By default, parts are loaded from the container, for example, by calling the extension method `ComposeParts()` on the `CompositionContainer`. With the help of the `Lazy<T>` class, the parts can be loaded on first access. The type `Lazy<T>` allows the late instantiation of any type `T` and defines the properties `IsValueCreated` and `Value`. `IsValueCreated` is a Boolean that returns the information if the contained type `T` is already instantiated. `Value` initializes the contained type `T` on first access and returns the instance.

The import of an add-in can be declared to be of type `Lazy<T>`, as shown in the `Lazy<ICalculator>` example.

```
[Import(typeof(ICalculator))]
public Lazy<ICalculator> Calculator { get; set; }
```

code snippet WPFCalculator/CalculatorImport.cs

Calling the imported property also requires some changes to access the `Value` property of the `Lazy<T>` type. `calcImport` is a variable of type `CalculatorImport`. The `Calculator` property returns `Lazy<ICalculator>`. The `Value` property instantiates the imported type lazily and returns the `ICalculator` interface, where now the `GetOperations()` method can be invoked to get all supported operations from the calculator add-in.

```
private void InitializeOperations()
{
    Contract.Requires(calcImport != null);
    Contract.Requires(calcImport.Calculator != null);

    var operators = calcImport.Calculator.Value.GetOperations();
    foreach (var op in operators)
    {
        var b = new Button();
        b.Width = 40;
```

```
                b.Height = 30;
                b.Content = op.Name;
                b.Margin = new Thickness(2);
                b.Padding = new Thickness(4);
                b.Tag = op;
                b.Click += new RoutedEventHandler(DefineOperation);
                listOperators.Items.Add(b);
            }
        }
```

code snippet WPFCalculator/MainWindow.xaml.cs

CONTAINERS AND EXPORT PROVIDERS

The import of parts happens with help of a container. The types for hosting parts are defined in the namespace `System.ComponentModel.Composition.Hosting`. The class `CompositionContainer` is the container for parts. In the constructor of this class, multiple `ExportProvider` objects can be assigned, as well as a `ComposablePartCatalog`. Catalogs are sources of parts and are discussed in the next section. Export providers allow you to access all exports programmatically with overloaded `GetExport<T>()` methods. An export provider is used to access the catalog, and the `CompositionContainer` itself is an export provider. This makes it possible to nest containers in other containers.

Parts are loaded when the `Compose()` method is invoked (if they are not lazy loaded). So far, we've always used the `ComposePart()` method, as shown in the `InitializeContainer()` method:

```
        private void InitializeContainer()
        {
            catalog = new DirectoryCatalog(
                              Properties.Settings.Default.AddInDirectory);
            container = new CompositionContainer(catalog);
            calcImport = new CalculatorImport();
            calcImport.ImportsSatisfied += (sender, e) =>
                {
                    textStatus.Text += String.Format("{0}\n", e.StatusMessage);
                };
            container.ComposeParts(calcImport);

            InitializeOperations();
        }
```

code snippet WPFCalculator/MainWindow.xaml.cs

`ComposePart()` is an extension method defined with the class `AttributedModelServices`. This class provides methods that use attributes and .NET reflection to access part information and add parts to the container. Instead of using this extension method, the `Compose()` method of `CompositionContainer` can be used. The `Compose()` method works with the class `CompositionBatch`. A `CompostionBatch` can be used to define which parts should be added and which parts should be removed from the container. The methods `AddPart()` and `RemovePart()` have overloads where either an attributed part can be added (`calcImport` is an instance of the `CalculatorImport` class and contains `Import` attributes) or a part that derives from the base class `ComposablePart`.

```
            var batch = new CompositionBatch();
            batch.AddPart(calcImport);
            container.Compose(batch);
```

The hosting application WPFCalculator loads two different kinds of parts. The first part implements the `ICalculator` interface and is loaded in the `InitializeContainer` method shown previously. The parts that implement the interface `ICalculatorExtension` are loaded in the `RefreshExtensions` method. `Container.ComposeParts` gets the import from the `CalculatorExtensionImport` class and connects it to all available exports from the catalog. Because here multiple add-ins are dynamically loaded (the user can select the add-in to use), the `Menu` control is dynamically extended. The application iterates through all the calculator extensions, and a new `MenuItem` is created for each extension. The header of the `MenuItem` control contains a `Label` with the `Title` property of the extension and a `CheckBox`. The `CheckBox` will later be used to remove the export dynamically. The `ToolTip` property of the `MenuItem` is set to the `Description` property of the extender control. The `Tag` property is set to the extender control itself, which makes it easy to get to the extender control when the menu item is selected. The `Click` event of the `MenuItem` is set to the method `ShowAddIn()`. This method invokes the `GetUI()` method of the extender control for displaying the control within a new `TabItem` of a `TabControl`.

```
private void RefreshExensions()
{
    catalog.Refresh();
    calcExtensionImport = new CalculatorExtensionImport();
    calcExtensionImport.ImportsSatisfied += (sender, e) =>
        {
            this.textStatus.Text += String.Format("{0}\n", e.StatusMessage);
        };

    container.ComposeParts(calcExtensionImport);
    menuAddins.Items.Clear();
    foreach (var extension in calcExtensionImport.CalculatorExtensions)
    {
        var menuItemHeader = new StackPanel { Orientation = Orientation.Horizontal };
        menuItemHeader.Children.Add(new Label { Content = extension.Title });
        var menuCheck = new CheckBox { IsChecked = true };
        menuItemHeader.Children.Add(menuCheck);

        var menuItem = new MenuItem {
                                      Header = menuItemHeader,
                                      ToolTip = extension.Description,
                                      Tag = extension
                                    };
        menuCheck.Tag = menuItem;
        menuItem.Click += ShowAddIn;
        menuAddins.Items.Add(menuItem);
    }
}

private void ShowAddIn(object sender, RoutedEventArgs e)
{
    var mi = e.Source as MenuItem;
    var ext = mi.Tag as ICalculatorExtension;
    FrameworkElement uiControl = ext.GetUI();
    var headerPanel = new StackPanel { Orientation = Orientation.Horizontal };
    headerPanel.Children.Add(new Label { Content = ext.Title });
    var closeButton = new Button { Content = "X" };
    var ti = new TabItem { Header = headerPanel, Content = uiControl };
    closeButton.Click += delegate
        {
            tabExtensions.Items.Remove(ti);
        };
    headerPanel.Children.Add(closeButton);

    tabExtensions.SelectedIndex = tabExtensions.Items.Add(ti);
}
```

code snippet WPFCalculator/MainWindow.xaml.cs

To remove exports dynamically, the `Unchecked` event is set in the `CheckBox` control that's within the `MenuItem` header. The `ICalculatorExtension` can be accessed from the `Tag` property of the `MenuItem` control because it was set in the previous code snippet. To remove a part from the container, a `CompositeBatch` object must be created that contains parts for removal. The `RemovePart()` method of the `CompositeBatch` class requires a `ComposablePart` object; there's no overload for attributed objects. With the help of the class `AttributedModelServices` from an attributed object, a `ComposablePart` can be created with the `CreatePart()` method. The `CompositonBatch` is then passed to the `Compose()` method of the `CompositionContainer` to remove the part from it:

```
menuCheck.Unchecked += (sender1, e1) =>
    {
        MenuItem mi = (sender1 as CheckBox).Tag as MenuItem;
        ICalculatorExtension ext = mi.Tag as ICalculatorExtension;
        ComposablePart part =
                AttributedModelServices.CreatePart(ext);
        var batch = new CompositionBatch();
        batch.RemovePart(part);
        container.Compose(batch);
        MenuItem parentMenu = mi.Parent as MenuItem;
        parentMenu.Items.Remove(mi);
    };
```

Removing parts is only possible if the `AllowRecomposition` *property of the* `Import` *attribute is set to* `true`.

With an export provider, you can get information on exports added and removed by implementing a handler to the `ExportsChanged` event. The parameter `e` of type `ExportsChangedEventArgs` contains a list of added exports and removed exports that are written to a `TextBlock` control:

```
var container = new CompositionContainer(catalog);
container.ExportsChanged += (sender, e) =>
    {
        var sb = new StringBuilder();

        foreach (var item in e.AddedExports)
        {
            sb.AppendFormat("added export {0}\n", item.ContractName);
        }
        foreach (var item in e.RemovedExports)
        {
            sb.AppendFormat("removed export {0}\n", item.ContractName);
        }
        this.textStatus.Text += sb.ToString();
    };
```

CATALOGS

A catalog defines where MEF searches for requested parts. The sample application uses a `DirectoryCatalog` to load the assemblies with parts from a specified directory. With the `DirectoryCatalog`, you can get change information with the `Changed` event and iterate through all added and removed definitions. The `DirectoryCatalog` does not itself register to file system changes. Instead, you need to invoke the `Refresh()` method of the `DirectoryCatalog`, and if changes were made since the last read, the `Changing` and `Changed` events are fired.

```
private void InitializeContainer()
{
    catalog = new DirectoryCatalog(Properties.Settings.Default.AddInDirectory);
    container = new CompositionContainer(catalog);
```

```
            catalog.Changed += (sender, e) =>
                {
                    var sb = new StringBuilder();

                    foreach (var definition in e.AddedDefinitions)
                    {
                        foreach (var metadata in definition.Metadata)
                        {
                            sb.AppendFormat(
                                             "added definition with metadata - key: {0}, " +
                                             "value: {1}\n", metadata.Key, metadata.Value);
                        }
                    }

                    foreach (var definition in e.RemovedDefinitions)
                    {
                        foreach (var metadata in definition.Metadata)
                        {
                            sb.AppendFormat(
                                             "removed definition with metadata - key: {0}, " +
                                             "value: {1}\n", metadata.Key, metadata.Value);
                        }
                    }
                    this.textStatus.Text += sb.ToString();
                };
                //...
```

code snippet WPFCalculator/MainWindow.xaml.cs

To get immediate notification of new add-ins loaded to a directory, you can use the `System.IO.FileSystemWatcher` *to register for changes on the add-in directory, and invoke the* `Refresh` *method of the* `DirectoryCatalog` *with the* `Changed` *event of the* `FileSystemWatcher`.

The `CompositionContainer` just needs a `ComposablePartCatalog` to find parts. `DirectoryCatalog` derives from `ComposablePartCatalog`. Other catalogs are `AssemblyCatalog`, `TypeCatalog`, and `AggregateCatalog`. Let's compare all these catalogs:

- The `DirectoryCatalog` searches parts within a directory.
- The `AssemblyCatalog` searches for parts directly within a referenced assembly. Contrary to the `DirectoryCatalog`, where assemblies might change in the directory during runtime, the `AssemblyCatalog` is immutable and parts cannot change.
- The `TypeCatalog` searches for imports within a list of types. `IEnumerable<Type>` can be passed to the constructor of this catalog.
- The `AggregateCatalog` is a catalog of catalogs. This catalog can be created from multiple `ComposablePartCatalog` objects and searches in all these catalogs. For example, you can create an `AssemblyCatalog` to search for imports within an assembly, two `DirectoryCatalog` objects to search in two different directories, and an `AggregateCatalog` that combines the three catalogs for import searches.

When running the sample application (see Figure 28-4), the `SimpleCalculator` add-in is loaded, and you can do some calculations with operations supported by the add-in. From the AddIns menu, you can start add-ins that implement the interface `ICalculatorExtender` and see the user interface from these add-ins in the tab control. Information about exports and changes in the directory catalog is shown with the status information at the bottom. You can also remove an `ICalculatorExtender` add-in from the add-in directory (while the application is not running), copy the add-in to the directory while the application is running, and do a refresh of the add-ins to see the new add-ins during runtime.

FIGURE 28-4

SUMMARY

In this chapter, you read about a new technology in .NET 4: MEF. The MEF implementation uses attributes to find and connect add-ins. You saw how add-ins can be created and loaded and the possibilities for using interfaces or methods with exports. You learned how catalogs can be used to find add-ins dynamically and how to use containers to map imports to exports.

This book has another chapter on add-ins: online Chapter 50 is about MAF, which offers a better separation between hosts and add-ins via separate appdomains and separate processes, but also has a higher development cost.

The next chapter is on reading and writing files, directories, and the registry.

29

Manipulating Files and the Registry

WHAT'S IN THIS CHAPTER?

- ➤ Exploring the directory structure
- ➤ Moving, copying, and deleting files and folders
- ➤ Reading and writing text in files
- ➤ Reading and writing keys in the registry
- ➤ Reading and writing to isolated storage

This chapter examines how to perform tasks involving reading from and writing to files and the C# system registry. Microsoft has provided very intuitive object models covering these areas, and in this chapter, you learn how to use .NET base classes to perform the listed tasks. In the case of file system operations, the relevant classes are almost all found in the `System.IO` namespace, whereas registry operations are dealt with by classes in the `Microsoft.Win32` namespace.

The .NET base classes also include a number of classes and interfaces in the `System.Runtime.Serialization` *namespace concerned with serialization — that is, the process of converting data (for example, the contents of a document) into a stream of bytes for storage. This chapter does not focus on these classes; it focuses on the classes that give you direct access to files.*

Note that security is particularly important when modifying either files or registry entries. Security is covered entirely in Chapter 21, "Security." In this chapter, however, we assume that you have sufficient access rights to run all the examples that modify files or registry entries, which should be the case if you are running from an account with administrator privileges.

MANAGING THE FILE SYSTEM

The classes that are used to browse around the file system and perform operations such as moving, copying, and deleting files are shown in Figure 29-1.

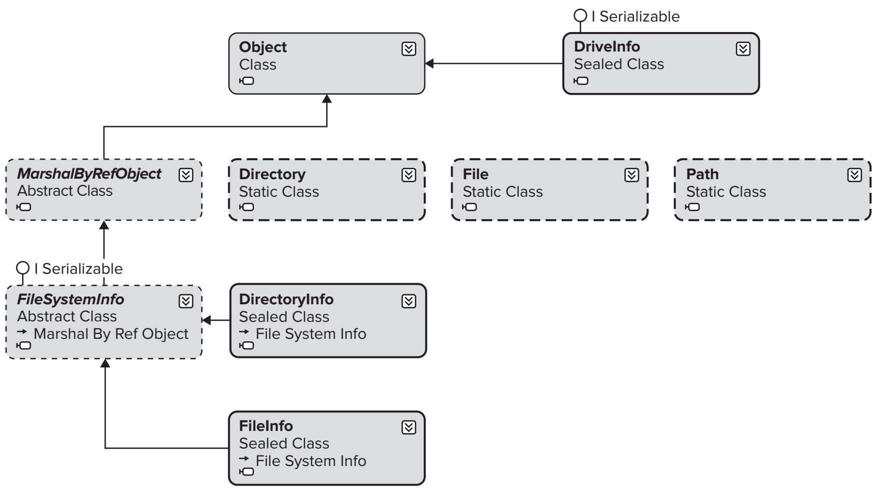

FIGURE 29-1

The following list explains the function of these classes:

- `System.MarshalByRefObject` — This is the base object class for .NET classes that are remotable; it permits marshaling of data between application domains. The rest of the items in this list are part of the `System.IO` namespace.
- `FileSystemInfo` — This is the base class that represents any file system object.
- `FileInfo` and `File` — These classes represent a file on the file system.
- `DirectoryInfo` and `Directory` — These classes represent a folder on the file system.
- `Path` — This class contains static members that you can use to manipulate pathnames.
- `DriveInfo` — This class provides properties and methods that provide information on a selected drive.

.NET Classes That Represent Files and Folders

You will notice from the previous list that two classes are used to represent a folder and two classes are used to represent a file. Which one of these classes you use depends largely on how many times you need to access that folder or file:

- `Directory` and `File` contain only static methods and are never instantiated. You use these classes by supplying the path to the appropriate file system object whenever you call a member method. If you want to do only one operation on a folder or file, using these classes is more efficient because it saves the overhead of instantiating a .NET class.

- ➤ `DirectoryInfo` and `FileInfo` implement roughly the same public methods as `Directory` and `File`, as well as some public properties and constructors, but they are stateful and the members of these classes are not static. You need to instantiate these classes before each instance is associated with a particular folder or file. This means that these classes are more efficient if you are performing multiple operations using the same object. That's because they read in the authentication and other information for the appropriate file system object on construction, and then do not need to read that information again, no matter how many methods you call against each object (class instance). In comparison, the corresponding stateless classes need to check the details of the file or folder again with every method you call.

In this section, you are mostly using the `FileInfo` and `DirectoryInfo` classes, but it so happens that many (though not all) of the methods called are also implemented by `File` and `Directory` (although in those cases these methods require an extra parameter — the pathname of the file system object; also, a couple of the methods have slightly different names). For example:

```
FileInfo myFile = new FileInfo(@"C:\Program Files\My Program\ReadMe.txt");
myFile.CopyTo(@"D:\Copies\ReadMe.txt");
```

has the same effect as:

```
File.Copy(@"C:\Program Files\My Program\ReadMe.txt", @"D:\Copies\ReadMe.txt");
```

The first code snippet takes slightly longer to execute because of the need to instantiate a `FileInfo` object, `myFile`, but it leaves `myFile` ready for you to perform further actions on the same file. By using the second example, there is no need to instantiate an object to copy the file.

