatorExtension.Y>11</local:CalculatorExtension.Y>
                </local:CalculatorExtension>
            </TextBlock.Text>
        </TextBlock>
    </StackPanel>
</Window>
```

code snippet MarkupExtensionDemo/MainWindow.xaml

XAML-Defined Markup Extensions

Markup extensions provide a lot of capabilities. And indeed XAML-defined markup extensions have already been used in this chapter. `x:Array`, which was shown in the "Collections" section, is defined as the markup extension class `ArrayExtension`. With this markup extension, using the attribute syntax is not possible because it would be difficult to define a list of elements.

Other markup extensions that are defined with XAML are the `TypeExtension` (`x:Type`), which returns the type based on string input; `NullExtension` (`x:Null`), which can be used to set values to null in XAML; and `StaticExtension` (`x:Static`) to invoke static members of a class.

WPF, WF, and WCF define markup extensions that are specific to these technologies. WPF uses markup extensions to access resources, for data binding, and color conversion; WF uses markup extensions with activities; and WCF defines markup extensions for endpoint definitions.

READING AND WRITING XAML

Several APIs exist for reading and writing XAML. There are high-level APIs that are easy to use but have less functionality and low-level APIs with more features. Technology-specific APIs that make use of specific WPF or WF features are also available. XAML can be read from a textual XML form, from BAML, or from object trees, and written to XML or object trees.

Generic high-level APIs are available in the namespace `System.Xaml`. The class `XamlServices` allows loading, parsing, saving, and transforming XAML. `XamlServices.Load()` can load XAML code from a file, a stream, or a reader, or by using a `XamlReader` object. `XamlReader` (in the namespace `System.Xaml`) is an abstract base class that has several concrete implementations. `XamlObjectReader` reads an object tree, `XamlXmlReader` reads XAML from an XML file, `Baml2006Reader` reads the binary form of XAML. `XamlDebuggerXmlReader` from the namespace `System.Activities.Debugger` is a special reader for WF with special debugging support.

When passing XAML code in a string to `XamlServices`, the `Parse()` method can be used. `XamlServices.Save()` can be used to save XAML code. With the `Save()` method you can use similar data sources as with the `Load()` method. The object passed can be saved to a string, a stream, a `TextWriter`, a `XamlWriter`, or an `XmlWriter`. `XamlWriter` is an abstract base class. Classes that derive from `XamlWriter` are `XamlObjectWriter` and `XamlXmlWriter`. In the release of .NET 4, there's no writer for BAML code, but it is expected to have a BAML writer available at a later time.

When converting XAML from one format in another, you can use `XamlServices.Transform()`. With the `Transform` method, you pass a `XamlReader` and a `XamlWriter` so that you can convert any format that is supported by specific readers and writers.

Instead of using the high-level API `XamlServices` class, you can use generic low-level APIs directly, which means using specific `XamlReader` and `XamlWriter` classes. With a reader, you can read node by node from a XAML tree with the `Read()` method.

The generic `XamlServices` class doesn't support specific WPF features such as dependency properties or freezable objects. To read and write WPF XAML, you can use the classes `XamlReader` and `XamlWriter` from the namespace `System.Windows.Markup` that is defined in the assembly `PresentationFramework` and thus has access to the WPF features. The names of these classes might be confusing, as the same class names are used with classes from different namespaces. `System.Xaml.XamlReader` is the abstract base class for readers; `System.Windows.Markup.XamlReader` is the WPF class to read XAML. This can be even more confusing when using the `Load` method of the WPF `XamlReader` class that accepts a `System.Xaml.XamlReader` as argument.

An optimized version to read XAML for WF is `WorkflowXamlServices` in the namespace `System.Activities`. This class is used to create dynamic activities during runtime.

Dynamic activities and Windows Workflow Foundation 4 are explained in Chapter 44, "Windows Workflow Foundation 4."

A simple example to load XAML dynamically from a file to create an object tree and to attach the object tree to a container element, such as a `StackPanel`, is shown here.

```
FileStream stream = File.OpenRead("Demo1.xaml");
object tree = System.Windows.Markup.XamlReader.Load(stream);