You can instantiate a `FileInfo` or `DirectoryInfo` class by passing to the constructor a string containing the path to the corresponding file system object. You have just seen the process for a file. For a folder, the code looks similar:

```
DirectoryInfo myFolder = new DirectoryInfo(@"C:\Program Files");
```

If the path represents an object that does not exist, an exception will not be thrown at construction, but will instead be thrown the first time that you call a method that actually requires the corresponding file system object to be there. You can find out whether the object exists and is of the appropriate type by checking the `Exists` property, which is implemented by both of these classes:

```
FileInfo test = new FileInfo(@"C:\Windows");
Console.WriteLine(test.Exists.ToString());
```

Note that for this property to return `true`, the corresponding file system object must be of the appropriate type. In other words, if you instantiate a `FileInfo` object supplying the path of a folder, or you instantiate a `DirectoryInfo` object, giving it the path of a file, `Exists` will have the value `false`. Most of the properties and methods of these objects will return a value if possible — they won't necessarily throw an exception just because the wrong type of object has been called, unless they are asked to do something that really is impossible. For example, the preceding code snippet might first display `false` (because `C:\Windows` is a folder). However, it still displays the time the folder was created because a folder still has that information. But if you tried to open the folder as if it were a file, using the `FileInfo.Open()` method, you'd get an exception.

After you have established whether the corresponding file system object exists, you can (if you are using the `FileInfo` or `DirectoryInfo` class) find out information about it using the properties in the following table.

PROPERTY	DESCRIPTION
`CreationTime`	Time in which the file or folder was created
`DirectoryName` (`FileInfo` only)	Full pathname of the containing folder
`Parent` (`DirectoryInfo` only)	The parent directory of a specified subdirectory
`Exists`	Whether a file or folder exists
`Extension`	Extension of the file; it returns blank for folders
`FullName`	Full pathname of the file or folder

continues

(continued)

PROPERTY	DESCRIPTION
`LastAccessTime`	Time the file or folder was last accessed
`LastWriteTime`	Time the file or folder was last modified
`Name`	Name of the file or folder
`Root` (`DirectoryInfo` only)	The root portion of the path
`Length` (`FileInfo` only)	The size of the file in bytes

You can also perform actions on the file system object using the methods in the following table.

METHOD	PURPOSE
`Create()`	Creates a folder or empty file of the given name. For a `FileInfo` this also returns a stream object to let you write to the file. (Streams are covered later in this chapter.)
`Delete()`	Deletes the file or folder. For folders, there is an option for the `Delete` to be recursive.
`MoveTo()`	Moves and/or renames the file or folder.
`CopyTo()`	(`FileInfo` only) Copies the file. Note that there is no copy method for folders. If you are copying complete directory trees you will need to individually copy each file and create new folders corresponding to the old folders.
`GetDirectories()`	(`DirectoryInfo` only) Returns an array of `DirectoryInfo` objects representing all folders contained in this folder.
`GetFiles()`	(`DirectoryInfo` only) Returns an array of `FileInfo` objects representing all files contained in this folder.
`GetFileSystemInfos()`	(`DirectoryInfo` only) Returns `FileInfo` and `DirectoryInfo` objects representing all objects contained in this folder, as an array of `FileSystemInfo` references.

Note that these tables list the main properties and methods and are not intended to be exhaustive.

Interestingly, the creation time, last access time, and last write time are all writable:

```
// displays the creation time of a file,
// then changes it and displays it again
FileInfo test = new FileInfo(@"C:\MyFile.txt");
Console.WriteLine(test.Exists.ToString());
Console.WriteLine(test.CreationTime.ToString());
test.CreationTime = new DateTime(2010, 1, 1, 7, 30, 0);
Console.WriteLine(test.CreationTime.ToString());
```

Running this application produces results similar to the following:

```
True
2/5/2009 2:59:32 PM
1/1/2010 7:30:00 AM
```

Being able to manually modify these properties might seem strange at first, but it can be quite useful. For example, if you have a program that effectively modifies a file by simply reading it in, deleting it, and creating a new file with the new contents, you would probably want to modify the creation date to match the original creation date of the old file.

The Path Class

The `Path` class is not a class that you would instantiate. Rather, it exposes some static methods that make operations on pathnames easier. For example, suppose that you want to display the full pathname for a file, `ReadMe.txt`, in the folder `C:\My Documents`. You could find the path to the file using the following code:

```
Console.WriteLine(Path.Combine(@"C:\My Documents", "ReadMe.txt"));
```

Using the `Path` class is a lot easier than using separation symbols manually, especially because the `Path` class is aware of different formats for pathnames on different operating systems. At the time of this writing, Windows is the only operating system supported by .NET. However, if .NET is ported to UNIX, `Path` would be able to cope with UNIX paths, in which case `/`, rather than `\`, would be used as a separator in pathnames. `Path.Combine()` is the method of this class that you are likely to use most often, but `Path` also implements other methods that supply information about the path or the required format for it.

Some of the static fields available to the `Path` class include the following:

PROPERTY	DESCRIPTION
`AltDirectorySeparatorChar`	Provides a platform-agnostic way to specify an alternative character to separate directory levels. in Windows, a / symbol is used, whereas in UNIX, a \ symbol is used.
`DirectorySeparatorChar`	Provides a platform-agnostic way to specify a character to separate directory levels. In Windows, a / symbol is used, whereas in UNIX, a \ symbol is used.
`PathSeparator`	Provides a platform-agnostic way to specify path strings which divide environmental variables. The default value of this setting is a semicolon.
`VolumeSeparatorChar`	Provides a platform-agnostic way to specify a volume separator. The default value of this setting is a colon.

The following example illustrates how to browse directories and view the properties of files.

A FileProperties Sample

This section presents a sample C# application called `FileProperties`. This application presents a simple user interface that allows you to browse the file system and view the creation time, last access time, last write time, and size of files. (You can download the sample code for this application from the Wrox web site at `www.wrox.com`.)

The `FileProperties` application works like this. You type in the name of a folder or file in the main text box at the top of the window and click the Display button. If you type in the path to a folder, its contents are listed in the list boxes. If you type in the path to a file, its details are displayed in the text boxes at the bottom of the form and the contents of its parent folder are displayed in the list boxes. Figure 29-2 shows the `FileProperties` sample application in action.

The user can very easily navigate around the file system by clicking any folder in the right-hand list box to move down to that folder or by clicking the Up button to move up to the parent folder. Figure 29-2 shows the contents of my User folder. The user can also select a file by clicking its name in the list box. This displays the file's properties in the text boxes at the bottom of the application (see Figure 29-3).

Details of Selected File

File name: NTUSER.DAT

File Size: 4718592 bytes

Creation time: 6:19:32 PM

Last modification time: Sunday, August 15, 2007

Last access time: Wednesday, August 15, 2007

FIGURE 29-3

Note that if you want to, you can also display the creation time, last access time, and last modification time for folders using the `DirectoryInfo` property. You display these properties only for a selected file to keep things simple.

You create the project as a standard C# Windows application in Visual Studio 2010. Add the various text boxes and the list box from the Windows Forms area of the toolbox. You also renamed the controls with the more intuitive names of `textBoxInput`, `textBoxFolder`, `buttonDisplay`, `buttonUp`, `listBoxFiles`, `listBoxFolders`, `textBoxFileName`, `textBoxCreationTime`, `textBoxLastAccessTime`, `textBoxLastWriteTime`, and `textBoxFileSize`.

Next, you need to indicate that you will be using the `System.IO` namespace:

```
using System;
using System.IO;
using System.Windows.Forms;
```

You need to do this for all the file-system-related examples in this chapter, but this part of the code will not be explicitly shown in the remaining examples. You then add a member field to the main form:

```
    public partial class Form1: Form
    {
       private string currentFolderPath;
```

code download FileProperties.sln

`currentFolderPath` stores the path of the folder whose contents are displayed in the list boxes.

Next, you need to add event handlers for the user-generated events. The possible user inputs are:

- User clicks the Display button — You need to determine whether what the user has typed in the main text box is the path to a file or folder. If it is a folder, you list the files and subfolders of this folder in the list boxes. If it is a file, you still do this for the folder containing that file, but you also display the file properties in the lower text boxes.
- User clicks a filename in the Files list box — You display the properties of this file in the lower text boxes.
- User clicks a folder name in the Folders list box — You clear all the controls and then display the contents of this subfolder in the list boxes.
- User clicks the Up button — You clear all the controls and then display the contents of the parent of the currently selected folder.

Before you see the code for the event handlers, here is the code for the methods that do all the work. First, you need to clear the contents of all the controls. This method is fairly self-explanatory:

```
protected void ClearAllFields()
{
   listBoxFolders.Items.Clear();
   listBoxFiles.Items.Clear();
   textBoxFolder.Text = "";
   textBoxFileName.Text = "";
   textBoxCreationTime.Text = "";
   textBoxLastAccessTime.Text = "";
   textBoxLastWriteTime.Text = "";
   textBoxFileSize.Text = "";
}
```

code download FileProperties.sln

Next, you define a method, `DisplayFileInfo()`, that handles the process of displaying the information for a given file in the text boxes. This method takes one parameter, the full pathname of the file as a `String`, and works by creating a `FileInfo` object based on this path:

```
protected void DisplayFileInfo(string fileFullName)
{
   FileInfo theFile = new FileInfo(fileFullName);

   if (!theFile.Exists)
```

```
      {
         throw new FileNotFoundException("File not found: " + fileFullName);
      }

      textBoxFileName.Text = theFile.Name;
      textBoxCreationTime.Text = theFile.CreationTime.ToLongTimeString();
      textBoxLastAccessTime.Text = theFile.LastAccessTime.ToLongDateString();
      textBoxLastWriteTime.Text = theFile.LastWriteTime.ToLongDateString();
      textBoxFileSize.Text = theFile.Length.ToString() + " bytes";
   }
```

code download FileProperties.sln

Note that you take the precaution of throwing an exception if there are any problems locating a file at the specified location. The exception itself will be handled in the calling routine (one of the event handlers). Finally, you define a method, `DisplayFolderList()`, which displays the contents of a given folder in the two list boxes. The full pathname of the folder is passed in as a parameter to this method:

```
   protected void DisplayFolderList(string folderFullName)
   {
      DirectoryInfo theFolder = new DirectoryInfo(folderFullName);

      if (!theFolder.Exists)
      {
         throw new DirectoryNotFoundException("Folder not found: " + folderFullName);
      }

      ClearAllFields();
      textBoxFolder.Text = theFolder.FullName;
      currentFolderPath = theFolder.FullName;

      // list all subfolders in folder
      foreach(DirectoryInfo nextFolder in theFolder.GetDirectories())
         listBoxFolders.Items.Add(nextFolder.Name);

      // list all files in folder
      foreach(FileInfo nextFile in theFolder.GetFiles())
         listBoxFiles.Items.Add(nextFile.Name);
   }
```

code download FileProperties.sln

Next, you examine the event handlers. The event handler that manages the event that is triggered when the user clicks the Display button is the most complex because it needs to handle three different possibilities for the text the user enters in the text box. For instance, it could be the pathname of a folder, the pathname of a file, or neither of these:

```
   protected void OnDisplayButtonClick(object sender, EventArgs e)
   {
      try
      {
         string folderPath = textBoxInput.Text;
         DirectoryInfo theFolder = new DirectoryInfo(folderPath);

         if (theFolder.Exists)
         {
            DisplayFolderList(theFolder.FullName);
            return;
         }

         FileInfo theFile = new FileInfo(folderPath);
         if (theFile.Exists)
         {
            DisplayFolderList(theFile.Directory.FullName);
            int index = listBoxFiles.Items.IndexOf(theFile.Name);
            listBoxFiles.SetSelected(index, true);
            return;
         }

         throw new FileNotFoundException("There is no file or folder with "
                                          + "this name: " + textBoxInput.Text);
      }
      catch(Exception ex)
      {
         MessageBox.Show(ex.Message);
      }
   }
```

code download FileProperties.sln

In this code, you establish if the supplied text represents a folder or file by instantiating `DirectoryInfo` and `FileInfo` instances and examining the `Exists` property of each object. If neither exists, you throw an exception. If it's a folder, you call `DisplayFolderList()` to populate the list boxes. If it's a file, you need to populate the list boxes and sort out the text boxes that display the file properties. You handle this case by first populating the list boxes. You then programmatically select the appropriate filename in the Files list box. This has exactly the same effect as if the user had selected that item — it raises the item-selected event. You can then simply exit the current event handler, knowing that the selected item event handler will immediately be called to display the file properties.

The following code is the event handler that is called when an item in the Files list box is selected, either by the user or, as indicated previously, programmatically. It simply constructs the full pathname of the selected file, and passes it to the `DisplayFileInfo()` method presented earlier:

```
protected void OnListBoxFilesSelected(object sender, EventArgs e)
{
   try
   {
      string selectedString = listBoxFiles.SelectedItem.ToString();
      string fullFileName = Path.Combine(currentFolderPath, selectedString);
      DisplayFileInfo(fullFileName);
   }
   catch(Exception ex)
   {
      MessageBox.Show(ex.Message);
   }
}
```

code download FileProperties.sln

The event handler for the selection of a folder in the Folders list box is implemented in a very similar way, except that in this case you call `DisplayFolderList()` to update the contents of the list boxes:

```
protected void OnListBoxFoldersSelected(object sender, EventArgs e)
{
   try
   {
      string selectedString = listBoxFolders.SelectedItem.ToString();
      string fullPathName = Path.Combine(currentFolderPath, selectedString);
      DisplayFolderList(fullPathName);
   }
   catch(Exception ex)
```

```
        {
           MessageBox.Show(ex.Message);
        }
     }
```

code download FileProperties.sln

Finally, when the Up button is clicked, `DisplayFolderList()` must also be called, except that this time you need to obtain the path of the parent of the folder currently being displayed. This is done with the `FileInfo.DirectoryName` property, which returns the parent folder path:

```
     protected void OnUpButtonClick(object sender, EventArgs e)
     {
        try
        {
           string folderPath = new FileInfo(currentFolderPath).DirectoryName;
           DisplayFolderList(folderPath);
        }
        catch(Exception ex)
        {
           MessageBox.Show(ex.Message);
        }
     }
```

code download FileProperties.sln

MOVING, COPYING, AND DELETING FILES

As mentioned, moving and deleting files or folders is done by the `MoveTo()` and `Delete()` methods of the `FileInfo` and `DirectoryInfo` classes. The equivalent methods on the `File` and `Directory` classes are `Move()` and `Delete()`. The `FileInfo` and `File` classes also implement the methods `CopyTo()` and `Copy()`, respectively. However, no methods exist to copy complete folders — you need to do that by copying each file in the folder.

Using all these methods is quite intuitive — you can find detailed descriptions in the SDK documentation. This section illustrates their use for the particular cases of calling the static `Move()`, `Copy()`, and `Delete()` methods on the `File` class. To do this, you will build on the previous `FileProperties` example and call its iteration `FilePropertiesAndMovement`. This example will have the extra feature that whenever the properties of a file are displayed, the application gives you the option of deleting that file or moving or copying the file to another location.

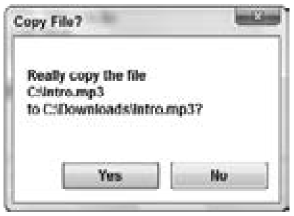
FIGURE 29-4

FilePropertiesAndMovement Sample

Figure 29-4 shows the user interface of the new sample application.

As you can see, `FilePropertiesAndMovement` is similar in appearance to `FileProperties`, except for the group of three buttons and a text box at the bottom of the window. These controls are enabled only when the example is actually displaying the properties of a file; at all other times, they are disabled. The existing controls are also squashed up a bit to stop the main form from getting too big. When the properties of a selected file are displayed, `FilePropertiesAndMovement` automatically places the full pathname of that file in the bottom text box for the user to edit. Users can then click any of the buttons to perform the appropriate operation. When they do, a message box is displayed that confirms the action taken by the user (see Figure 29-5).



Copy File?

Really copy the file
C:\Intro.mp3
to C:\Downloads\Intro.mp3?

FIGURE 29-5

When the user clicks the Yes button, the action is initiated. There are some actions in the form that the user can take that will then cause the display to be incorrect. For instance, if the user moves or deletes a file, you obviously cannot continue to display the contents of that file in the same location. In addition, if you change the name of a file in the same folder, your display will also be out of date. In these cases, `FilePropertiesAndMovement` resets its controls to display only the folder where the file resides after the file operation.

Looking at the Code for FilePropertiesAndMovement

To code this process, you need to add the relevant controls, as well as their event handlers, to the code for the `FileProperties` sample. The new controls are given the names `buttonDelete`, `buttonCopyTo`, `buttonMoveTo`, and `textBoxNewPath`.

First, look at the event handler that is called when the user clicks the Delete button:

```
protected void OnDeleteButtonClick(object sender, EventArgs e)
{
   try
   {
      string filePath = Path.Combine(currentFolderPath,
                                     textBoxFileName.Text);
      string query = "Really delete the file\n" + filePath + y?";
      if (MessageBox.Show(query,
         "Delete File?", MessageBoxButtons.YesNo) == DialogResult.Yes)
      {
         File.Delete(filePath);
         DisplayFolderList(currentFolderPath);
      }
   }
   catch(Exception ex)
   {
      MessageBox.Show("Unable to delete file. The following exception"
                      + " occurred:\n" + ex.Message, "Failed");
   }
}
```

code download FilePropertiesAndMovement.sln

The code for this method is contained in a `try` block because of the obvious risk of an exception being thrown if, for example, you don't have permission to delete the file, or the file is moved by another process after it has been displayed but before the user presses the Delete button. You construct the path of the file to be deleted from the `CurrentParentPath` field, which contains the path of the parent folder, and the text in the `textBoxFileName` text box, which contains the name of the file.

The methods to move and copy the file are structured in a very similar manner:

```
protected void OnMoveButtonClick(object sender, EventArgs e)
{
   try
   {
      string filePath = Path.Combine(currentFolderPath,
                                     textBoxFileName.Text);
```

```
         string query = "Really move the file\n" + filePath + "\nto "
                         + textBoxNewPath.Text + "?";
         if (MessageBox.Show(query,
            "Move File?", MessageBoxButtons.YesNo) == DialogResult.Yes)
         {
            File.Move(filePath, textBoxNewPath.Text);
            DisplayFolderList(currentFolderPath);
         }
      }
      catch(Exception ex)
      {
         MessageBox.Show("Unable to move file. The following exception"
                           + " occurred:\n" + ex.Message, "Failed");
      }
   }

   protected void OnCopyButtonClick(object sender, EventArgs e)
   {
      try
      {
         string filePath = Path.Combine(currentFolderPath,
                                        textBoxFileName.Text);
         string query = "Really copy the file\n" + filePath + "\nto "
                         + textBoxNewPath.Text + "?";
         if (MessageBox.Show(query,
            "Copy File?", MessageBoxButtons.YesNo) == DialogResult.Yes)
         {
            File.Copy(filePath, textBoxNewPath.Text);
            DisplayFolderList(currentFolderPath);
         }
      }
      catch(Exception ex)
      {
         MessageBox.Show("Unable to copy file. The following exception"
                          + " occurred:\n" + ex.Message, "Failed");
      }
   }
```

code download FilePropertiesAndMovement.sln

You are not quite done. You also need to make sure that the new buttons and text box are enabled and disabled at the appropriate times. To enable them when you are displaying the contents of a file, you add the following code to `DisplayFileInfo()`:

```
   protected void DisplayFileInfo(string fileFullName)
   {
      FileInfo theFile = new FileInfo(fileFullName);

      if (!theFile.Exists)
      {
         throw new FileNotFoundException("File not found: " + fileFullName);
      }

      textBoxFileName.Text = theFile.Name;
      textBoxCreationTime.Text = theFile.CreationTime.ToLongTimeString();
      textBoxLastAccessTime.Text = theFile.LastAccessTime.ToLongDateString();
      textBoxLastWriteTime.Text = theFile.LastWriteTime.ToLongDateString();
      textBoxFileSize.Text = theFile.Length.ToString() + " bytes";

      // enable move, copy, delete buttons
      textBoxNewPath.Text = theFile.FullName;
      textBoxNewPath.Enabled = true;
```

```
        buttonCopyTo.Enabled = true;
        buttonDelete.Enabled = true;
        buttonMoveTo.Enabled = true;
    }
```

code download FilePropertiesAndMovement.sln

You also need to make one change to `DisplayFolderList`:

```
    protected void DisplayFolderList(string folderFullName)
    {
        DirectoryInfo theFolder = new DirectoryInfo(folderFullName);

        if (!theFolder.Exists)
        {
            throw new DirectoryNotFoundException("Folder not found: " + folderFullName);
        }

        ClearAllFields();
        DisableMoveFeatures();
        textBoxFolder.Text = theFolder.FullName;
        currentFolderPath = theFolder.FullName;

        // list all subfolders in folder
        foreach(DirectoryInfo nextFolder in theFolder.GetDirectories())
            listBoxFolders.Items.Add(NextFolder.Name);

        // list all files in folder
        foreach(FileInfo nextFile in theFolder.GetFiles())
            listBoxFiles.Items.Add(NextFile.Name);
    }
```

code download FilePropertiesAndMovement.sln

`DisableMoveFeatures` is a small utility function that disables the new controls:

```
        void DisableMoveFeatures()
        {
            textBoxNewPath.Text = "";
            textBoxNewPath.Enabled = false;
            buttonCopyTo.Enabled = false;
            buttonDelete.Enabled = false;
            buttonMoveTo.Enabled = false;
        }
```

code download FilePropertiesAndMovement.sln

You also need to add extra code to `ClearAllFields()` to clear the extra text box:

```
        protected void ClearAllFields()
        {
            listBoxFolders.Items.Clear();
            listBoxFiles.Items.Clear();
            textBoxFolder.Text = "";
            textBoxFileName.Text = "";
            textBoxCreationTime.Text = "";
            textBoxLastAccessTime.Text = "";
            textBoxLastWriteTime.Text = "";
            textBoxFileSize.Text = "";
            textBoxNewPath.Text = "";
        }
```

code download FilePropertiesAndMovement.sln

The next section takes a look at reading and writing to files.

READING AND WRITING TO FILES

Reading and writing to files is in principle very simple; however, it is not done through the `DirectoryInfo` or `FileInfo` objects. Instead, using the .NET Framework 4, you can do it through the `File` object. Later in this chapter, you see how to accomplish this using a number of other classes that represent a generic concept called a *stream*.

Before .NET Framework 2.0, it took a bit of wrangling to read and write to files. It was possible using the available classes from the framework, but it was not that straightforward. The .NET Framework 2.0 has expanded the `File` class to make it as simple as just one line of code to read or write to a file. This same functionality is also available in .NET Framework 4.

Reading a File

For an example of reading a file, create a Windows Forms application that contains a regular text box, a button, and a multiline text box. In the end, your form should appear similar to Figure 29-6.

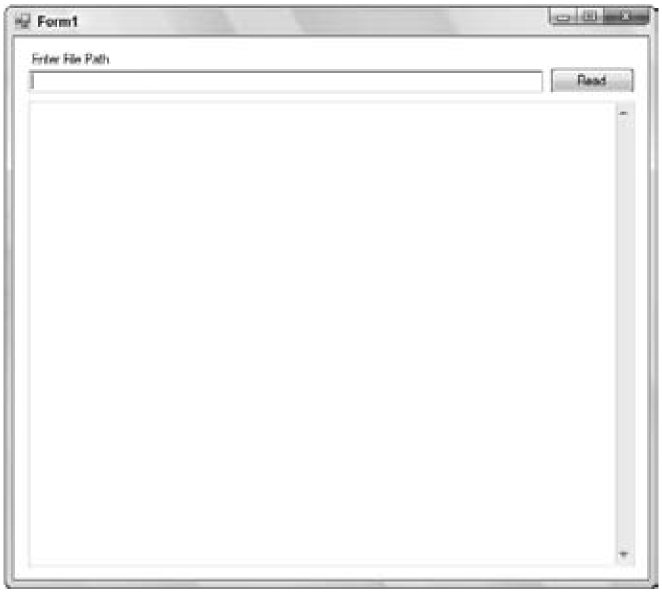


FIGURE 29-6

The idea of this form is that the end user will enter the path of a specific file in the first text box and click the Read button. From there, the application will read the specified file and display the file's contents in the multiline text box. This is illustrated in the following code example:

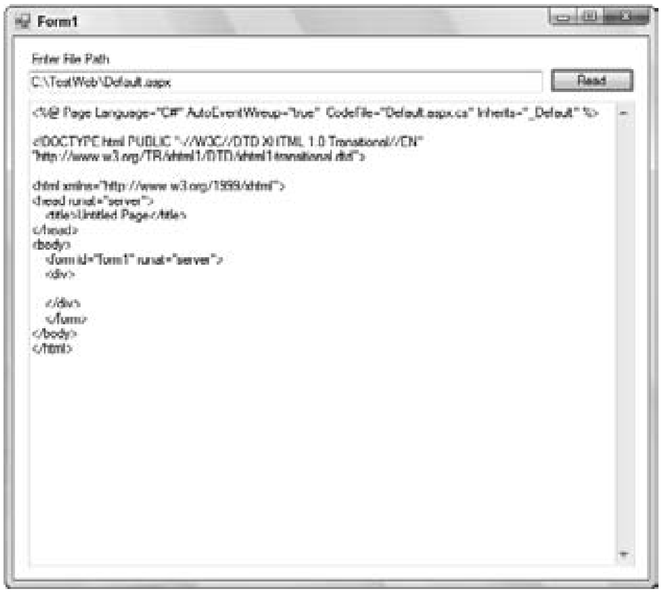
```
using System;
using System.IO;
using System.Windows.Forms;

namespace ReadingFiles
{
    public partial class Form1: Form
    {
        public Form1()
        {
                InitializeComponent();
            }

            private void button1_Click(object sender, EventArgs e)
            {
                textBox2.Text = File.ReadAllText(textBox1.Text);
            }
        }
    }
```

code download ReadingFiles.sln

In building this example, the first step is to add the `using` statement to bring in the `System.IO` namespace. From there, simply use the `button1_Click` event for the Send button on the form to populate the text box with what comes back from the file. You can now access the file's contents by using the `File.ReadAllText()` method. As you can see, you can read files with a single statement. The `ReadAllText()` method opens the specified file, reads the contents, and then closes the file. The return value of the `ReadAllText()` method is a string containing the entire contents of the file specified. The result would be something similar to what is shown in Figure 29-7.



C:\TestWeb\Default.aspx

```
<%@ Page Language="C#" AutoEventWireup="true"  CodeFile="Default.aspx.cs" Inherits="_Default" %>

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
"http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">

<html xmlns="http://www.w3.org/1999/xhtml">
<head runat="server">
    <title>Untitled Page</title>
</head>
<body>
    <form id="form1" runat="server">
    <div>

    </div>
    </form>
</body>
</html>
```

FIGURE 29-7

The `File.ReadAllText()` signature shown in the preceding example is of the following construction:

```
File.ReadAllText(FilePath);
```

The other option is to also specify the encoding of the file being read:

```
File.ReadAllText(FilePath, Encoding);
```

Using this signature allows you to specify the encoding to use when opening and reading the contents of the file. Therefore, this means that you could do something like the following:

```
File.ReadAllText(textBox1.Text, Encoding.ASCII);
```

Some of the other options for opening and working with files include using the `ReadAllBytes()` and the `ReadAllLines()` methods. The `ReadAllBytes()` method allows you to open a binary file and read the contents into a byte array. The `ReadAllText()` method shown earlier gives you the entire contents of the specified file in a single string instance. You might not be interested in this, but instead might be interested in working with what comes back from the file in a line-by-line fashion. In this case, you should use the `ReadAllLines()` method because it allows for this kind of functionality and will return a string array for you to work with.

Writing to a File

Besides making reading from files an extremely simple process under the .NET Framework umbrella, the base class library has made writing to files just as easy. Just as the base class library (BCL) gives you the `ReadAllText()`, `ReadAllLines()`, and `ReadAllBytes()` methods to read files in a few different ways, it gives you the `WriteAllText()`, `WriteAllBytes()`, and `WriteAllLines()` methods to write files.

For an example of how to write to a file, use the same Windows Forms application, but use the multiline text box in the form to input data into a file. The code for the `button1_Click` event handler should appear as shown here:

```
private void button1_Click(object sender, EventArgs e)
{
   File.WriteAllText(textBox1.Text, textBox2.Text);
}
```

Build and start the form, type `C:\Testing.txt` in the first text box, type some random content in the second text box, and then click the button. Nothing will happen visually, but if you look in your root C: drive, you will see the `Testing.txt` file with the content you specified.

The `WriteAllText()` method went to the specified location, created a new text file, and provided the specified contents to the file before saving and closing the file. Not bad for just one line of code!

If you run the application again, and specify the same file (`Testing.txt`) but with some new content, pressing the button again will cause the application to perform the same task. This time though, the new content is not added to the previous content you specified — instead, the new content completely overrides the previous content. In fact, `WriteAllText()`, `WriteAllBytes()`, and `WriteAllLines()` all override any previous files, so you must be careful when using these methods.

The `WriteAllText()` method in the previous example uses the following signature:

```
File.WriteAllText(FilePath, Contents)
```

You can also specify the encoding of the new file:

```
File.WriteAllText(FilePath, Contents, Encoding)
```

The `WriteAllBytes()` method allows you to write content to a file using a byte array, and the `WriteAllLines()` method allows you to write a string array to a file. An example of this is illustrated in the following event handler:

```
private void button1_Click(object sender, EventArgs e)
{
   string[] movies =
      {"Grease",
       "Close Encounters of the Third Kind",
       "The Day After Tomorrow"};

   File.WriteAllLines(@"C:\Testing.txt", movies);
}
```

Now clicking the button for such an application will give you a `Testing.txt` file with the following contents:

```
    Grease
    Close Encounters of the Third Kind
    The Day After Tomorrow
```

The `WriteAllLines()` method writes out the string array with each array item taking its own line in the file.

Because data may be written not only to disk but to other places as well (such as to named pipes or to memory), it is also important to understand how to deal with file I/O in .NET using streams as a means of moving file contents around. This is shown in the following section.

Streams

The idea of a stream has been around for a very long time. A stream is an object used to transfer data. The data can be transferred in one of two directions:

- If the data is being transferred from some outside source into your program, it is called *reading* from the stream.
- If the data is being transferred from your program to some outside source, it is called *writing* to the stream.

Very often, the outside source will be a file, but that is not always the case. Other possibilities include:

- Reading or writing data on the network using some network protocol, where the intention is for this data to be picked up by or sent from another computer
- Reading or writing to a named pipe
- Reading or writing to an area of memory

Of these examples, Microsoft has supplied a .NET base class for writing to or reading from memory, the `System.IO.MemoryStream` object. The `System.Net.Sockets.NetworkStream` object handles network data. There are no base stream classes for writing to or reading from pipes, but there is a generic stream class, `System.IO.Stream`, from which you would inherit if you wanted to write such a class. `Stream` does not make any assumptions about the nature of the external data source.

The outside source might even be a variable within your own code. This might sound paradoxical, but the technique of using streams to transmit data between variables can be a useful trick for converting data between data types. The C language used something similar — the `sprintf` function — to convert between integer data types and strings or to format strings.

The advantage of having a separate object for the transfer of data, rather than using the `FileInfo` or `DirectoryInfo` classes to do this, is that separating the concept of transferring data from the particular data source makes it easier to swap data sources. Stream objects themselves contain a lot of generic code that concerns the movement of data between outside sources and variables in your code. By keeping this code separate from any concept of a particular data source, you make it easier for this code to be reused (through inheritance) in different circumstances. For example, the `StringReader` and `StringWriter` classes are part of the same inheritance tree as two classes that you will be using later on to read and write text files. The classes will almost certainly share a substantial amount of code behind the scenes.

Figure 29-8 illustrates the actual hierarchy of stream-related classes in the `System.IO` namespace.

As far as reading and writing files, the classes that concern us most are:

- `FileStream` — This class is intended for reading and writing binary data in a binary file. However, you can also use it to read from or write to any file.
- `StreamReader` and `StreamWriter` — These classes are designed specifically for reading from and writing to text files.

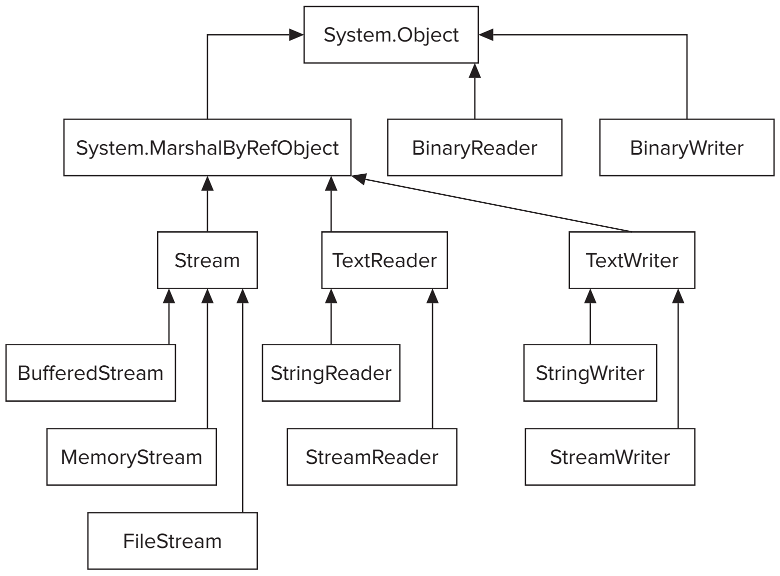


FIGURE 29-8

You might also find the `BinaryReader` and `BinaryWriter` classes useful, although they are not used in the examples here. These classes do not actually implement streams themselves, but they are able to provide wrappers around other stream objects. `BinaryReader` and `BinaryWriter` provide extra formatting of binary data, which allows you to directly read or write the contents of C# variables to or from the relevant stream. Think of the `BinaryReader` and `BinaryWriter` as sitting between the stream and your code, providing extra formatting (see Figure 29-9).

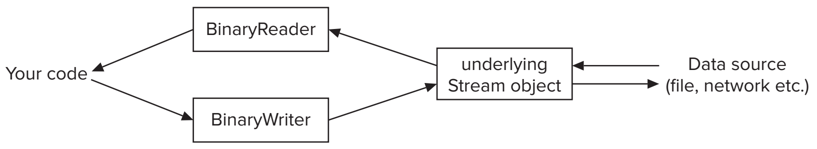

FIGURE 29-9

The difference between using these classes and directly using the underlying stream objects is that a basic stream works in bytes. For example, suppose that as part of the process of saving some document you want to write the contents of a variable of type `long` to a binary file. Each `long` occupies 8 bytes, and if you used an ordinary binary stream, you would have to explicitly write each of those 8 bytes of memory.

In C# code, you would have to perform some bitwise operations to extract each of those 8 bytes from the `long` value. Using a `BinaryWriter` instance, you can encapsulate the entire operation in an overload of the `BinaryWriter.Write()` method, which takes a `long` as a parameter, and which will place those 8 bytes into the stream (and if the stream is directed to a file, into the file). A corresponding `BinaryReader.Read()` method will extract 8 bytes from the stream and recover the value of the `long`. For more information on the `BinaryReader` and `BinaryWriter` classes, refer to the SDK documentation.

Buffered Streams

For performance reasons, when you read or write to or from a file, the output is buffered. This means that if your program asks for the next 2 bytes of a file stream, and the stream passes the request on to Windows, then Windows will not connect to the file system and then locate and read the file off the disk, just to get

2 bytes. Instead, Windows will retrieve a large block of the file at one time and store this block in an area of memory known as a *buffer*. Subsequent requests for data from the stream are satisfied from the buffer until the buffer runs out, at which point, Windows grabs another block of data from the file.