container1.Children.Add(tree as UIElement);
```

SUMMARY

In this chapter, you've seen the core functionality of XAML and some specific characteristics such as dependency properties, attached properties, and markup extensions. You have seen the extensibility of XAML, which serves as the base for other technologies such as WPF and WF. In other chapters that make use of XAML, you can see a lot of different uses for these XAML characteristics.

You can read more about XAML and see XAML in action in a lot of chapters in this book. In particular, you should read Chapters 35 and 36 for WPF, Chapter 37 for XPS, Chapter 38 for Silverlight, and Chapter 44 for Windows Workflow Foundation.

The next chapter is about MEF, the Managed Extensibility Framework.

28

Managed Extensibility Framework

WHAT'S IN THIS CHAPTER?

- ➤ Architecture of the Managed Extensibility Framework
- ➤ Contracts
- ➤ Exports and imports of parts
- ➤ Containers used by hosting applications
- ➤ Catalogs for finding parts

Add-ins (or plugins) allow you to add functionality to an application at a later time. You can create a hosting application that gains more and more functionality over time — such functionality might be written by your team of developers, but different vendors can also extend your application by creating add-ins.

Today, add-ins are used with many different applications, such as Internet Explorer and Visual Studio. Internet Explorer is a hosting application that offers an add-in framework that is used by many companies to provide extensions when viewing web pages. The Shockwave Flash Object allows you to view web pages with Flash content. The Google toolbar offers specific Google features that can be accessed quickly from Internet Explorer. Visual Studio also has an add-in model that allows you to extend Visual Studio with different levels of extensions.

For your custom applications, it has always been possible to create an add-in model to dynamically load and use functionality from assemblies. However, all the issues with finding and using add-ins need to be resolved. This task can be accomplished automatically using the Managed Extensibility Framework.

The major namespace that is covered in this chapter is `System.ComponentModel.Composition`.

MEF ARCHITECTURE

The .NET 4 Framework offers two technologies for writing flexible applications that load add-ins dynamically. One technology is the Managed Extensibility Framework (MEF), which is covered in this chapter. Another technology that has been available since .NET 3.5 is the Managed Add-in

Framework (MAF), which is covered in the downloadable Chapter 50, “Managed Add-In Framework.” MAF uses a pipeline for communication between the add-in and the host application that makes the development process more complex but also offers separation of add-ins via appdomains or even different processes. In that regard, MEF is the simpler of these two technologies. MAF and MEF can be combined to get the advantage of each (but also doubles the work).

MEF is built up with parts and containers, as shown in Figure 28-1. A container finds parts from a catalog. The catalog finds parts within an assembly or a directory. The container connects imports to exports and, thus, makes parts available to the hosting application.

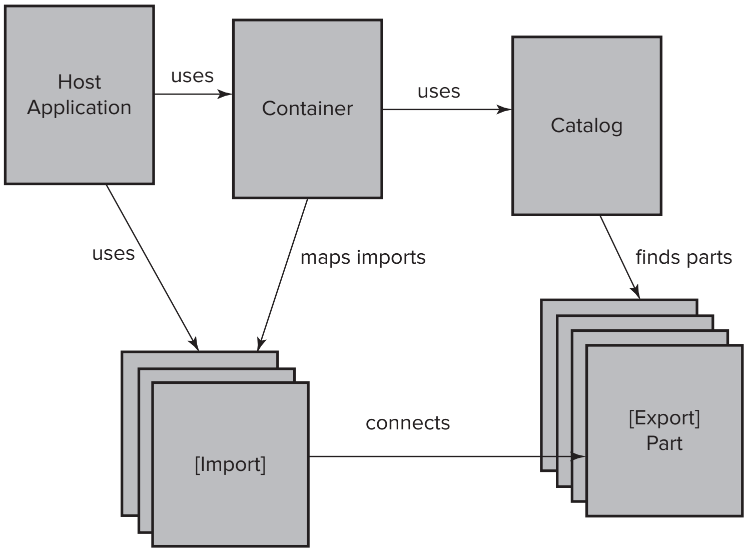

FIGURE 28-1

Here’s the full picture of how parts are loaded. Parts are found within a catalog. The catalog uses exports to find its parts. An export provider accesses the catalog to offer the exports from the catalog. Multiple export providers can be connected in chains for customizing exports, for example, with a custom export provider to only allow parts for specific users or roles. The container uses export providers to connect imports to exports and is itself an export provider.

MEF consists of three large categories: classes for hosting, primitives, and classes for the attribute-based mechanism. Hosting classes include catalogs and containers. Primitive classes can be used as base classes to extend the MEF architecture to use other techniques to connect exports and imports. And of course, the classes that make up the implementation of the attribute-based mechanism with reflection, such as the `Export` and `Import` attributes, and classes that offer extension methods make it easier to work with attribute-based parts are also part of MEF.

Let's start with a simple example to demonstrate the MEF architecture. The hosting application can dynamically load add-ins. With MEF, an add-in is referred to as a *part*. Parts are defined as *exports* and are loaded into a container that *imports* parts. The container finds parts by using a catalog. The catalog lists parts.

In this example, a simple Console application that is the host is created to host calculator-add-ins from a library. To create independence from the host and the calculator add-in, three assemblies are required. One assembly, `SimpleContract`, holds the contracts that are used by both the add-in assembly and the hosting executable. The add-in assembly `SimpleCalculator` implements the contract defined by the contract assembly. The host uses the contract assembly to invoke the add-in.

The contracts in the assembly `SimpleContract` are defined by two interfaces, `ICalculator` and `IOperation`. The `ICalculator` interface defines the methods `GetOperations()` and `Operate()`. The `GetOperations()` method returns a list of all operations that the add-in calculator supports, and with the `Operate()` method an operation is invoked. This interface is flexible in that the calculator can support different operations. If the interface defined `Add()` and `Subtract()` methods instead of the flexible `Operate()` method, a new version of the interface would be required to support `Divide()` and `Multiply()` methods. With the `ICalculator` interface as it is defined in this example, however, the calculator can offer any number of operations with any number of operands.

```
using System.Collections.Generic;

namespace Wrox.ProCSharp.MEF
{
    public interface ICalculator
    {
        IList<IOperation> GetOperations();
        double Operate(IOperation operation, double[] operands);
    }
}
```

code snippet SimpleContract/ICalculator.cs

The `ICalculator` interface uses the `IOperation` interface to return the list of operations and to invoke an operation. The `IOperation` interface defines the read-only properties `Name` and `NumberOperands`.

```
namespace Wrox.ProCSharp.MEF
{
    public interface IOperation
    {
        string Name { get; }
        int NumberOperands { get; }
    }
}
```

code snippet SimpleContract/IOperation.cs

The `SimpleContract` assembly doesn't require any reference to MEF assemblies. Only simple .NET interfaces are contained within it.

The Add-in assembly `SimpleCalculator` contains classes that implement the interfaces defined by the contracts. The class `Operation` implements the interface `IOperation`. This class contains just two properties as defined by the interface. The interface defines `get` accessors of the properties; internal `set` accessors are used to set the properties from within the assembly.

```
namespace Wrox.ProCSharp.MEF
{
    public class Operation : IOperation
    {
        public string Name { get; internal set; }
```

```
            public int NumberOperands { get; internal set; }
        }
    }
```

code snippet SimpleCalculator/Operation.cs

The `Calculator` class provides the functionality of this add-in by implementing the `ICalculator` interface. The `Calculator` class is exported as a part as defined by the `Export` attribute. This attribute is defined in the `System.ComponentModel.Composition` namespace in the `System.ComponentModel.Composition` assembly.

```
    using System;
    using System.Collections.Generic;
    using System.ComponentModel.Composition;

    namespace Wrox.ProCSharp.MEF
    {
        [Export(typeof(ICalculator))]
        public class Calculator : ICalculator
        {
            public IList<IOperation> GetOperations()
            {
                return new List<IOperation>()
                {
                    new Operation { Name="+", NumberOperands=2},
                    new Operation { Name="-", NumberOperands=2},
                    new Operation { Name="/", NumberOperands=2},
                    new Operation { Name="*", NumberOperands=2}
                };
            }

            public double Operate(IOperation operation, double[] operands)
            {
                double result = 0;
                switch (operation.Name)
                {
                    case "+":
                        result = operands[0] + operands[1];
                        break;
                    case "-":
                        result = operands[0] - operands[1];
                        break;
                    case "/":
                        result = operands[0] / operands[1];
                        break;
                    case "*":
                        result = operands[0] * operands[1];
                        break;
                    default:
                        throw new InvalidOperationException(
                            String.Format("invalid operation {0}", operation.Name));
                }
                return result;
            }
        }
    }
```

code snippet SimpleCalculator/Calculator.cs

The hosting application is a simple console application. The add-in uses an `Export` attribute to define what is exported; with the hosting application, the `Import` attribute defines what is used. Here, the `Import` attribute annotates the Calculator property that sets and gets an object implementing ICalculator. So, any calculator add-in that implements this interface can be used here.

```
using System;
using System.Collections.Generic;
using System.ComponentModel.Composition;
using System.ComponentModel.Composition.Hosting;
using Wrox.ProCSharp.MEF.Properties;

namespace Wrox.ProCSharp.MEF
{
    class Program
    {
        [Import]
        public ICalculator Calculator { get; set; }
```

code snippet SimpleHost/Program.cs

In the entry method Main() of the console application, a new instance of the Program class is created, and then the Run() method is invoked. In the Run() method, a DirectoryCatalog is created that is initialized with the AddInDirectory , which is configured in the application configuration file. Settings.Default .AddInDirectory makes use of the project property Settings to use a strongly typed class to access a custom configuration.

The CompositionContainer class is a repository of parts. This container is initialized with the DirectoryCatalog to get the parts from the directory that is served by this catalog. ComposeParts() is an extension method that extends the class CompositionContainer and is defined with the class AttributedModelServices. This method requires parts with an Import attribute passed with the arguments. Because the Program class has an Import attribute with the property Calculator, the instance of the Program class can be passed to this method. With the implementation for the imports, exports are searched and mapped. After a successful call of this method, exports mapped to the imports can be used. If not all imports can be mapped to exports, an exception of type ChangeRejectedException is thrown, which is caught to write the error message and to exit from the Run() method.

```
        static void Main()
        {
            var p = new Program();
            p.Run();
        }

        public void Run()
        {
            var catalog = new DirectoryCatalog(Settings.Default.AddInDirectory);
            var container = new CompositionContainer(catalog);
            try
            {
                container.ComposeParts(this);
            }
            catch (ChangeRejectedException ex)
            {
                Console.WriteLine(ex.Message);
                return;
            }
```

With the Calculator property, the methods from the interface ICalculator can be used. GetOperations() invokes the methods of the previously created add-in, which returns four operations. After asking the user what operation should be invoked and asking for the operand values, the add-in method Operate() is called.

```
            var operations = Calculator.GetOperations();
            var operationsDict = new SortedList<string, IOperation>();
```

```
                foreach (var item in operations)
                {
                    Console.WriteLine("Name: {0}, number operands: {1}", item.Name,
                                      item.NumberOperands);
                    operationsDict.Add(item.Name, item);
                }
                Console.WriteLine();
                string selectedOp = null;
                do
                {
                    try
                    {
                        Console.Write("Operation? ");
                        selectedOp = Console.ReadLine();
                        if (selectedOp.ToLower() == "exit" ||
                            !operationsDict.ContainsKey(selectedOp))
                            continue;

                        var operation = operationsDict[selectedOp];
                        double[] operands = new double[operation.NumberOperands];
                        for (int i = 0; i < operation.NumberOperands; i++)
                        {
                            Console.Write("\t operand {0}? ", i + 1);
                            string selectedOperand = Console.ReadLine();
                            operands[i] = double.Parse(selectedOperand);
                        }
                        Console.WriteLine("calling calculator");
                        double result = Calculator.Operate(operation, operands);
                        Console.WriteLine("result: {0}", result);
                    }
                    catch (FormatException ex)
                    {
                        Console.WriteLine(ex.Message);
                        Console.WriteLine();
                        continue;
                    }
                } while (selectedOp != "exit");
            }
        }
    }
```

The output of one sample run of the application is shown here:

```
Name: +, number operands: 2
Name: -, number operands: 2
Name: /, number operands: 2
Name: *, number operands: 2

Operation? +
         operand 1? 3
         operand 2? 5
calling calculator
result: 8
Operation? -
         operand 1? 7
         operand 2? 2
calling calculator
result: 5
Operation? exit
```

Without recompiling the host application, it is possible to use a completely different add-in library. The assembly `AdvCalculator` defines a different implementation for the `Calculator` class to offer more operations. This calculator can be used in place of the other one by copying the assembly to the directory that is specified by the `DirectoryCatalog` in the hosting application.

```
using System;
using System.Collections.Generic;
using System.ComponentModel.Composition;

namespace Wrox.ProCSharp.MEF
{
    [Export(typeof(ICalculator))]
    public class Calculator : ICalculator
    {
        public IList<IOperation> GetOperations()
        {
            return new List<IOperation>()
            {
                new Operation { Name="+", NumberOperands=2},
                new Operation { Name="-", NumberOperands=2},
                new Operation { Name="/", NumberOperands=2},
                new Operation { Name="*", NumberOperands=2},
                new Operation { Name="%", NumberOperands=2},
                new Operation { Name="++", NumberOperands=1},
                new Operation { Name="--", NumberOperands=1}
            };
        }

        public double Operate(IOperation operation, double[] operands)
        {
            double result = 0;
            switch (operation.Name)
            {
                case "+":
                    result = operands[0] + operands[1];
                    break;
                case "-":
                    result = operands[0] - operands[1];
                    break;
                case "/":
                    result = operands[0] / operands[1];
                    break;
                case "*":
                    result = operands[0] * operands[1];
                    break;
                case "%":
                    result = operands[0] % operands[1];
                    break;
                case "++":
                    result = ++operands[0];
                    break;
                case "--":
                    result = --operands[0];
                    break;
                default:
                    throw new InvalidOperationException(
                        String.Format("invalid operation {0}", operation.Name));
            }
            return result;
        }
    }
}
```

code snippet AdvCalculator/Calculator.cs

Now you've seen imports, exports, and catalogs from the MEF architecture. Let's get into the details and different options of MEF by using a WPF application to host add-ins.

CONTRACTS

The following sample application extends the first one. The hosting application is a WPF application that loads calculator add-ins for calculation functionality and other add-ins that bring their own user interface into the host.

For the calculation, the same contracts that were defined earlier are used: `ICalculator` and `IOperation`. Another contract is `ICalculatorExtension`. This interface defines the `Title` and `Description` properties that can be used by the hosting application. The method `GetUI()` returns a `FrameworkElement` that allows the add-in to return any WPF element that derives from `FrameworkElement` to be shown as the user interface within the host.

```
using System.Windows;

namespace Wrox.ProCSharp.MEF
{
    public interface ICalculatorExtension
    {
        string Title { get; }
        string Description { get; }

        FrameworkElement GetUI();
    }
}
```

code snippet CalculatorContract/ICalculatorExtension.cs

.NET interfaces make a good contract between the hosting application and the add-in. If the interface is defined in a separate assembly, as with the `CalculatorContract` assembly, the hosting application and the add-in don't have a direct dependency. Instead, the hosting application and the add-in just reference the contract assembly.

From a MEF standpoint, an interface contract is not required at all. The contract can be a simple string. To avoid conflicts with other contracts, the name of the string should contain a namespace name, for example, `Wrox.ProCSharp.MEF.SampleContract`, as shown in the following code snippet. Here, the class `Foo` is exported by using the `Export` attribute and a string passed to the attribute instead of the interface.

```
    [Export("Wrox.ProCSharp.MEF.SampleContract")]
    public class Foo
    {
        public string Bar()
        {
            return "Foo.Bar";
        }
    }
```

The problem with using a contract as a string is that the methods, properties, and events provided by the type are not strongly defined. Either the caller needs a reference to the type `Foo` to use it, or .NET reflection can be used to access its members. The C# 4 `dynamic` keyword makes reflection easier to use and can be very helpful in such scenarios.

The hosting application can use the `dynamic` type to import a contract with the name `Wrox.ProCSharp.MEF.SampleContract`:

```
[Import("Wrox.ProCSharp.MEF.SampleContract")]
public dynamic Foo { get; set; }
```

With the `dynamic` keyword, the `Foo` property can now be used to access the `Bar()` method directly. The call to this method is resolved during runtime:

```
string s = Foo.Bar();
```

The `dynamic` *type is explained in Chapter 12, "Dynamic Language Extensions."*

Contract names and interfaces can also be used in conjunction to define that the contract is used only if both the interface and the contract name are the same. This way, you can use the same interface for different contracts.

EXPORTS

In the previous example, you saw the part `SimpleCalculator`, which exports the type `Calculator` with all its methods and properties. The following example contains the `SimpleCalculator` as well, with the same implementation that was shown previously. Another part that is used here is a WPF User Control library named `TemperatureConversion` that defines a user interface, as shown in Figure 28-2. This control provides conversion between Celsius, Fahrenheit, and Kelvin scales. With the first and second combo box, the conversion source and target can be selected. The `Calculate` button starts the calculation to do the conversion.

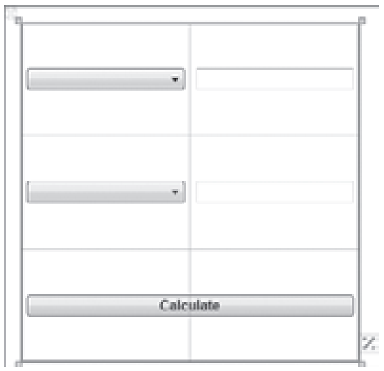

FIGURE 28-2

The user control has a simple implementation for temperature conversion. The enumeration `TempConversionType` defines the different conversions that are possible with that control. The enumeration values are shown in the two combo boxes by setting the `DataContext` property of the user control in the constructor. The method `ToCelsiusFrom()` converts the argument *t* from its original value to Celsius. The temperature source type is defined with the second argument `TempConversionType`. The method `FromCelsiusTo()` converts a Celsius value to the selected temperature scale. The method `OnCalculate()` is the handler of the `Button.Click` event and invokes the `ToCelsiusFrom()` and `FromCelsiusTo()` methods to do the conversion according to the user's selected conversion type.

```
using System;
using System.Windows;
using System.Windows.Controls;

namespace Wrox.ProCSharp.MEF
{
    public enum TempConversionType
    {
        Celsius,
        Fahrenheit,
        Kelvin
    }

    public partial class TemperatureConversion : UserControl
    {
        public TemperatureConversion()
        {
            InitializeComponent();
            this.DataContext = Enum.GetNames(typeof(TempConversionType));
        }

        private double ToCelsiusFrom(double t, TempConversionType conv)
        {
            switch (conv)
            {
                case TempConversionType.Celsius:
                    return t;
                case TempConversionType.Fahrenheit:
                    return (t - 32) / 1.8;
                case TempConversionType.Kelvin:
                    return (t - 273.15);
                default:
                    throw new ArgumentException("invalid enumeration value");
            }
        }

        private double FromCelsiusTo(double t, TempConversionType conv)
        {
            switch (conv)
            {
                case TempConversionType.Celsius:
                    return t;
                case TempConversionType.Fahrenheit:
                    return (t * 1.8) + 32;
                case TempConversionType.Kelvin:
                    return t + 273.15;
                default:
                    throw new ArgumentException("invalid enumeration value");
            }
        }

        private void OnCalculate(object sender, System.Windows.RoutedEventArgs e)
        {
            try
            {
                TempConversionType from;
                TempConversionType to;
                if (Enum.TryParse<TempConversionType>(
                        (string)comboFrom.SelectedValue, out from) &&
                    Enum.TryParse<TempConversionType>(
                        (string)comboTo.SelectedValue, out to))
                {
                    double result = FromCelsiusTo(
                        ToCelsiusFrom(double.Parse(textInput.Text), from), to);
                    textOutput.Text = result.ToString();
                }

            }
            catch (FormatException ex)
            {
                MessageBox.Show(ex.Message);
            }
        }
    }
}
```

code snippet TemperatureConversion/TemperatureConversion.xaml.cs

So far, this control is just a simple WPF user control. To create a MEF part, the class `TemperatureCalculatorExtension` is exported by using the `Export` attribute. The class implements the interface `ICalculatorExtension`, offering `Title` and `Description` information, and returning the `UserControl TemperatureConversion` from the `GetUI()` method.

```
using System.ComponentModel.Composition;
using System.Windows;

namespace Wrox.ProCSharp.MEF
{
    [Export(typeof(ICalculatorExtension))]
    public class TemperatureCalculatorExtension : ICalculatorExtension
    {
        public string Title
        {
            get { return "Temperature Conversion"; }
        }

        public string Description
        {
            get { return "Convert Celsius to Fahrenheit and " +
                         "Fahrenheit to Celsius"; }
        }

        public FrameworkElement GetUI()
        {
            return new TemperatureConversion();
        }
    }
}
```

code snippet TemperatureConversion/TemperatureCalculatorExtension.cs

Another user control that implements the interface `ICalculatorExtension` is `FuelEconomy`. With this control either miles per gallon or liters per 100 km can be calculated.

```
using System.Collections.Generic;
using System.Windows;
using System.Windows.Controls;

namespace Wrox.ProCSharp.MEF
{
    public partial class FuelEconomyUC : UserControl
    {
        private List<FuelEconomyType> fuelEcoTypes;

        public FuelEconomyUC()
        {
            InitializeComponent();
            InitializeFuelEcoTypes();
        }

        private void InitializeFuelEcoTypes()
        {
            var t1 = new FuelEconomyType
            {
                Id = "lpk",
                Text = "L/100 km",
                DistanceText = "Distance (kilometers)",
                FuelText = "Fuel used (liters)"
            };
            var t2 = new FuelEconomyType
            {
                Id = "mpg",
                Text = "Miles per gallon",
                DistanceText = "Distance (miles)",
                FuelText = "Fuel used (gallons)"
            };
            fuelEcoTypes = new List<FuelEconomyType>() { t1, t2 };
            this.DataContext = fuelEcoTypes;
        }

        private void OnCalculate(object sender, RoutedEventArgs e)
        {
            double fuel = double.Parse(textFuel.Text);
            double distance = double.Parse(textDistance.Text);
            FuelEconomyType ecoType = comboFuelEco.SelectedItem as FuelEconomyType;
            double result = 0;
            switch (ecoType.Id)
            {
                case "lpk":
                    result = fuel / (distance / 100);
                    break;
                case "mpg":
                    result = distance / fuel;
                    break;
                default:
                    break;
            }
            this.textResult.Text = result.ToString();
        }
    }
}
```

code snippet FuelEconomy/FuelEconomyUC.xaml.cs

Again, the interface `ICalculatorExtension` is implemented and exported with the `Export` attribute:

```
using System.ComponentModel.Composition;
using System.Windows;

namespace Wrox.ProCSharp.MEF
{
    [Export(typeof(ICalculatorExtension))]
    public class FuelCalculatorExtension : ICalculatorExtension
    {
        public string Title
        {
            get { return "Fuel Economy"; }
        }

        public string Description
        {
            get { return "Calculate fuel economy"; }
        }

        public FrameworkElement GetUI()
        {
            return new FuelEconomyUC();
        }
    }
}
```

code snippet FuelEconomy/FuelCalculatorExtension.cs

Before continuing the WPF calculator example to import the user controls, let's take a look at what other options you have with exports. With exports you can not only export complete types but also properties and methods, and also add metadata information to the exports.

Exporting Properties and Methods

Instead of exporting complete classes with properties, methods, and events, it is possible to export just properties or methods. Exporting properties makes it possible to use classes that you don't have under control by adding the `Export` attribute to them (for example, classes from the .NET Framework or third-party libraries). For this, you just have to define a property of this specific type and export the property.

Exporting methods allows for a finer control than with types. The caller doesn't need to know about the type. Methods are exported with the help of delegates. The following code snippet defines the `Add()` and `Subtract()` methods with exports. The type of the export is the delegate `Func<double, double, double>`, which is a delegate that accepts two double parameters and a double return type. For methods without return types, the `Action<T>` delegate can be used.

> *You can read about the* `Func<T>` *and* `Action<T>` *delegates in Chapter 8, "Delegates, Lambdas, and Events."*

```
using System;
using System.ComponentModel.Composition;

namespace Wrox.ProCSharp.MEF
{
    public class Operations
    {
        [Export("Add", typeof(Func<double, double, double>))]
        public double Add(double x, double y)
        {
            return x + y;
        }

        [Export("Subtract", typeof(Func<double, double, double>))]
        public double Subtract(double x, double y)
        {
            return x - y;
        }
    }
}
```

code snippet Operations/Operations.cs

The exported methods are imported from the `SimpleCalculator` add-in. A part itself can use other parts. For using the exported methods, delegates are declared with the attribute `Import`. This attribute contains the same name and the delegate type that was declared with the export.

> `SimpleCalculator` *itself is a part that exports the* `ICalculator` *interface and consists of parts that are imported.*

```
    [Export(typeof(ICalculator))]
    public class Calculator : ICalculator
    {
        [Import("Add", typeof(Func<double, double, double>))]
        public Func<double, double, double> Add { get; set; }
    [Import("Subtract", typeof(Func<double, double, double>))]
    public Func<double, double, double> Subtract { get; set; }
```

code snippet SimpleCalculator/Calculator.cs

The imported methods that are represented by the `Add` and `Subtract` delegates are invoked via these delegates in the `Operate()` method.

```
public double Operate(IOperation operation, double[] operands)
  {
      double result = 0;
      switch (operation.Name)
      {
          case "+":
              result = Add(operands[0], operands[1]);
              break;
          case "-":
              result = Subtract(operands[0], operands[1]);
              break;
          case "/":
              result = operands[0] / operands[1];
              break;
          case "*":
              result = operands[0] * operands[1];
              break;
          default:
              throw new InvalidOperationException(
                  String.Format("invalid operation {0}", operation.Name));
      }
      return result;
  }
```

code snippet SimpleCalculator/Calculator.cs

Exporting Metadata

With exports, you can also attach metadata information. Metadata allows you to add information in addition to a name and a type. This can be used to add capability information and decide on the import side which of the exports should be used.

The exported `Add()` method is now changed to add speed capabilities with the attribute `ExportMetadata`:

```
    [Export("Add", typeof(Func<double, double, double>))]
    [ExportMetadata("speed", "fast")]
    public double Add(double x, double y)
    {
        return x + y;
    }
```

code snippet Operations/Operation.cs

To have the option to choose from another implementation of the `Add()` method, another method with different speed capabilities but the same delegate type and name is implemented:

```
public class Operations2
{
    [Export("Add", typeof(Func<double, double, double>))]
    [ExportMetadata("speed", "slow")]
    public double Add(double x, double y)
    {
            Thread.Sleep(3000);
            return x + y;
        }
    }
```

code snippet Operations/Operation2.cs

Because there is more than one exported `Add` method available, the import definition must be changed. The attribute `ImportMany` is used if more than one export of the same name and type is available. This attribute is applied to an array or `IEnumeration<T>` interface. `ImportMany` is explained with more detail in the next section. For accessing metadata, an array of `Lazy<T, TMetadata>` can be used. The class `Lazy<T>` is new in .NET 4 and is used to support lazy initialization of types on first use. `Lazy<T, TMetadata>` derives from `Lazy<T>` and supports, in addition to the base class, access to metadata information with the `Metadata` property. In the sample, the method is referenced by the delegate `Func<double, double, double>`, which is the first generic parameter of `Lazy<T, TMetadata>`. The second generic parameter is `IDictionary<string, object>` for the metadata collection. The `ExportMetadata` attribute can be used multiple times to add more than one capability, and always consists of a key of type string and a value of type object.

```
        [ImportMany("Add", typeof(Func<double, double, double>))]
        public Lazy<Func<double, double, double>, IDictionary<string, object>>[]
                AddMethods { get; set; }

        //[Import("Add", typeof(Func<double, double, double>))]
        //public Func<double, double, double> Add { get; set; }
```

code snippet SimpleCalculator/Calculator.cs

The call to the `Add` method is now changed to iterate through the collection of `Lazy<Func<double, double, double>, IDictionary<string, object>>` elements. With the `Metadata` property, the key for the capability is checked; if the speed capability has the value `fast`, the operation is invoked by using the `Value` property of `Lazy<T>` to get to the delegate:

```
                case "+":
                    // result = Add(operands[0], operands[1]);
                    foreach (var addMethod in AddMethods)
                    {
                        if (addMethod.Metadata.ContainsKey("speed") &&
                                (string)addMethod.Metadata["speed"] == "fast")
                            result = addMethod.Value(operands[0], operands[1]);
                    }
                    // result = operands[0] + operands[1];
                    break;
```

Instead of using the attribute `ExportMetadata`, you can create a custom export attribute class that derives from `ExportAttribute`. The class `SpeedExportAttribute` defines an additional `Speed` property that is of type `Speed`:

```
using System;
using System.ComponentModel.Composition;

namespace Wrox.ProCSharp.MEF
{
    public enum Speed
    {
        Fast,
        Slow
    }

    [MetadataAttribute]
    [AttributeUsage(AttributeTargets.Method | AttributeTargets.Class)]
    public class SpeedExportAttribute : ExportAttribute
```

```
        {
            public SpeedExportAttribute(string contractName, Type contractType)
                : base(contractName, contractType) { }

            public Speed Speed { get; set; }
        }
    }
```

code snippet CalculatorUtils/ExportAttribute.cs

To get more information about how to create custom attributes, read Chapter 14, "Reflection."

With the exported `Add()` method, now the `SpeedExport` attribute can be used instead of the `Export` and `ExportMetadata` attributes:

```
        [SpeedExport("Add", typeof(Func<double, double, double>), Speed=Speed.Fast)]
        public double Add(double x, double y)
        {
            return x + y;
        }
```

code snippet Operations/Operations.cs

For the import, an interface with all the metadata is required. This makes it possible to access the strongly typed capabilities. The capabilities that are defined by the attribute `SpeedExport` are just the speed. The interface `ISpeedCapabilities` defines the property `Speed` by using the same enumeration type `Speed` that was used with the `SpeedExport` attribute:

```
    namespace Wrox.ProCSharp.MEF
    {
        public interface ISpeedCapabilities
        {
            Speed Speed { get; }
        }
    }
```

code snippet CalculatorUtils/ISpeedCapabilities.cs

Now it's possible to change the definition of the import by using the interface `ISpeedCapabilities` instead of the dictionary defined earlier:

```
        [ImportMany("Add", typeof(Func<double, double, double>))]
        public Lazy<Func<double, double, double>, ISpeedCapabilities>[]
                AddMethods { get; set; }
```

code snippet SimpleCalculator/Calculator.cs

Using the imports, the `Speed` property of the interface, `ISpeedCapability`, can now be used directly:

```
                foreach (var addMethod in AddMethods)
                {
                    if (addMethod.Metadata.Speed == Speed.Fast)
                        result = addMethod.Value(operands[0], operands[1]);
                }
```

IMPORTS

Now let's get into using the WPF User Controls with a WPF hosting application. The design view of the hosting application is shown in Figure 28-3. The application WPFCalculator is a WPF application that loads the functional calculator add-in, which implements the interfaces `ICalculator` and `IOperation`, and add-ins with user interfaces that implement the interface ICalculatorExtension. To connect to the exports of the parts, you need imports.

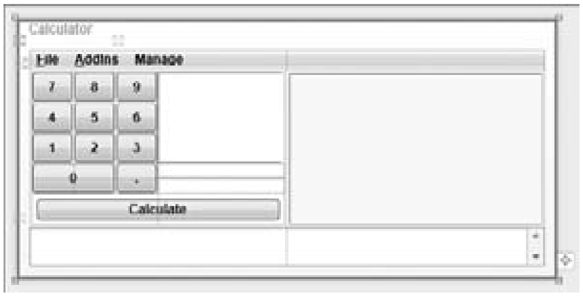

FIGURE 28-3

An import connects to an export. When using exported parts, an import is needed to make the connection. With the Import attribute, it's possible to connect to a single export. If more than one add-in should be loaded, the ImportMany attribute is required and needs to be defined as an array type or IEnumerable<T>. Because the hosting calculator application allows many calculator extensions that implement the interface ICalculatorExtension to be loaded, the class CalculatorExtensionImport defines the property CalculatorExtensions of type IEnumerable <ICalculatorExtension> to access all the calculator extension parts.

```
using System.Collections.Generic;
using System.ComponentModel.Composition;

namespace Wrox.ProCSharp.MEF
{
    public class CalculatorExtensionImport
    {
        [ImportMany(AllowRecomposition=true)]
        public IEnumerable<ICalculatorExtension> CalculatorExtensions { get; set; }
    }
}
```

code snippet WPFCalculator/CalculatorExtensionImport.cs

The Import and ImportMany attributes allow the use of ContractName and ContractType to map the import to an export. Other properties that can be set with these attributes are AllowRecomposition and RequiredCreationPolicy. AllowRecomposition allows dynamic mapping to new exports while the application is running, and also the unloading of exports. With RequiredCreationPolicy, you can choose if the parts should be shared (CreationPolicy.Shared) or not shared (CreationPolicy.NonShared) between requestors, or if the policy should be defined by the container (CreationPolicy.Any).

To see that all imports are successful, the interface IPartImportsSatisfiedNotification can be implemented. This interface just defines a single method, OnImportsSatifsifed(), that is called when all imports of the class are successful. In the CalculatorImport class, the method fires an ImportsSatisfied event:

```
using System;
using System.ComponentModel.Composition;
using System.Windows.Controls;

namespace Wrox.ProCSharp.MEF
{
    public class CalculatorImport : IPartImportsSatisfiedNotification
    {
        public event EventHandler<ImportEventArgs> ImportsSatisfied;

        [Import(typeof(ICalculator))]
        public ICalculator Calculator { get; set; }

        public void OnImportsSatisfied()
       {
            if (ImportsSatisfied != null)
```

```
                ImportsSatisfied(this, new ImportEventArgs {
                        StatusMessage = "ICalculator import successful" });
            }
        }
    }
```

code snippet WPFCalculator/CalculatorImport.cs

The event of the `CalculatorImport` is connected to an event handler on creation of the `CalculatorImport` to write a message to a `TextBlock` for displaying status information:

```
private void InitializeContainer()
{
    var catalog = new DirectoryCatalog(
                          Properties.Settings.Default.AddInDirectory);
    container = new CompositionContainer(catalog);
    calcImport = new CalculatorImport();
    calcImport.ImportsSatisfied += (sender, e) =>
      {
            textStatus.Text += String.Format("{0}\n", e.StatusMessage);
      };
    container.ComposeParts(calcImport);

    InitializeOperations();
}
```

code snippet WPFCalculator/MainWindow.xaml.cs

Lazy Loading of Parts