Writing to files works in the same way. For files, this is done automatically by the operating system, but you might have to write a stream class to read from some other device that is not buffered. If so, you can derive your class from `BufferedStream`, which implements a buffer itself. (Note, however, that `BufferedStream` is not designed for the situation in which an application frequently alternates between reading and writing data.)

Reading and Writing to Binary Files Using FileStream

Reading and writing to and from binary files can be done using the `FileStream` class. (Note that if you are working with the .NET Framework 1.x, this will most likely be the case.)

The FileStream Class

A `FileStream` instance is used to read or write data to or from a file. To construct a `FileStream`, you need four pieces of information:

1. The *file* you want to access.
2. The *mode*, which indicates how you want to open the file. For example, are you intending to create a new file or open an existing file? And if you are opening an existing file, should any write operations be interpreted as overwriting the contents of the file or appending to the file?
3. The *access*, which indicates how you want to access the file. For example, do you want to read from or write to the file or do both?
4. The *share* access, which specifies whether you want exclusive access to the file. Or, are you willing to have other streams access the file simultaneously? If so, should other streams have access to read the file, to write to it, or to do both?

The first of these pieces of information is usually represented by a string that contains the full pathname of the file, and this chapter considers only those constructors that require a string here. Besides those constructors, however, some additional ones take an old Windows-API-style Windows handle to a file instead. The remaining three pieces of information are represented by three .NET enumerations called `FileMode`, `FileAccess`, and `FileShare`. The values of these enumerations are listed in the following table and are self-explanatory.

ENUMERATION	VALUES
`FileMode`	`Append`, `Create`, `CreateNew`, `Open`, `OpenOrCreate`, or `Truncate`
`FileAccess`	`Read`, `ReadWrite`, or `Write`
`FileShare`	`Delete`, `Inheritable`, `None`, `Read`, `ReadWrite`, or `Write`

Note that in the case of `FileMode`, exceptions can be thrown if you request a mode that is inconsistent with the existing status of the file. `Append`, `Open`, and `Truncate` will throw an exception if the file does not already exist, and `CreateNew` will throw an exception if it does. `Create` and `OpenOrCreate` will cope with either scenario, but `Create` will delete any existing file to replace it with a new, initially empty, one. The `FileAccess` and `FileShare` enumerations are bitwise flags, so values can be combined with the C# bitwise OR operator, `|`.

There are a large number of constructors for the `FileStream`. The three simplest ones work as follows:

```
// creates file with read-write access and allows other streams read access
FileStream fs = new FileStream(@"C:\C# Projects\Project.doc",
                    FileMode.Create);
// as above, but we only get write access to the file
```

```
FileStream fs2 = new FileStream(@"C:\C# Projects\Project2.doc",
                     FileMode.Create, FileAccess.Write);
// as above but other streams don't get access to the file while
// fs3 is open
FileStream fs3 = new FileStream(@"C:\C# Projects\Project3.doc",
                     FileMode.Create, FileAccess.Write, FileShare.None);
```

As this code reveals, the overloads of these constructors have the effect of providing default values of `FileAccess.ReadWrite` and `FileShare.Read` to the third and fourth parameters depending upon the `FileMode` value. It is also possible to create a file stream from a `FileInfo` instance in various ways:

```
FileInfo myFile4 = new FileInfo(@"C:\C# Projects\Project4.doc");
FileStream fs4 = myFile4.OpenRead();
FileInfo myFile5= new FileInfo(@"C:\C# Projects\Project5doc");
FileStream fs5 = myFile5.OpenWrite();
FileInfo myFile6= new FileInfo(@"C:\C# Projects\Project6doc");
FileStream fs6 = myFile6.Open(FileMode.Append, FileAccess.Write,
                 FileShare.None);
FileInfo myFile7 = new FileInfo(@"C:\C# Projects\Project7.doc");
FileStream fs7 = myFile7.Create();
```

`FileInfo.OpenRead()` supplies a stream that gives you read-only access to an existing file, whereas `FileInfo.OpenWrite()` gives you read-write access. `FileInfo.Open()` allows you to specify the mode, access, and file share parameters explicitly.

Of course, after you have finished with a stream, you should close it:

```
fs.Close();
```

Closing the stream frees up the resources associated with it and allows other applications to set up streams to the same file. This action also flushes the buffer. In between opening and closing the stream, you should read data from it and/or write data to it. `FileStream` implements a number of methods to do this.

`ReadByte()` is the simplest way of reading data. It grabs 1 byte from the stream and casts the result to an `int` that has a value between 0 and 255. If you have reached the end of the stream, it returns `-1`:

```
int NextByte = fs.ReadByte();
```

If you prefer to read a number of bytes at a time, you can call the `Read()` method, which reads a specified number of bytes into an array. `Read()` returns the number of bytes actually read — if this value is zero, you know that you are at the end of the stream. Here is an example where you read into a byte array called `ByteArray`:

```
int nBytesRead = fs.Read(ByteArray, 0, nBytes);
```

The second parameter to `Read()` is an offset, which you can use to request that the `Read` operation start populating the array at some element other than the first. The third parameter is the number of bytes to read into the array.

If you want to write data to a file, two parallel methods are available, `WriteByte()` and `Write()`. `WriteByte()` writes a single byte to the stream:

```
byte NextByte = 100;
fs.WriteByte(NextByte);
```

`Write()`, however, writes out an array of bytes. For instance, if you initialized the `ByteArray` mentioned before with some values, you could use the following code to write out the first `nBytes` of the array:

```
fs.Write(ByteArray, 0, nBytes);
```

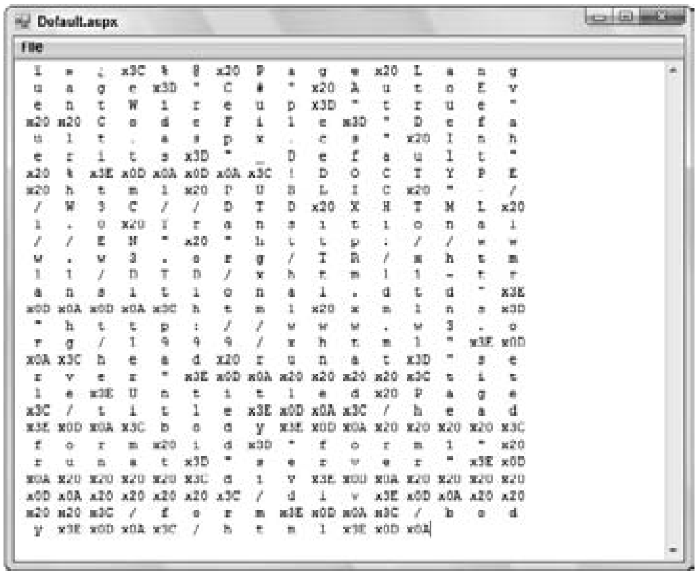
As with `Read()`, the second parameter allows you to start writing from some point other than the beginning of the array. Both `WriteByte()` and `Write()` return `void`.

In addition to these methods, `FileStream` implements various other methods and properties related to bookkeeping tasks such as determining how many bytes are in the stream, locking the stream, or flushing the buffer. These other methods are not usually required for basic reading and writing, but if you need them, full details are in the SDK documentation.

BinaryFileReader Sample

The use of the `FileStream` class is illustrated by writing a sample, `BinaryFileReader`, which reads in and displays any file. Create the project in Visual Studio 2010 as a Windows application. It has one menu item, which brings up a standard `OpenFileDialog` asking what file to read in and then displays the file as binary code. As you are reading in binary files, you need to be able to display nonprintable characters. You will do this by displaying each byte of the file individually, showing 16 bytes on each line of a multiline text box. If the byte represents a printable ASCII character, you will display that character; otherwise, you will display the value of the byte in a hexadecimal format. In either case, you pad out the displayed text with spaces so that each byte displayed occupies four columns; this way, the bytes line up nicely under each other.

Figure 29-10 shows what the `BinaryFileReader` application looks like when viewing a text file. (Because `BinaryFileReader` can view any file, it is quite possible to use it on text files as well as binary ones.) In this case, the application has read in a basic ASP.NET page (`.aspx`).



```

FIGURE 29-10

Clearly, this format is more suited for looking at the values of individual bytes than for displaying text! Later in this chapter, when you develop a sample that is specifically designed to read text files, you will see what this file really says. The advantage of this sample is that you can look at the contents of any file.

This sample does not demonstrate writing to files because you don't want to get bogged down in the complexities of trying to translate the contents of a text box as the one shown in Figure 29-10 into a binary stream! You see how to write to files later when you develop a sample that can read or write, but only to and from text files.

Here is the code used to get these results. First, you need to make sure that you have brought in the `System.IO` namespace through the use of the `using` statement:

```
using System.IO;
```

Next, you add a couple of fields to the main form class — one representing the file dialog and a string that gives the path of the file currently being viewed:

```
partial class Form1: Form
{
   private readonly OpenFileDialog chooseOpenFileDialog =
      new OpenFileDialog();
   private string chosenFile;
```

code download BinaryFileReader.sln

You also need to add some standard Windows Forms code to deal with the handlers for the menu and the file dialog:

```
public Form1()
{
   InitializeComponent();
   menuFileOpen.Click += OnFileOpen;
   chooseOpenFileDialog.FileOk += OnOpenFileDialogOK;
}

void OnFileOpen(object Sender, EventArgs e)
{
   chooseOpenFileDialog.ShowDialog();
}

void OnOpenFileDialogOK(object Sender, CancelEventArgs e)
{
   chosenFile = chooseOpenFileDialog.FileName;
   this.Text = Path.GetFileName(chosenFile);
   DisplayFile();
}
```

code download BinaryFileReader.sln

As this code demonstrates, when the user clicks OK to select a file in the file dialog, you call the `DisplayFile()` method, which does the work of reading in the selected file:

```
void DisplayFile()
{
   int nCols = 16;
   FileStream inStream = new FileStream(chosenFile, FileMode.Open,
                                                    FileAccess.Read);
   long nBytesToRead = inStream.Length;
   if (nBytesToRead > 65536/4)
      nBytesToRead = 65536/4;

   int nLines = (int)(nBytesToRead/nCols) + 1;
   string [] lines = new string[nLines];
   int nBytesRead = 0;

   for (int i=0; i<nLines; i++)
   {
      StringBuilder nextLine = new StringBuilder();
      nextLine.Capacity = 4*nCols;

      for (int j = 0; j<nCols; j++)
      {
         int nextByte = inStream.ReadByte();
         nBytesRead++;
         if (nextByte < 0 || nBytesRead > 65536)
            break;
         char nextChar = (char)nextByte;
```

```
               if (nextChar < 16)
                  nextLine.Append(" x0" + string.Format("{0,1:X}",
                                                      (int)nextChar));
               else if
                  (char.IsLetterOrDigit(nextChar) ||
                                       char.IsPunctuation(nextChar))
                  nextLine.Append("  " + nextChar + " ");
               else
                  nextLine.Append(" x" + string.Format("{0,2:X}",
                                        (int)nextChar));
            }
            lines[i] = nextLine.ToString();
         }
         inStream.Close();
         this.textBoxContents.Lines = lines;
      }
```

code download BinaryFileReader.sln

There is quite a lot going on in this method, so here is the breakdown. You instantiate a FileStream object for the selected file, which specifies that you want to open an existing file for reading. You then work out how many bytes there are to read in and how many lines should be displayed. The number of bytes will normally be the number of bytes in the file. This example limits the display of the contents in the textbox control to a maximum of only 65,536 characters — with the chosen display format, you are displaying four characters for every byte in the file.

You might want to look up the RichTextBox *class in the* System.Windows.Forms *namespace.* RichTextBox *is similar to a text box, but has many more advanced formatting facilities.* TextBox *is used here to keep the example simple and focused on the process of reading in files.*

The bulk of the method is given to two nested for loops that construct each line of text to be displayed. You use a StringBuilder class to construct each line for performance reasons: you are appending suitable text for each byte to the string that represents each line 16 times. If on each occasion you allocate a new string and take a copy of the half-constructed line, you are not only going to be spending a lot of time allocating strings but will also be wasting a lot of memory on the heap. Notice that the definition of *printable* characters is anything that is a letter, digit, or punctuation, as indicated by the relevant static System.Char methods. You exclude any character with a value less than 16 from the printable list, however; this means that you will trap the carriage return (13) and line feed (10) as binary characters (a multiline text box isn't able to display these characters properly if they occur individually within a line).

Furthermore, using the Properties window, you change the Font property for the text box to a fixed-width font. In this case, you choose Courier New 9pt regular and set the text box to have vertical and horizontal scrollbars.

Upon completion, you close the stream and set the contents of the text box to the array of strings that you have built up.

Reading and Writing to Text Files

Theoretically, it is perfectly possible to use the FileStream class to read in and display text files. You have, after all, just done that. The format in which the Default.aspx file is displayed in the preceding sample is not particularly user-friendly, but that has nothing to do with any intrinsic problem with the FileStream class, only with how you choose to display the results in the text box.

Having said that, if you know that a particular file contains text, you will usually find it more convenient to read and write it using the `StreamReader` and `StreamWriter` classes instead of the `FileStream` class. That is because these classes work at a slightly higher level and are specifically geared to reading and writing text. The methods that they implement are able to automatically detect convenient points to stop reading text, based on the contents of the stream. In particular:

- These classes implement methods to read or write one line of text at a time, `StreamReader.ReadLine()` and `StreamWriter.WriteLine()`. In the case of reading, this means that the stream will automatically determine for you where the next carriage return is and stop reading at that point. In the case of writing, it means that the stream will automatically append the carriage return–line feed combination to the text that it writes out.
- By using the `StreamReader` and `StreamWriter` classes, you don't need to worry about the encoding (the text format) used in the file. Possible encodings include ASCII (1 byte for each character), or any of the Unicode-based formats, Unicode, UTF7, UTF8, and UTF32. Text files on Windows 9x systems are always in ASCII because Windows 9x does not support Unicode; however, because Windows NT, 2000, XP, 2003, Vista, Windows Server 2008, and Windows 7 all support Unicode, text files might theoretically contain Unicode, UTF7, UTF8, or UTF32 data instead of ASCII data. The convention is that if the file is in ASCII format, it will simply contain the text. If it is in any Unicode format, this will be indicated by the first 2 or 3 bytes of the file, which are set to particular combinations of values to indicate the format used in the file.

These bytes are known as the *byte code markers*. When you open a file using any of the standard Windows applications, such as Notepad or WordPad, you do not need to worry about this because these applications are aware of the different encoding methods and will automatically read the file correctly. This is also true for the `StreamReader` class, which correctly reads in a file in any of these formats, and the `StreamWriter` class is capable of formatting the text it writes out using whatever encoding technique you request. If you want to read in and display a text file using the `FileStream` class, however, you need to handle this yourself.

The StreamReader Class

`StreamReader` is used to read text files. Constructing a `StreamReader` is in some ways easier than constructing a `FileStream` instance because some of the `FileStream` options are not required when using `StreamReader`. In particular, the mode and access types are not relevant to `StreamReader` because the only thing you can do with a `StreamReader` is read! Furthermore, there is no direct option to specify the sharing permissions. However, there are a couple of new options:

- You need to specify what to do about the different encoding methods. You can instruct the `StreamReader` to examine the byte code markers in the beginning of the file to determine the encoding method, or you can simply tell the `StreamReader` to assume that the file uses a specified encoding method.
- Instead of supplying a filename to be read from, you can supply a reference to another stream.

This last option deserves a bit more discussion because it illustrates another advantage of basing the model for reading and writing data on the concept of streams. Because the `StreamReader` works at a relatively high level, you might find it useful if you have another stream that is there to read data from some other source, but you would like to use the facilities provided by `StreamReader` to process that other stream as if it contained text. You can do so by simply passing the output from this stream to a `StreamReader`. In this way, `StreamReader` can be used to read and process data from any data source — not only files. This is essentially the situation discussed earlier with regard to the `BinaryReader` class. However, in this book you only use `StreamReader` to connect directly to files.

The result of these possibilities is that `StreamReader` has a large number of constructors. Not only that, but there is another `FileInfo` method that returns a `StreamReader` reference: `OpenText()`. The following just illustrates some of the constructors.

The simplest constructor takes just a filename. This `StreamReader` examines the byte order marks to determine the encoding:

```
StreamReader sr = new StreamReader(@"C:\My Documents\ReadMe.txt");
```

Alternatively, you can specify that UTF8 encoding should be assumed:

```
StreamReader sr = new StreamReader(@"C:\My Documents\ReadMe.txt",
                                     Encoding.UTF8);
```

You specify the encoding by using one of several properties on a class, `System.Text.Encoding`. This class is an abstract base class, from which a number of classes are derived and which implements methods that actually perform the text encoding. Each property returns an instance of the appropriate class, and the possible properties you can use are here:

- `ASCII`
- `Unicode`
- `UTF7`
- `UTF8`
- `UTF32`
- `BigEndianUnicode`

The following example demonstrates how to hook up a `StreamReader` to a `FileStream`. The advantage of this is that you can specify whether to create the file and the share permissions, which you cannot do if you directly attach a `StreamReader` to the file:

```
FileStream fs = new FileStream(@"C:\My Documents\ReadMe.txt",
                    FileMode.Open, FileAccess.Read, FileShare.None);
StreamReader sr = new StreamReader(fs);
```

For this example, you specify that the `StreamReader` will look for byte code markers to determine the encoding method used, as it will do in the following examples, in which the `StreamReader` is obtained from a `FileInfo` instance:

```
FileInfo myFile = new FileInfo(@"C:\My Documents\ReadMe.txt");
StreamReader sr = myFile.OpenText();
```

Just as with a `FileStream`, you should always close a `StreamReader` after use. Failure to do so will result in the file remaining locked to other processes (unless you used a `FileStream` to construct the `StreamReader` and specified `FileShare.ShareReadWrite`):

```
sr.Close();
```

Now that you have gone to the trouble of instantiating a `StreamReader`, you can do something with it. As with the `FileStream`, you will simply see the various ways to read data, and the other, less commonly used `StreamReader` methods are left to the SDK documentation.

Possibly the easiest method to use is `ReadLine()`, which keeps reading until it gets to the end of a line. It does not include the carriage return–line feed combination that marks the end of the line in the returned string:

```
string nextLine = sr.ReadLine();
```

Alternatively, you can grab the entire remainder of the file (or strictly, the remainder of the stream) in one string:

```
string restOfStream = sr.ReadToEnd();
```

You can read a single character:

```
int nextChar = sr.Read();
```

This overload of `Read()` casts the returned character to an `int`. This is so that it has the option of returning a value of `-1` if the end of the stream has been reached.

Finally, you can read a given number of characters into an array, with an offset:

```
// to read 100 characters in.

int nChars = 100;
char [] charArray = new char[nChars];
int nCharsRead = sr.Read(charArray, 0, nChars);
```

`nCharsRead` will be less than `nChars` if you have requested to read more characters than are left in the file.

The StreamWriter Class

This works in the same way as the `StreamReader`, except that you can use `StreamWriter` only to write to a file (or to another stream). Possibilities for constructing a `StreamWriter` include this:

```
StreamWriter sw = new StreamWriter(@"C:\My Documents\ReadMe.txt");
```

This will use UTF8 encoding, which is regarded by .NET as the default encoding method. If you want, you can specify alternative encoding:

```
StreamWriter sw = new StreamWriter(@"C:\My Documents\ReadMe.txt", true,
   Encoding.ASCII);
```

In this constructor, the second parameter is a `Boolean` that indicates whether the file should be opened for appending. There is, oddly, no constructor that takes only a filename and an encoding class.

Of course, you may want to hook up `StreamWriter` to a file stream to give you more control over the options for opening the file:

```
FileStream fs = new FileStream(@"C:\My Documents\ReadMe.txt",
   FileMode.CreateNew, FileAccess.Write, FileShare.Read);
StreamWriter sw = new StreamWriter(fs);
```

`FileStream` does not implement any methods that return a `StreamWriter` class.

Alternatively, if you want to create a new file and start writing data to it, you will find this sequence useful:

```
FileInfo myFile = new FileInfo(@"C:\My Documents\NewFile.txt");
StreamWriter sw = myFile.CreateText();
```

Just as with all other stream classes, it is important to close a `StreamWriter` class when you are finished with it:

```
sw.Close();
```

Writing to the stream is done using any of 17 overloads of `StreamWriter.Write()`. The simplest writes out a string:

```
string nextLine = "Groovy Line";
sw.Write(nextLine);
```

It is also possible to write out a single character:

```
char nextChar = 'a';
sw.Write(nextChar);
```

And an array of characters:

```
char [] charArray = new char[100];

// initialize these characters

sw.Write(charArray);
```

It is even possible to write out a portion of an array of characters:

```
int nCharsToWrite = 50;
int startAtLocation = 25;
char [] charArray = new char[100];
```

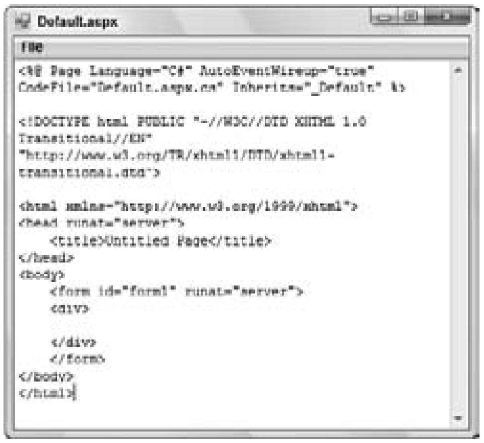
```
    // initialize these characters

    sw.Write(charArray, startAtLocation, nCharsToWrite);
```

ReadWriteText Sample

The `ReadWriteText` sample displays the use of the `StreamReader` and `StreamWriter` classes. It is similar to the earlier `ReadBinaryFile` sample, but it assumes that the file to be read in is a text file and displays it as such. It is also capable of saving the file (with any modifications you have made to the text in the text box). It will save any file in Unicode format.

The screenshot in Figure 29-11 shows `ReadWriteText` displaying the same `Default.aspx` file that you used earlier. This time, however, you are able to read the contents a bit more easily!



```
<%@ Page Language="C#" AutoEventWireup="true"
CodeFile="Default.aspx.cs" Inherits="_Default" %>

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0
Transitional//EN"
"http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">

<html xmlns="http://www.w3.org/1999/xhtml">
<head runat="server">
    <title>Untitled Page</title>
</head>
<body>
    <form id="form1" runat="server">
    <div>

    </div>
    </form>
</body>
</html>
```

FIGURE 29-11

We don't cover the details of adding the event handlers for the Open File dialog box, because they are basically the same as in the earlier `BinaryFileReader` sample. As with that sample, opening a new file causes the `DisplayFile()` method to be called. The only real difference between this sample and the previous one is the implementation of `DisplayFile` as well as that you now have the option to save a file. This is represented by another menu option, Save. The handler for this option calls another method you have added to the code, `SaveFile()`. (Note that the new file always overwrites the original file; this sample does not have an option to write to a different file.)

You look at `SaveFile()` first because it is the simplest function. You simply write each line of the text box, in turn, to a `StreamWriter` stream, relying on the `StreamReader.WriteLine()` method to append the trailing carriage return and line feed to the end of each line:

```
void SaveFile()
{
   StreamWriter sw = new StreamWriter(chosenFile, false, Encoding.Unicode);

   foreach (string line in textBoxContents.Lines)
      sw.WriteLine(line);

   sw.Close();
}
```

code download ReadWriteText.sln

`chosenFile` is a string field of the main form, which contains the name of the file you have read in (just as for the previous example). Notice that you specify Unicode encoding when you open the stream. If you want to write files in some other format, you simply need to change the value of this parameter. The second parameter to this constructor is set to `true` to append to a file, but you do not in this case. The encoding must be set at construction time for a `StreamWriter`. It is subsequently available as a read-only property, `Encoding`.

Now you examine how files are read in. The process of reading in is complicated by the fact that you don't know how many lines it is going to contain until you have read in the file. For example, you don't know how many `(char)13(char)10` sequences are in the file because `char(13)char(10)` is the carriage return–line feed combination that occurs at the end of a line. You solve this problem by initially reading the file into an instance of the `StringCollection` class, which is in the `System.Collections.Specialized` namespace. This class is designed to hold a set of strings that can be dynamically expanded. It implements two methods that you will be interested in: `Add()`, which adds a string to the collection, and `CopyTo()`, which copies the string collection into a normal array (a `System.Array` instance). Each element of the `StringCollection` object holds one line of the file.

The `DisplayFile()` method calls another method, `ReadFileIntoStringCollection()`, which actually reads in the file. After doing this, you now know how many lines there are, so you are in a position to copy the `StringCollection` into a normal, fixed-size array and feed it into the text box. Because only the references to the strings, not the strings themselves, are copied when you actually make the copy, the process is reasonably efficient:

```
void DisplayFile()
{
   StringCollection linesCollection = ReadFileIntoStringCollection();
   string [] linesArray = new string[linesCollection.Count];
   linesCollection.CopyTo(linesArray, 0);
   this.textBoxContents.Lines = linesArray;
}
```

code download ReadWriteText.sln

The second parameter of `StringCollection.CopyTo()` indicates the index within the destination array of where you want the collection to start.

Now you examine the `ReadFileIntoStringCollection()` method. You use a `StreamReader` to read in each line. The main complication here is the need to count the characters read in to make sure that you do not exceed the capacity of the text box:

```
StringCollection ReadFileIntoStringCollection()
{
   const int MaxBytes = 65536;
   StreamReader sr = new StreamReader(chosenFile);
   StringCollection result = new StringCollection();
   int nBytesRead = 0;
   string nextLine;
   while ( (nextLine = sr.ReadLine()) != null)
   {
      nBytesRead += nextLine.Length;
      if (nBytesRead > MaxBytes)
         break;
      result.Add(nextLine);
   }
   sr.Close();
   return result;
}
```

code download ReadWriteText.sln

That completes the code for this sample.

If you run `ReadWriteText`, read in the `Default.aspx` file, and then save it, the file will be in Unicode format. You would not be able to tell this from any of the usual Windows applications. Notepad, WordPad, and even the `ReadWriteText` example will still read the file in and display it correctly under most versions of Windows, although, because Windows 9x doesn't support Unicode, applications like Notepad won't be able to understand the Unicode file on those platforms. (If you download the example from the Wrox Press web site at `www.wrox.com`, you can try this!) However, if you try to display the file again using the earlier `BinaryFileReader` sample, you can see the difference immediately, as shown in Figure 29-12. The two initial bytes that indicate the file is in Unicode format are visible, and thereafter you see that every character is represented by 2 bytes. This last fact is obvious because the high-order byte of every character in this particular file is zero, so every second byte in this file now displays `x00`.

FIGURE 29-12

MAPPED-MEMORY FILES

If you have been working your entire coding life with only managed code, then mapped-memory files might be a brand new concept. .NET Framework 4 now supplies mapped-memory files as part of your toolkit for building applications with the introduction of the `System.IO.MemoryMappedFiles` namespace.

It is always possible to use the concept of mapped-memory files by doing some P/Invokes to the underlying Windows APIs, but now with the introduction of the `System.IO.MemoryMappedFiles` namespace, you can work with managed code rather than operating in the cumbersome P/Invoke world.

Mapped-memory files and the use of this namespace are ideal when your application requires frequent or random access to files. Using this approach allows you to load part or all of the file into a segment of virtual memory, which then appears to your application as if this file is contained within the primary memory for the application.

Interestingly, you can use this file in memory as a shared resource among more than one process. Prior to this, you might have been using Windows Communication Foundation (WCF) or Named Pipes to communicate a shared resource between multiple processes, but now you can share a mapped-memory file between processes using a shared name.

To work with mapped-memory files, you have to work with a couple of objects. The first is a mapped-memory file instance that loads the file. The second is an accessor object. The following code writes to the mapped-memory file object and then reads from it. You also see that the write is also happening when the object is disposed:

```
using System;
using System.IO.MemoryMappedFiles;
using System.Text;

namespace MappedMemoryFiles
```

```
{
    class Program
    {
        static void Main(string[] args)
        {
            using (var mmFile= MemoryMappedFile.CreateFromFile(
              @"C:\Users\Bill\Document\Visual Studio 10\Projects\
               MappedMemoryFiles\MappedMemoryFiles\TextFile1.txt",
              System.IO.FileMode.Create, "fileHandle", 1024 * 1024))
            {
                string valueToWrite = "Written to the mapped-memory file on " +
                   DateTime.Now.ToString();
                var myAccessor = mmFile.CreateViewAccessor();

                myAccessor.WriteArray<byte>(0,
                   Encoding.ASCII.GetBytes(valueToWrite), 0,
                   valueToWrite.Length);

                var readOut = new byte[valueToWrite.Length];
                myAccessor.ReadArray<byte>(0, readOut, 0, readOut.Length);
                var finalValue = Encoding.ASCII.GetString(readOut);

                Console.WriteLine("Message: " + finalValue);
                Console.ReadLine();
            }
        }
    }
}
```

code download MappedMemoryFiles.sln

In this case, a mapped-memory file is created from a physical file using the `CreateFromFile()` method. In addition to a mapped-memory file, you then need to create an accessor object to this mapping. That is done using the following:

```
var myAccessor = mmFile.CreateViewAccessor();
```

After the accessor is in place, you can then write or read to this mapped-memory location as shown in the code example.

It is also possible to create multiple accessors to the same mapped-memory location as shown here:

```
var myAccessor1 = mmFile.CreateViewAccessor();
var myAccessor2 = mmFile.CreateViewAccessor();
```

READING DRIVE INFORMATION

In addition to working with files and directories, the .NET Framework includes the ability to read information from a specified drive. This is done using the `DriveInfo` class. The `DriveInfo` class can perform a scan of a system to provide a list of available drives and then can dig in deeper, providing you with tons of details about any of the drives.

For an example of using the `DriveInfo` class, create a simple Windows Form that will list all the available drives on a computer and then provide details on a user-selected drive. Your Windows Form will consist of a simple `ListBox` and should look like Figure 29-13.

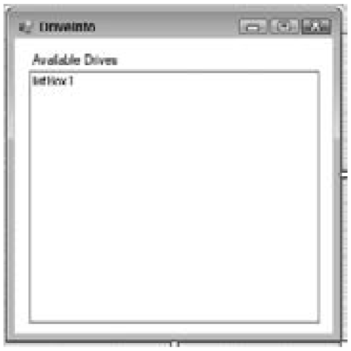

FIGURE 29-13

When you have the form all set, the code consists of two events — one for when the form loads and another for when the end user makes a drive selection in the list box. The code for this form is shown here:

```
using System;
using System.IO;
using System.Windows.Forms;

namespace DriveViewer
{
    public partial class Form1: Form
    {
        public Form1()
        {
            InitializeComponent();
        }

        private void Form1_Load(object sender, EventArgs e)
        {
            DriveInfo[] di = DriveInfo.GetDrives();

            foreach (DriveInfo itemDrive in di)
            {
                listBox1.Items.Add(itemDrive.Name);
            }
        }

        private void listBox1_SelectedIndexChanged(object sender, EventArgs e)
        {
            DriveInfo di = new DriveInfo(listBox1.SelectedItem.ToString());

            MessageBox.Show("Available Free Space: "
               + di.AvailableFreeSpace + "\n" +
               "Drive Format: " + di.DriveFormat + "\n" +
               "Drive Type: " + di.DriveType + "\n" +
               "Is Ready: " + di.IsReady + "\n" +
               "Name: " + di.Name + "\n" +
               "Root Directory: " + di.RootDirectory + "\n" +
               "ToString() Value: " + di + "\n" +
               "Total Free Space: " + di.TotalFreeSpace + "\n" +
               "Total Size: " + di.TotalSize + "\n" +
               "Volume Label: " + di.VolumeLabel, di.Name +
               " DRIVE INFO");
        }
    }
}
```

code download DriveViewer.sln

The first step is to bring in the `System.IO` namespace with the `using` keyword. Within the `Form1_Load` event, you use the `DriveInfo` class to get a list of all the available drives on the system. This is done using an array of `DriveInfo` objects and populating this array with the `DriveInfo.GetDrives()` method. Then using a `foreach` loop, you are able to iterate through each drive found and populate the list box with the results. This produces something similar to what is shown in Figure 29-14.

This form allows the end user to select one of the drives in the list. After a drive is selected, a message box appears that contains details about that drive. As you can see in Figure 29-14, I have six drives on my current computer. Selecting a couple of these drives produces the message boxes collectively shown in Figure 29-15.

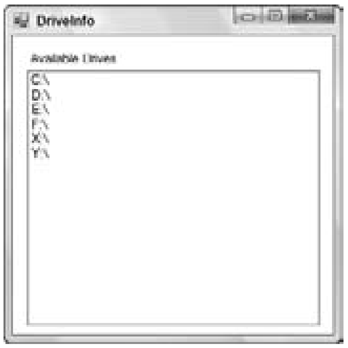

FIGURE 29-14

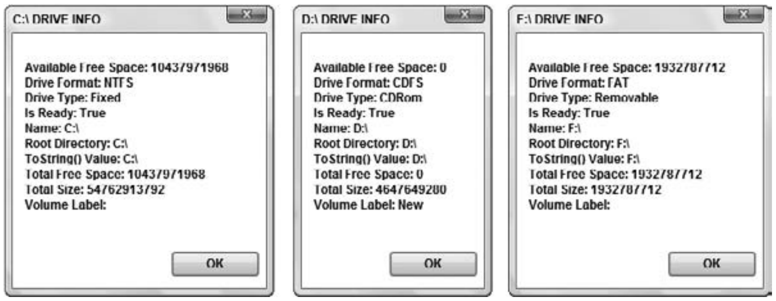

```
Available Free Space: 10437971968
Drive Format: NTFS
Drive Type: Fixed
Is Ready: True
Name: C:\
Root Directory: C:\
ToString() Value: C:\
Total Free Space: 10437971968
Total Size: 54762913792
Volume Label:
```

```
Available Free Space: 0
Drive Format: CDFS
Drive Type: CDRom
Is Ready: True
Name: D:\
Root Directory: D:\
ToString() Value: D:\
Total Free Space: 0
Total Size: 4647649280
Volume Label: New
```

```
Available Free Space: 1932787712
Drive Format: FAT
Drive Type: Removable
Is Ready: True
Name: F:\
Root Directory: F:\
ToString() Value: F:\
Total Free Space: 1932787712
Total Size: 1932787712
Volume Label:
```

FIGURE 29-15

From here, you can see that these message boxes provide details about three entirely different drives. The first, drive `C:\`, is my hard drive, as the message box shows its drive type as `Fixed`. The second drive, drive `D:\`, is my CD/DVD drive. The third drive, drive `F:\`, is my USB pen and is labeled with a `Removable` drive type.

FILE SECURITY

When the .NET Framework 1.0/1.1 was first introduced, it didn't come with a way to easily access and work access control lists (ACLs) for files, directories, and registry keys. To do such things at that time usually meant some work with COM interop, thus also requiring a more advanced programming knowledge of working with ACLs.

This has considerably changed after the release of the .NET Framework 2.0 came out. This made the process of working with ACLs considerably easier with a namespace — `System.Security.AccessControl`. With this namespace, it is now possible to manipulate security settings for files, registry keys, network shares, Active Directory objects, and more.

Reading ACLs from a File

For an example of working with `System.Security.AccessControl`, this section looks at working with the ACLs for both files and directories. It starts by looking at how you would review the ACLs for a particular file. This example is accomplished in a console application and is illustrated here:

```
using System;
using System.IO;
using System.Security.AccessControl;
using System.Security.Principal;

namespace ReadingACLs
{
    internal class Program
    {
        private static string myFilePath;

        private static void Main()
        {
            Console.Write("Provide full file path: ");
            myFilePath = Console.ReadLine();

            try
            {
                using (FileStream myFile =
                   new FileStream(myFilePath, FileMode.Open, FileAccess.Read))
```

```
                    {
                        FileSecurity fileSec = myFile.GetAccessControl();

                        foreach (FileSystemAccessRule fileRule in
                            fileSec.GetAccessRules(true, true,
                               typeof (NTAccount)))
                        {
                            Console.WriteLine("{0} {1} {2} access for {3}",
                               myFilePath,
                               fileRule.AccessControlType ==
                               AccessControlType.Allow
                                  ? "provides": "denies",
                                  fileRule.FileSystemRights,
                                  fileRule.IdentityReference);
                        }
                    }
                }
                catch
                {
                    Console.WriteLine("Incorrect file path given!");
                }

                Console.ReadLine();
            }
        }
    }
```

code download ReadingACLs.sln

For this example to work, the first step is to refer to the `System.Security.AccessControl` namespace. This will give you access to the `FileSecurity` and the `FileSystemAccessRule` classes later in the program.

After the specified file is retrieved and placed in a `FileStream` object, the ACLs of the file are grabbed using the `GetAccessControl()` method now found on the `File` object. This information from the `GetAccessControl()` method is then placed in a `FileSecurity` class. This class has access rights to the referenced item. Each individual access right is then represented by a `FileSystemAccessRule` object. That is why a `foreach` loop is used to iterate through all the access rights found in the created `FileSecurity` object.

Running this example with a simple text file in the root directory produces something similar to the following results:

```
Provide full file path: C:\Sample.txt
C:\Sample.txt provides FullControl access for BUILTIN\Administrators
C:\Sample.txt provides FullControl access for NT AUTHORITY\SYSTEM
C:\Sample.txt provides ReadAndExecute, Synchronize access for BUILTIN\Users
C:\Sample.txt provides Modify, Sychronize access for
      NT AUTHORITY\Authenticated Users
```

The next section presents reading ACLs from a directory instead of a file.

Reading ACLs from a Directory

Reading ACL information about a directory instead of an actual file is not much different from the preceding example. The code for this is illustrated in the following example:

```
using System;
using System.IO;
using System.Security.AccessControl;
using System.Security.Principal;

namespace ConsoleApplication1
{
    internal class Program
    {
        private static string mentionedDir;

        private static void Main()
        {
            Console.Write("Provide full directory path: ");
            mentionedDir = Console.ReadLine();

            try
            {
                DirectoryInfo myDir = new DirectoryInfo(mentionedDir);

                if (myDir.Exists)
                {
                    DirectorySecurity myDirSec = myDir.GetAccessControl();

                    foreach (FileSystemAccessRule fileRule in
                        myDirSec.GetAccessRules(true, true,
                                                typeof (NTAccount)))
                    {
                        Console.WriteLine("{0} {1} {2} access for {3}",
                           mentionedDir, fileRule.AccessControlType ==
                              AccessControlType.Allow
                              ? "provides": "denies",
                              fileRule.FileSystemRights,
                              fileRule.IdentityReference);
                    }
                }
            }
            catch
            {
                Console.WriteLine("Incorrect directory provided!");
            }

            Console.ReadLine();
        }
    }
}
```

code download ReadingACLsFromDirectory.sln

The big difference with this example is that it uses the `DirectoryInfo` class, which now also includes the `GetAccessControl()` method to pull information about the directory's ACLs. Running this example produces the following results when using Windows 7:

```
Provide full directory path: C:\Test
C:\Test provides FullControl access for BUILTIN\Administrators
C:\Test provides 268435456 access for BUILTIN\Administrators
C:\Test provides FullControl access for NT AUTHORITY\SYSTEM
C:\Test provides 268435456 access for NT AUTHORITY\SYSTEM
C:\Test provides ReadAndExecute, Synchronize access for BUILTIN\Users
C:\Test provides Modify, Synchronize access for
         NT AUTHORITY\Authenticated Users
C:\Test provides -536805376 access for NT AUTHORITY\Authenticated Users
```

The final thing you will look at when working with ACLs is using the new `System.Security.AccessControl` namespace to add and remove items to and from a file's ACL.

Adding and Removing ACLs from a File

It is also possible to manipulate the ACLs of a resource using the same objects that were used in the previous examples. The following code example changes a previous code example where a file's ACL information was read. Here, the ACLs are read for a specified file, changed, and then read again:

```
try
{
   using (FileStream myFile = new FileStream(myFilePath,
      FileMode.Open, FileAccess.ReadWrite))
   {
      FileSecurity fileSec = myFile.GetAccessControl();

      Console.WriteLine("ACL list before modification:");

      foreach (FileSystemAccessRule fileRule in
         fileSec.GetAccessRules(true, true,
          typeof(System.Security.Principal.NTAccount)))
      {
         Console.WriteLine("{0} {1} {2} access for {3}", myFilePath,
            fileRule.AccessControlType == AccessControlType.Allow ?
            "provides": "denies",
            fileRule.FileSystemRights,
            fileRule.IdentityReference);
      }

      Console.WriteLine();
      Console.WriteLine("ACL list after modification:");

      FileSystemAccessRule newRule = new FileSystemAccessRule(
         new System.Security.Principal.NTAccount(@"PUSHKIN\Tuija"),
         FileSystemRights.FullControl,
         AccessControlType.Allow);

      fileSec.AddAccessRule(newRule);
      File.SetAccessControl(myFilePath, fileSec);

      foreach (FileSystemAccessRule fileRule in
         fileSec.GetAccessRules(true, true,
         typeof(System.Security.Principal.NTAccount)))
      {
         Console.WriteLine("{0} {1} {2} access for {3}", myFilePath,
            fileRule.AccessControlType == AccessControlType.Allow ?
            "provides": "denies",
            fileRule.FileSystemRights,
            fileRule.IdentityReference);
      }
   }
}
```

In this case, a new access rule is added to the file's ACL. This is done by using the `FileSystemAccessRule` object. The `FileSystemAccessRule` class is an abstraction access control entry (ACE) instance. The ACE defines the user account to use, the type of access that this user account can deal with, and whether or not to allow or deny this access. In creating a new instance of this object, a new `NTAccount` is created and given `Full Control` to the file. Even though a new `NTAccount` is created, it must still reference an existing user. Then the `AddAccessRule` method of the `FileSecurity` class is used to assign the new rule. From there, the `FileSecurity` object reference is used to set the access control to the file in question using the `SetAccessControl()` method of the `File` class.

Next, the file's ACL is listed again. The following is an example of what the preceding code could produce:

```
Provide full file path: C:\Users\Bill\Sample.txt
ACL list before modification:
C:\Sample.txt provides FullControl access for NT AUTHORITY\SYSTEM
C:\Sample.txt provides FullControl access for BUILTIN\Administrators
C:\Sample.txt provides FullControl access for PUSHKIN\Bill

ACL list after modification:
C:\Sample.txt provides FullControl access for PUSHKIN\Tuija
C:\Sample.txt provides FullControl access for NT AUTHORITY\SYSTEM
C:\Sample.txt provides FullControl access for BUILTIN\Administrators
C:\Sample.txt provides FullControl access for PUSHKIN\Bill
```

To remove a rule from the ACL list, there is really not much that needs to be done to the code. From the previous code example, you simply need to change the line

```
fileSec.AddAccessRule(newRule);
```

to the following to remove the rule that was just added:

```
fileSec.RemoveAccessRule(newRule);
```

READING AND WRITING TO THE REGISTRY

In all versions of Windows since Windows 95, the registry has been the central repository for all configuration information relating to Windows setup, user preferences, and installed software and devices. Almost all commercial software these days uses the registry to store information about itself, and COM components must place information about themselves in the registry in order to be called by clients. The .NET Framework and its accompanying concept of zero-impact installation has slightly reduced the significance of the registry for applications in the sense that assemblies are entirely self-contained; no information about particular assemblies needs to be placed in the registry, even for shared assemblies. In addition, the .NET Framework has brought the concept of isolated storage — applications can store information that is particular to each user in files — and .NET Framework ensures that data is stored separately for each user registered on a machine.

The fact that applications can now be installed using the Windows Installer also frees developers from some of the direct manipulation of the registry that used to be involved in installing applications. However, despite this, the possibility exists that if you distribute any complete application, your application will use the registry to store information about its configuration. For instance, if you want your application to show up in the Add/Remove Programs dialog box in the Control Panel, this will involve appropriate registry entries. You may also need to use the registry for backward compatibility with legacy code.

As you would expect from a library as comprehensive as the .NET library, it includes classes that give you access to the registry. Two classes are concerned with the registry, and both are in the `Microsoft.Win32` namespace. The classes are `Registry` and `RegistryKey`. Before you examine these classes, the following section briefly reviews the structure of the registry itself.

The Registry

The registry has a hierarchical structure much like that of the file system. The usual way to view or modify the contents of the registry is with one of two utilities: `regedit` or `regedt32`. Of these, `regedit` comes standard with all versions of Windows since Windows 95. `regedt32` comes with Windows NT and Windows 2000; it is less user-friendly than `regedit`, but allows access to security information that `regedit` is unable to view. Windows Server 2003 has merged `regedit` and `regedt32` into a single new editor simply called `regedit`. For the discussion here, you will use `regedit` from Windows 7, which you can launch by typing **regedit** in the Run dialog or at the command prompt.

Figure 29-16 shows what you get when you launch `regedit` for the first time.

regedit has a tree view/list view-style user interface similar to Windows Explorer, which matches the hierarchical structure of the registry itself. However, you will see some key differences shortly.

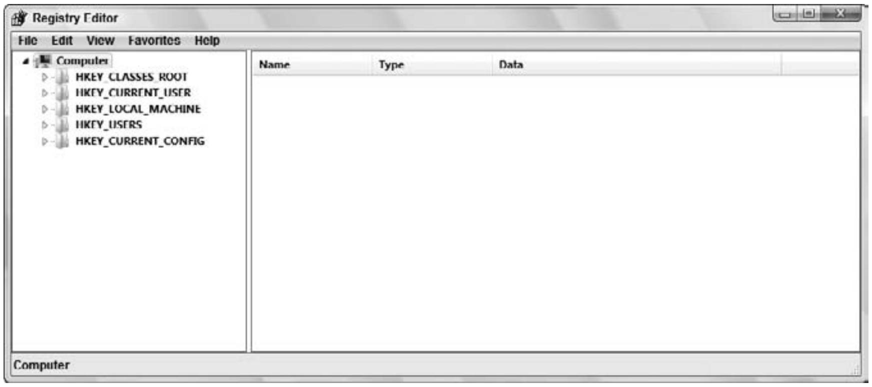

FIGURE 29-16

In a file system, the topmost-level nodes can be thought of as being the partitions on your disks, `C:\`, `D:\`, and so on. In the registry, the equivalent to a partition is the *registry hive*. It is not possible to change the existing hives — they are fixed, and there are seven of them, although only five are actually visible through `regedit`:

- ➤ `HKEY_CLASSES_ROOT` (HKCR) contains details of types of files on the system (`.txt`, `.doc`, and so on) and which applications are able to open files of each type. It also contains registration information for all COM components (this latter area is usually the largest single area of the registry because Windows, these days, comes with a huge number of COM components).
- ➤ `HKEY_CURRENT_USER` (HKCU) contains details of user preferences for the user currently logged on to the machine locally. These settings include desktop settings, environment variables, network and printer connections, and other settings that define the user operating environment of the user.
- ➤ `HKEY_LOCAL_MACHINE` (HKLM) is a huge hive that contains details of all software and hardware installed on the machine. These settings are not user-specific but are for all users that log on to the machine. This hive also includes the HKCR hive; HKCR is actually not really an independent hive in its own right but is simply a convenient mapping onto the registry key `HKLM/SOFTWARE/Classes`.
- ➤ `HKEY_USERS` (HKUSR) contains details of user preferences for all users. As you might guess, it also contains the HKCU hive, which is simply a mapping onto one of the keys in `HKEY_USERS`.
- ➤ `HKEY_CURRENT_CONFIG` (HKCF) contains details of hardware on the machine.

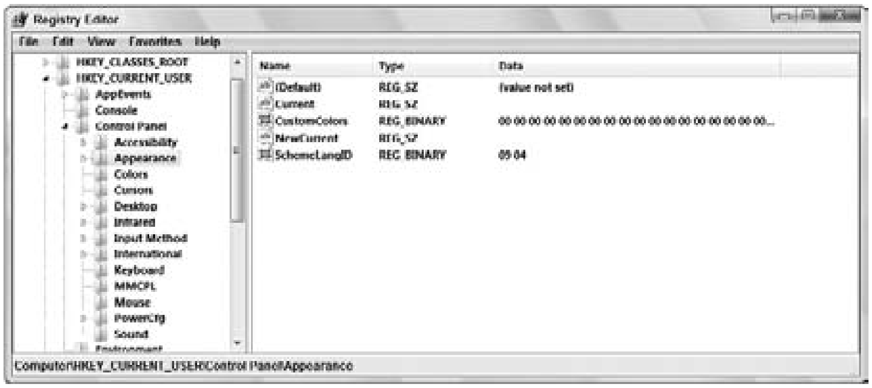
The remaining two keys contain information that is temporary and that changes frequently:

- ➤ `HKEY_DYN_DATA` is a general container for any volatile data that needs to be stored somewhere in the registry.
- ➤ `HKEY_PERFORMANCE_DATA` contains information concerning the performance of running applications.

Within the hives is a tree structure of registry *keys*. Each key is in many ways analogous to a folder or file on the file system. However, there is one very important difference. The file system distinguishes between files (which are there to contain data) and folders (which are primarily there to contain other files or folders), but in the registry there are only keys. A key may contain both data and other keys.

If a key contains data, it will be presented as a series of values. Each value will have an associated name, data type, and data. In addition, a key can have a default value, which is unnamed.

You can see this structure by using `regedit` to examine registry keys. Figure 29-17 shows the contents of the key `HKCU\Control Panel\Appearance`, which contains the details of the chosen color scheme of the currently logged-in user. `regedit` shows which key is being examined by displaying it with an open folder icon in the tree view.



Name	Type	Data
(Default)	REG_SZ	(value not set)
Current	REG_SZ	
CustomColors	REG_BINARY	00 00 00 00 00 00 00 00 00 00 00 00 00 00 00 00 00 00...
NewCurrent	REG_SZ	
SchemeLangID	REG_BINARY	09 04

Computer\HKEY_CURRENT_USER\Control Panel\Appearance

FIGURE 29-17

The `HKCU\Control Panel\Appearance` key has three named values set, although the default value does not contain any data. The column in the screenshot marked Type details the data type of each value. Registry entries can be formatted as one of three data types:

- ➤ `REG_SZ` (which roughly corresponds to a .NET string instance; the matching is not exact because the registry data types are not .NET data types)
- ➤ `REG_DWORD` (corresponds roughly to `uint`)
- ➤ `REG_BINARY` (array of bytes)

An application that stores data in the registry will do so by creating a number of registry keys, usually under the key `HKLM\Software\<CompanyName>`. Note that it is not necessary for these keys to contain any data. Sometimes the very fact that a key exists provides the data that an application needs.

The .NET Registry Classes

Access to the registry is available through two classes in the `Microsoft.Win32` namespace: `Registry` and `RegistryKey`. A `RegistryKey` instance represents a registry key. This class implements methods to browse child keys, to create new keys, or to read or modify the values in the key — in other words, to do everything you would normally want to do with a registry key, including setting the security levels for the key. `RegistryKey` will be the class you use for much of your work with the registry. `Registry`, by contrast, is a class that allows for singular access to registry keys for simple operations. Another role of the `Registry` class is simply to provide you with `RegistryKey` instances that represent the top-level keys, the different hives, to enable you to navigate the registry. `Registry` provides these instances through static properties, and there are seven of them called, respectively, `ClassesRoot`, `CurrentConfig`, `CurrentUser`, `DynData`, `LocalMachine`, `PerformanceData`, and `Users`. It should be obvious which property corresponds to which hive.

So, for example, to obtain a `RegistryKey` instance that represents the `HKLM` key, you would write:

```
RegistryKey hklm = Registry.LocalMachine;
```

The process of obtaining a reference to a `RegistryKey` object is known as opening the key.

Although you might expect that the methods exposed by `RegistryKey` would be similar to those implemented by `DirectoryInfo`, given that the registry has a similar hierarchical structure to the file system, this actually isn't the case. Often, the way that you access the registry is different from the way that you would use files and folders, and `RegistryKey` implements methods that reflect this.

The most obvious difference is in how you open a registry key at a given location in the registry. The `Registry` class does not have any public constructor that you can use, nor does it have any methods that let you go directly to a key, given its name. Instead, you are expected to browse down to that key from the top of the relevant hive. If you want to instantiate a `RegistryKey` object, the only way is to start off with the appropriate static property of `Registry`, and work down from there. So, for example, if you want to read some data in the `HKLM/Software/Microsoft` key, you would get a reference to it like this:

```
RegistryKey hklm = Registry.LocalMachine;
RegistryKey hkSoftware = hklm.OpenSubKey("Software");
RegistryKey hkMicrosoft = hkSoftware.OpenSubKey("Microsoft");
```

A registry key accessed in this way will give you read-only access. If you want to write to the key (that includes writing to its values or creating or deleting direct children of it), you need to use another override to `OpenSubKey`, which takes a second parameter, of type `bool`, that indicates whether you want read-write access to the key. For example, if you want to be able to modify the `Microsoft` key (and assuming that you are a system administrator with permission to do this), you would write this:

```
RegistryKey hklm = Registry.LocalMachine;
RegistryKey hkSoftware = hklm.OpenSubKey("Software");
RegistryKey hkMicrosoft = hkSoftware.OpenSubKey("Microsoft", true);
```

Incidentally, because this key contains information used by Microsoft's applications, in most cases you probably shouldn't be modifying this particular key.

The `OpenSubKey()` method is the one you call if you are expecting the key to be present. If the key isn't there, it returns a `null` reference. If you want to create a key, you should use the `CreateSubKey()` method (which automatically gives you read-write access to the key through the reference returned):

```
RegistryKey hklm = Registry.LocalMachine;
RegistryKey hkSoftware = hklm.OpenSubKey("Software");
RegistryKey hkMine = hkSoftware.CreateSubKey("MyOwnSoftware");
```

The way that `CreateSubKey()` works is quite interesting. It creates the key if it does not already exist, but if it does exist, it quietly returns a `RegistryKey` instance that represents the existing key. The reason for the method behaving in this manner has to do with how you normally use the registry. The registry, overall, contains long-term data such as configuration information for Windows and for various applications. It is not very common, therefore, that you find yourself in a situation where you need to explicitly create a key.

What is much more common is that your application needs to make sure that some data is present in the registry — in other words, create the relevant keys if they do not already exist, but do nothing if they do. `CreateSubKey()` fills that need perfectly. Unlike the situation with `FileInfo.Open()`, for example, there is no chance with `CreateSubKey()` of accidentally removing any data. If deleting registry keys is your intention, you will need to call the `RegistryKey.DeleteSubKey()` method. This makes sense given the importance of the registry to Windows. The last thing you want is to completely break Windows accidentally by deleting a couple of important keys while you are debugging your C# registry calls!

After you have located the registry key you want to read or modify, you can use the `SetValue()` or `GetValue()` methods to set or get at the data in it. Both of these methods take a string giving the name of the value as a parameter, and `SetValue()` requires an additional object reference containing details of the value. Because the parameter is defined as an object reference, it can actually be a reference to any class you want. `SetValue()` will decide from the type of class actually supplied whether to set the value as a `REG_SZ`, `REG_DWORD` or `REG_BINARY` value. For example:

```
RegistryKey hkMine = HkSoftware.CreateSubKey("MyOwnSoftware");
hkMine.SetValue("MyStringValue", "Hello World");
hkMine.SetValue("MyIntValue", 20);
```

This code sets the key with two values: `MyStringValue` will be of type `REG_SZ`, and `MyIntValue` will be of type `REG_DWORD`. These are the only two types you will consider here and use in the example presented later.

`RegistryKey.GetValue()` works in much the same way. It is defined to return an object reference, which means that it is free to actually return a `string` reference if it detects the value is of type `REG_SZ`, and an `int` if that value is of type `REG_DWORD`:

```
string stringValue = (string)hkMine.GetValue("MyStringValue");
int intValue = (int)hkMine.GetValue("MyIntValue");
```

Finally, after you have finished reading or modifying the data, close the key:

```
hkMine.Close();
```

`RegistryKey` implements a large number of methods and properties. The following table lists the most useful properties.

PROPERTY	DESCRIPTION
`Name`	Name of the key (read-only)
`SubKeyCount`	The number of children of this key
`ValueCount`	How many values the key contains

The following table lists the most useful methods.

METHOD	PURPOSE
`Close()`	Closes the key.
`CreateSubKey()`	Creates a subkey of a given name (or opens it if it already exists).
`DeleteSubKey()`	Deletes a given subkey.
`DeleteSubKeyTree()`	Recursively deletes a subkey and all its children.
`DeleteValue()`	Removes a named value from a key.
`GetAccessControl()`	Returns the ACL for a specified registry key. This method was added in .NET Framework 2.0.
`GetSubKeyNames()`	Returns an array of strings containing the names of the subkeys.
`GetValue()`	Returns a named value.
`GetValueKind()`	Returns a named value whose registry data type is to be retrieved. This method was added in .NET Framework 2.0.
`GetValueNames()`	Returns an array of strings containing the names of all the values of the key.
`OpenSubKey()`	Returns a reference to a `RegistryKey` instance that represents a given subkey.
`SetAccessControl()`	Allows you to apply an ACL to a specified registry key.
`SetValue()`	Sets a named value.

READING AND WRITING TO ISOLATED STORAGE

In addition to being able to read and write to and from the registry, another option is reading and writing values to and from what is called *isolated storage*. If you are having issues writing to the registry or to disk in general, then isolated storage is where you should turn. You can use isolated storage to store application state or user settings quite easily.

Think of isolated storage as a virtual disk where you can save items that can be shared only by the application that created them, or with other application instances. There are two types of access types for isolated storage. The first is user and assembly.

When accessing isolated storage by user and assembly, there is a single storage location on the machine, which is accessible via multiple application instances. Access is guaranteed through the user identity and the application (or assembly) identity. Figure 29-18 shows this.

This means that you can have multiple instances of the same application all working from the same store.

The second type of access for isolated storage is user, assembly, and domain. In this case, each application instance works off its own isolation store. This is detailed in Figure 29-19.

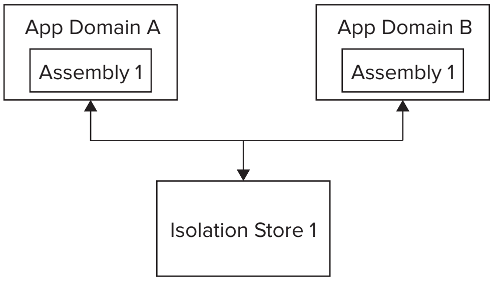


FIGURE 29-18

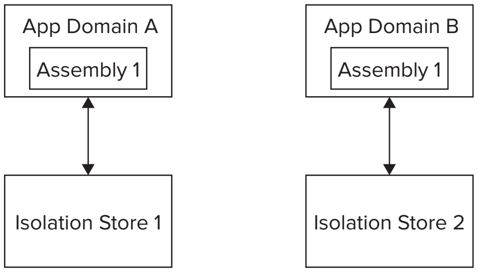

FIGURE 29-19

In this case, each application instance works off its own store, and the settings that each application instance records are related only to itself. This is a more fine-grained approach to isolated storage.

For an example of using isolated storage from a Windows Forms application (although you can use this from an ASP.NET application just as well), you can use the `ReadSettings()` and `SaveSettings()` methods shown next to read and write values to isolated storage as opposed to maybe doing the same directly in the registry.

It is important to note that the only code shown here is for the `ReadSettings()` *and* `SaveSettings()` *methods. There is more code to the application, and you can see the rest in the download code file in the sample titled* `SelfPlacingWindow`.

To start, you need to rework the `SaveSettings()` method. For this next bit of code to work, you need to add the following using directives:

```
using System.IO;
using System.IO.IsolatedStorage;
using System.Text;
```

The `SaveSettings()` method is detailed in the following code example:

```
void SaveSettings()
{
   IsolatedStorageFile storFile = IsolatedStorageFile.GetUserStoreForDomain();
   IsolatedStorageFileStream storStream = new
      IsolatedStorageFileStream("SelfPlacingWindow.xml",

      FileMode.Create, FileAccess.Write);

   System.Xml.XmlTextWriter writer = new
      System.Xml.XmlTextWriter(storStream, Encoding.UTF8);
   writer.Formatting = System.Xml.Formatting.Indented;

   writer.WriteStartDocument();
   writer.WriteStartElement("Settings");

   writer.WriteStartElement("BackColor");
   writer.WriteValue(BackColor.ToKnownColor().ToString());
   writer.WriteEndElement();
```

```
        writer.WriteStartElement("Red");
        writer.WriteValue(BackColor.R);
        writer.WriteEndElement();

        writer.WriteStartElement("Green");
        writer.WriteValue(BackColor.G);
        writer.WriteEndElement();

        writer.WriteStartElement("Blue");
        writer.WriteValue(BackColor.B);
        writer.WriteEndElement();

        writer.WriteStartElement("Width");
        writer.WriteValue(Width);
        writer.WriteEndElement();

        writer.WriteStartElement("Height");
        writer.WriteValue(Height);
        writer.WriteEndElement();

        writer.WriteStartElement("X");
        writer.WriteValue(DesktopLocation.X);
        writer.WriteEndElement();

        writer.WriteStartElement("Y");
        writer.WriteValue(DesktopLocation.Y);
        writer.WriteEndElement();

        writer.WriteStartElement("WindowState");
        writer.WriteValue(WindowState.ToString());
        writer.WriteEndElement();

        writer.WriteEndElement();

        writer.Flush();
        writer.Close();

        storStream.Close();
        storFile.Close();
    }
```

It is a bit more code than you might be used to when working with the registry, but that is mainly due to the code required to build the XML document placed in isolated storage. The first important thing happening with this code is presented here:

```
IsolatedStorageFile storFile = IsolatedStorageFile.GetUserStoreForDomain();
IsolatedStorageFileStream storStream = new
   IsolatedStorageFileStream("SelfPlacingWindow.xml",
   FileMode.Create, FileAccess.Write);
```

Here, an instance of an `IsolatedStorageFile` is created using a user, assembly, and domain type of access. A stream is created using the `IsolatedStorageFileStream` object, which creates the virtual `SelfPlacingWindow.xml` file.

From there, an `XmlTextWriter` object is created to build the XML document and the XML contents are written to the `IsolatedStorageFileStream` object instance:

```
System.Xml.XmlTextWriter writer = new
   System.Xml.XmlTextWriter(storStream, Encoding.UTF8);
```

After the `XmlTextWriter` object is created, all the values are written to the XML document node by node. When everything is written to the XML document, everything is closed and is stored in the isolated storage.

Reading from the storage is done through the `ReadSettings()` method. This method is presented in the following code example:

```
bool ReadSettings()
{
   IsolatedStorageFile storFile = IsolatedStorageFile.GetUserStoreForDomain();
   string[] userFiles = storFile.GetFileNames("SelfPlacingWindow.xml");

   foreach (string userFile in userFiles)
   {
      if(userFile == "SelfPlacingWindow.xml")
      {
         listBoxMessages.Items.Add("Successfully opened file " +
                                   userFile.ToString());

         StreamReader storStream =
            new StreamReader(new IsolatedStorageFileStream("SelfPlacingWindow.xml",
            FileMode.Open, storFile));
         System.Xml.XmlTextReader reader = new
            System.Xml.XmlTextReader(storStream);

         int redComponent = 0;
         int greenComponent = 0;
         int blueComponent = 0;

         int X = 0;
         int Y = 0;

         while (reader.Read())
         {
            switch (reader.Name)
            {
               case "Red":
                  redComponent = int.Parse(reader.ReadString());
                  break;
               case "Green":
                  greenComponent = int.Parse(reader.ReadString());
                  break;
               case "Blue":
                  blueComponent = int.Parse(reader.ReadString());
                  break;
               case "X":
                  X = int.Parse(reader.ReadString());
                  break;
               case "Y":
                  Y = int.Parse(reader.ReadString());
                  break;
               case "Width":
                  this.Width = int.Parse(reader.ReadString());
                  break;
               case "Height":
                  this.Height = int.Parse(reader.ReadString());
                  break;
               case "WindowState":
                  this.WindowState = (FormWindowState)FormWindowState.Parse
                    (WindowState.GetType(), reader.ReadString());
                  break;
               default:
                  break;
            }
         }
```

```
            this.BackColor =
               Color.FromArgb(redComponent, greenComponent, blueComponent);
            this.DesktopLocation = new Point(X, Y);

            listBoxMessages.Items.Add("Background color: " + BackColor.Name);
            listBoxMessages.Items.Add("Desktop location: " +
               DesktopLocation.ToString());
            listBoxMessages.Items.Add("Size: " + new Size(Width, Height).ToString());
            listBoxMessages.Items.Add("Window State: " + WindowState.ToString());

            storStream.Close();
            storFile.Close();
         }
      }
      return true;
   }
```

Using the `GetFileNames()` method, the `SelfPlacingWindow.xml` document is pulled from the isolated storage and then placed into a stream and parsed using the `XmlTextReader` object:

```
      IsolatedStorageFile storFile = IsolatedStorageFile.GetUserStoreForDomain();
      string[] userFiles = storFile.GetFileNames("SelfPlacingWindow.xml");

      foreach (string userFile in userFiles)
      {
         if(userFile == "SelfPlacingWindow.xml")
         {
            listBoxMessages.Items.Add("Successfully opened file " +
                                      userFile.ToString());

            StreamReader storStream =
               new StreamReader(new IsolatedStorageFileStream("SelfPlacingWindow.xml",
               FileMode.Open, storFile));
```

After the XML document is contained within the `IsolatedStorageFileStream` object, it is parsed using the `XmlTextReader` object:

```
            System.Xml.XmlTextReader reader = new
               System.Xml.XmlTextReader(storStream);
```

After, it is pulled from the stream via the `XmlTextReader`. The element values are then pushed back into the application. You will then find — just as was accomplished in the `SelfPlacingWindow` sample that used the registry to record and retrieve application state values — that using isolated storage is just as effective as working with the registry. The application remembers the color, size, and position just as before.

SUMMARY

In this chapter, you examined how to use the .NET base classes to access the file system and registry from your C# code. You have seen that in both cases the base classes expose simple, but powerful, object models that make it very simple to perform almost any kind of action in these areas. For the file system, these actions are copying files; moving, creating, and deleting files and folders; and reading and writing both binary and text files. For the registry, these are creating, modifying, or reading keys.

This chapter also reviewed isolated storage and how to use this from your applications to store them in the application state.

This chapter assumed that you were running your code from an account that has sufficient access rights to do whatever the code needs to do. Obviously, the question of security is an important one, and it is discussed in Chapter 21.

PART IV
Data

30 Core ADO.NET

WHAT'S IN THIS CHAPTER?

- Connecting to the database
- Executing commands
- Calling stored procedures
- The ADO.NET object model
- Using XML and XML schemas

This chapter discusses how to access data from your C# programs using ADO.NET. It shows you how to use the `SqlConnection` and `OleDbConnection` classes to connect to and disconnect from the database. You learn the various command object options and see how commands can be used for each of the options presented by the `Sql` and `OleDB` classes, how to call stored procedures with command objects, and how the results of those stored procedures can be integrated into the data cached on the client. The ADO.NET object model is significantly different from the objects available with ADO. The `DataSet`, `DataTable`, `DataRow`, and `DataColumn` classes are discussed as well as the relationships between tables and constraints that are part of `DataSet`. The class hierarchy has changed significantly since the release of the .NET Framework 2.0, and some of these changes are also described. Finally, you examine the XML framework on which ADO.NET is built.

The chapter begins with a brief tour of ADO.NET.

ADO.NET OVERVIEW

ADO.NET is more than just a thin veneer over some existing API. The similarity to ADO is fairly minimal — the classes and methods of accessing data are quite a bit different.

ADO (ActiveX Data Objects) is a library of COM components that has had many incarnations over the past few years. ADO consists primarily of the `Connection`, `Command`, `Recordset`, and `Field` objects. Using ADO, a connection is opened to the database, and some data is selected and placed into a record set consisting of fields; that data is then manipulated and updated on the server, and the connection is closed. ADO also introduced a so-called disconnected record set, which is used when keeping the connection open for long periods of time is not desirable.

There were several problems that ADO did not address satisfactorily, most notably the unwieldiness (in physical size) of a disconnected record set. This support was more necessary than ever with the evolution of web-centric computing, so a fresh approach was required. Upgrading to ADO.NET from ADO should not be too difficult because there are some similarities between the two. What's more, if you are using SQL Server, there is a fantastic set of managed classes that are tuned to squeeze maximum performance out of the database. This alone should be reason enough to migrate to ADO.NET.

ADO.NET ships with three database client namespaces: one for SQL Server, another for Open Database Connectivity (ODBC) data sources, and a third for any database exposed through OLE DB. If your database of choice is not SQL Server, use the OLE DB route unless you have no other choice than to use ODBC. If you are using Oracle as your database, you can visit the Oracle .NET Developer site and get their .NET provider, ODP.NET at `www.oracle.com/technology/tech/windows/odpnet/index.html`.

Namespaces

All of the examples in this chapter access data in one way or another. The namespaces in the following table expose the classes and interfaces used in .NET data access.

NAMESPACE	BRIEF DESCRIPTION
`System.Data`	All generic data access classes
`System.Data.Common`	Classes shared (or overridden) by individual data providers
`System.DataE.EntityClient`	Entity Framework classes
`System.Data.Linq.SqlClient`	LINQ to SQL provider classes
`System.Data.Odbc`	ODBC provider classes
`System.Data.OleDb`	OLE DB provider classes
`System.Data.ProviderBase`	New base classes and connection factory classes
`System.Data.Sql`	New generic interfaces and classes for SQL Server data access
`System.Data.SqlClient`	SQL Server provider classes
`System.Data.SqlTypes`	SQL Server data types

The main classes in ADO.NET are listed in the following subsections.

Shared Classes

ADO.NET contains a number of classes that are used regardless of whether you are using the SQL Server classes or the OLE DB classes. The following table lists the classes contained in the `System.Data` namespace.

CLASS	DESCRIPTION
`DataSet`	This object is designed for disconnected use and can contain a set of `DataTables` and relationships between these tables.
`DataTable`	A container of data that consists of one or more `DataColumns` and, when populated, will have one or more `DataRows` containing data.
`DataRow`	A number of values, akin to a row from a database table or a row from a spreadsheet.
`DataColumn`	This object contains the definition of a column, such as the name and data type.
`DataRelation`	A link between two `DataTable` classes within a `DataSet` class; used for foreign key and master/detail relationships.
`Constraint`	This class defines a rule for a `DataColumn` class (or set of data columns), such as unique values.

The following table lists the classes found in the `System.Data.Common` namespace.

CLASS	DESCRIPTION
`DataColumnMapping`	Maps the name of a column from the database to the name of a column within a `DataTable`.
`DataTableMapping`	Maps a table name from the database to a `DataTable` within a `DataSet`.

Database-Specific Classes

In addition to the shared classes introduced in the previous section, ADO.NET contains a number of database-specific classes. These classes implement a set of standard interfaces defined within the `System.Data` namespace, allowing the classes to be used in a generic manner if necessary. For example, both the `SqlConnection` and `OleDbConnection` classes derive from the `DbConnection` class, which implements the `IDbConnection` interface. The following table lists the database-specific classes.

CLASSES	DESCRIPTION
`SqlCommand`, `OleDbCommand`, and `ODBCCommand`	Used as wrappers for SQL statements or stored procedure calls. Examples for the `SqlCommand` class are shown later in the chapter.
`SqlCommandBuilder`, `OleDbCommandBuilder`, and `ODBCCommandBuilder`	Used to generate SQL commands (such as `INSERT`, `UPDATE`, and `DELETE` statements) from a `SELECT` statement.
`SqlConnection`, `OleDbConnection`, and `ODBCConnection`	Used to connect to the database and is similar to an ADO connection. Examples are shown later in the chapter.
`SqlDataAdapter`, `OleDbDataAdapter`, and `ODBCDataAdapter`	Used to hold `select`, `insert`, `update`, and `delete` commands, which are then used to populate a `DataSet` and update the database. Examples of the `SqlDataAdapter` are presented in this chapter.
`SqlDataReader`, `OleDbDataReader`, and `ODBCDataReader`	Used as a forward-only, connected data reader. Some examples of the `SqlDataReader` are shown in this chapter.
`SqlParameter`, `OleDbParameter`, and `ODBCParameter`	Used to define a parameter to a stored procedure. Examples of how to use the `SqlParameter` class are shown in this chapter.
`SqlTransaction`, `OleDbTransaction`, and `ODBCTransaction`	Used for a database transaction, wrapped in an object.

The most important feature of the ADO.NET classes is that they are designed to work in a disconnected manner, which is important in today's highly web-centric world. It is now common practice to architect a service (such as an online bookshop) to connect to a server, retrieve some data, and then work on that data on the client before reconnecting and passing the data back for processing. The disconnected nature of ADO.NET enables this type of behavior.

Classic ADO 2.1 introduced the disconnected record set, which permits data to be retrieved from a database, passed to the client for processing, and then reattached to the server. This used to be cumbersome to use because disconnected behavior was not part of the original design. The ADO.NET classes are different — in all but one case (the `[provider]DataReader`), they are designed for use offline from the database.

USING DATABASE CONNECTIONS

To access the database, you need to provide connection parameters, such as the machine that the database is running on and possibly your login credentials. Anyone who has worked with ADO will be familiar with the .NET connection classes: `OleDbConnection` and `SqlConnection`. Figure 30-1 shows two of the connection classes and includes the class hierarchy.

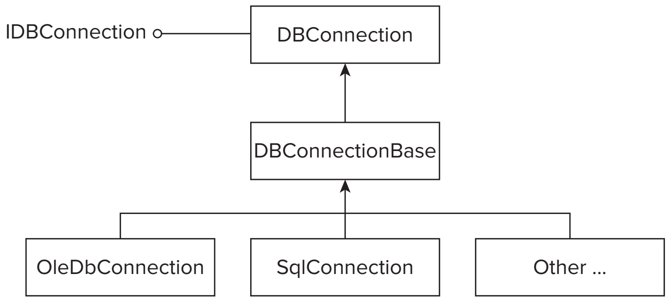

FIGURE 30-1

The examples in this chapter use the Northwind database, which you can find online. The following code snippet illustrates how to create, open, and close a connection to the Northwind database:

```
using System.Data.SqlClient;

string source = "server=(local);" +
                "integrated security=SSPI;" +
                "database=Northwind";
SqlConnection conn = new SqlConnection(source);
conn.Open();

// Do something useful

conn.Close();
```

The connection string should be very familiar to you if you have used ADO or OLE DB before — indeed, you should be able to cut and paste from your old code if you use the `OleDb` provider. In the example connection string, the parameters used are as follows (the parameters are delimited by a semicolon in the connection string):

- `server=(local)` — This denotes the database server to connect to. SQL Server permits a number of separate database server instances to be running on the same machine, and here you are connecting to the default SQL Server instance. If you are using SQL Express, change the server part to `server=./sqlexpress`.
- `integrated security=SSPI` — This uses Windows Authentication to connect to the database, which is highly recommended over using a username and password within the source code.
- `database=Northwind` — This describes the database instance to connect to; each SQL Server process can expose several database instances.

In case you forget the format of database connection strings (as many of us do now and then), the following URL is very handy: `www.connectionstrings.com`.

The example opens a database connection using the defined connection string and then closes that connection. Once the connection has been opened, you can issue commands against the data source, and when you are finished, the connection can be closed.

SQL Server has another mode of authentication — it can use Windows-integrated security, so that the credentials supplied at logon are passed to SQL Server. This is accomplished by removing the `uid` and `pwd` portions of the connection string, and adding in `Integrated Security=SSPI`.

In the download code available for this chapter, you will find the file `login.cs`, which simplifies the examples in this chapter. It is linked to all the sample code and includes database connection information used for the examples; you can alter this to supply your own server name, user, and password as appropriate. This, by default, uses Windows-integrated security; however, you can change the username and password as appropriate.

Managing Connection Strings

In the initial release of .NET, it was up to the developer to manage the database connection strings, which was often done by storing a connection string in the application configuration file or, more commonly, hard-coded somewhere within the application itself.

Beginning with .NET 2.0, you have a predefined way to store connection strings, and even use database connections in a type-agnostic manner — for example, it is now possible to write an application and then plug in various database providers, all without altering the main application.

To define a database connection string, you should use the `<connectionStrings>` section of the configuration file. Here, you can specify a name for the connection and the actual database connection string parameters; in addition, you can also specify the provider for this connection type. Here is an example:

```
<configuration>
  ...
  <connectionStrings>
    <add name="Northwind"
         providerName="System.Data.SqlClient"
         connectionString="server=(local);integrated security=SSPI;database=Northwind" />
  </connectionStrings>
</configuration>
```

code download Connection String Example.txt

You use this same connection string in the other examples in this chapter.

Once the database connection information has been defined within the configuration file, you then need to utilize this within the application. You will most likely want to create a method such as the following to retrieve a database connection based on the name of the connection:

```
private DbConnection GetDatabaseConnection ( string name )
{
  ConnectionStringSettings settings =
    ConfigurationManager.ConnectionStrings[name];

  DbProviderFactory factory = DbProviderFactories.GetFactory
    ( settings.ProviderName );
```

```
      DbConnection conn = factory.CreateConnection ( );
      conn.ConnectionString = settings.ConnectionString;

      return conn;
    }
```

code download GetDatabaseConnection.txt

This code reads the named connection string section (using the `ConnectionStringSettings` class), and then requests a provider factory from the base `DbProviderFactories` class. This uses the `ProviderName` property, which was set to `"System.Data.SqlClient"` in the application configuration file. You might be wondering how this maps to the actual factory class used to generate a database connection for SQL Server — in this case, it should utilize the `SqlClientFactory` class from `System.Data.SqlClient`. You will need to add a reference to the `System.Configuration` assembly in order to resolve the `ConfigurationManager` class used in the preceding code.

This may seem like a lot of unnecessary work to obtain a database connection, and indeed it is if your application is never going to run on any other database than the one it was designed for. If, however, you use the preceding factory method and also use the generic `Db*` classes (such as `DbConnection`, `DbCommand`, and `DbDataReader`), you will future-proof the application, and any move in the future to another database system will be fairly simple.

Using Connections Efficiently

In general, when using scarce resources in .NET, such as database connections, windows, or graphics objects, it is good practice to ensure that each resource is closed after use. Although the designers of .NET have implemented automatic garbage collection, which will tidy up eventually, it is necessary to release resources as early as possible to avoid starvation of resources.

This is all too apparent when writing code that accesses a database because keeping a connection open for slightly longer than necessary can affect other sessions. In extreme circumstances, not closing a connection can lock other users out of an entire set of tables, hurting application performance considerably. Closing database connections should be considered mandatory, so this section shows how to structure your code to minimize the risk of leaving a resource open.

You have two main ways to ensure that database connections and the like are released after use. These are explained in the following sections.

Option One: try . . . catch . . . finally

The first option to ensure that resources are cleaned up is to use `try...catch...finally` blocks, and ensure that you close any open connections within the `finally` block. Here is a short example:

```
try
{
   // Open the connection
   conn.Open();
   // Do something useful
}
catch ( SqlException ex )
{
   // Log the exception
}
finally
{
   // Ensure that the connection is freed
   conn.Close ( );
}
```

Within the `finally` block, you can release any resources you have used. The only trouble with this method is that you have to ensure that you close the connection — it is all too easy to forget to add the `finally` clause, so something less prone to vagaries in coding style might be worthwhile.

In addition, you might find that you open a number of resources (say two database connections and a file) within a given method, so the cascade of `try...catch...finally` blocks can sometimes become less easy to read. There is, however, another way to guarantee resource cleanup — the `using` statement.

Option Two: The using Block Statement

During development of C#, the debate on how .NET uses nondeterministic destruction became very heated.

In C++, as soon as an object went out of scope, its destructor would be automatically called. This was great news for designers of resource-based classes because the destructor was the ideal place to close the resource if the user had forgotten to do so. A C++ destructor is called whenever an object goes out of scope — so, for instance, if an exception were raised and not caught, all destructors would be called.

With C# and the other managed languages, there is no concept of automatic, deterministic destruction. Instead, there is the garbage collector, which disposes of resources at some point in the future. What makes this nondeterministic is that you have little say over when this process actually happens. Forgetting to close a database connection could cause all sorts of problems for a .NET executable. Luckily, help is at hand. The following code demonstrates how to use the `using` clause to ensure that objects that implement the `IDisposable` interface (see Chapter 13, "Memory Management and Pointers") are cleared up immediately after the block exits:

```
string source = "server=(local);" +
                "integrated security=SSPI;" +
                "database=Northwind";

using ( SqlConnection conn = new SqlConnection ( source ) )
{
   // Open the connection
   conn.Open ( );

   // Do something useful
}
```

In this instance, the `using` clause ensures that the database connection is closed, regardless of how the block is exited.

Looking at the IL code for the `Dispose()` method of the connection classes, you can see that all of them check the current state of the connection object and, if it is open, will call the `Close()` method. A great tool for browsing .NET assemblies is Reflector (available at `www.red-gate.com/products/reflector/`). This tool permits you to view the IL code for any .NET method and will also reverse-engineer the IL into C# source code, so you can easily see what a given method is doing.

When programming, you should use at least one of these methods, and probably both. Wherever you acquire resources, it is good practice to use the `using` statement; even though we all mean to write the `Close()` statement, sometimes we forget, and in the face of exceptions the `using` clause does the right thing. There is no substitute for good exception handling either, so in most instances, it is best to use both methods together, as in the following example:

```
try
{
   using (SqlConnection conn = new SqlConnection ( source ))
   {
      // Open the connection
      conn.Open ( );

      // Do something useful
```

```
         // Close it myself
         conn.Close ( );
      }
   }
   catch (SqlException e)
   {
      // Log the exception
   }
```

Note that this example called `Close()`, which is not strictly necessary, because the `using` clause will ensure that this is done anyway. However, you should ensure that any resources such as this are released as soon as possible — you might have more code in the rest of the block, and there is no point locking a resource unnecessarily.

In addition, if an exception is raised within the `using` block, the `IDisposable.Dispose` method will be called on the resource guarded by the `using` clause, which in this example ensures that the database connection is always closed. This produces easier-to-read code than having to ensure you close a connection within an exception clause. You might also note that the exception is defined as a `SqlException` rather than the catch-all `Exception` type — always try to catch as specific an exception as possible and let all others that are not explicitly handled rise up the execution stack. You really should only catch this exception if your specific data class can handle the error and do something with it.

In conclusion, if you are writing a class that wraps a resource, whatever that resource may be, always implement the `IDisposable` interface to close the resource. That way anyone coding with your class can use the `using()` statement and guarantee that the resource will be cleared up.

Transactions

Often when there is more than one update to be made to the database, these updates must be performed within the scope of a transaction. It is common in code to find a transaction object being passed around to many methods that update the database; however, since the release of the .NET Framework 2.0, the `TransactionScope` class has been available. This class is found within the `System.Transactions` assembly. This vastly simplifies writing transactional code because you can compose several transactional methods within a transaction scope, and the transaction will flow to each of these methods as necessary.

The following sequence of code initiates a transaction on a SQL Server connection:

```
   string source = "server=(local);" +
                   "integrated security=SSPI;" +
                   "database=Northwind";

   using (TransactionScope scope = new
      TransactionScope(TransactionScopeOption.Required))
   {
       using (SqlConnection conn = new SqlConnection(source))
       {
           // Do something in SQL
           .

           // Then mark complete
           scope.Complete();
       }
   }
```

Here, the transaction is explicitly marked as complete by using the `scope.Complete()` method. In the absence of this call, the transaction will be rolled back so that no changes are made to the database.

When you use a transaction scope, you can optionally choose the isolation level for commands executed within that transaction. The level determines how changes made in one database session are viewed by another. Not all database engines support all of the four levels presented in the following table.

ISOLATION LEVEL	DESCRIPTION
`ReadCommitted`	The default for SQL Server. This level ensures that data written by one transaction will be accessible in a second transaction only after the first transaction is committed.
`ReadUncommitted`	This permits your transaction to read data within the database, even data that has not yet been committed by another transaction. For example, if two users were accessing the same database, and the first inserted some data without concluding the transaction (by means of a `Commit` or `Rollback`), the second user with his or her isolation level set to `ReadUncommitted` could read the data.
`RepeatableRead`	This level, which extends the `ReadCommitted` level, ensures that if the same statement is issued within the transaction, regardless of other potential updates made to the database, the same data will always be returned. This level does require extra locks to be held on the data, which could adversely affect performance. This level guarantees that, for each row in the initial query, no changes can be made to that data. It does, however, permit "phantom" rows to show up — these are completely new rows that another transaction might have inserted while your transaction was running.
`Serializable`	This is the most "exclusive" transaction level, which in effect serializes access to data within the database. With this isolation level, phantom rows can never show up, so a SQL statement issued within a serializable transaction will always retrieve the same data. The negative performance impact of a `Serializable` transaction should not be underestimated — if you don't absolutely need to use this level of isolation, stay away from it.

The SQL Server default isolation level, `ReadCommitted`, is a good compromise between data coherence and data availability because fewer locks are required on data than in `RepeatableRead` or `Serializable` modes. However, situations exist where the isolation level should be increased, and so within .NET you can simply begin a transaction with a different level from the default. There are no fixed rules as to which levels to pick — that comes with experience.

COMMANDS

The "Using Database Connections" section briefly touched on the idea of issuing commands against a database. A command is, in its simplest form, a string of text containing SQL statements that is to be issued to the database. A command could also be a stored procedure, or the name of a table that will return all columns and all rows from that table (in other words, a `SELECT *`-style clause).

A command can be constructed by passing the SQL clause as a parameter to the constructor of the `Command` class, as shown in this example:

```
string source = "server=(local);" +
                "integrated security=SSPI;" +
                "database=Northwind";
string select = "SELECT ContactName,CompanyName FROM Customers";
SqlConnection conn = new SqlConnection(source);
conn.Open();
SqlCommand cmd = new SqlCommand(select, conn);
```

The `<provider>Command` classes have a property called `CommandType`, which is used to define whether the command is a SQL clause, a call to a stored procedure, or a full table statement (which simply selects all columns and rows from a given table). The following table summarizes the `CommandType` enumeration.

COMMANDTYPE	EXAMPLE
`Text` (default)	`String select = "SELECT ContactName FROM Customers";SqlCommand cmd = new SqlCommand(select, conn);`
`StoredProcedure`	`SqlCommand cmd = new SqlCommand("CustOrderHist", conn);cmd .CommandType = CommandType.StoredProcedure;cmd.Parameters .AddWithValue("@CustomerID", "QUICK");`
`TableDirect`	`OleDbCommand cmd = new OleDbCommand("Categories", conn);cmd .CommandType = CommandType.TableDirect;`

When executing a stored procedure, it might be necessary to pass parameters to that procedure. The previous example sets the `@CustomerID` parameter directly, although there are other ways of setting the parameter value, which you look at later in this chapter. Note that since .NET 2.0, the `AddWithValue()` method is included in the command parameters collection — and the `Add(name, value)` member was attributed as `Obsolete`. If you have used this original method of constructing parameters for calling a stored procedure, you will receive compiler warnings when you recompile your code. We suggest altering your code now because Microsoft will most likely remove the older method in a subsequent release of .NET.

Executing Commands

After you have defined the command, you need to execute it. A number of ways exist to issue the statement, depending on what you expect to be returned (if anything) from that command. The `<provider>Command` classes provide the following execute methods:

- `ExecuteNonQuery()` — Executes the command but does not return any output
- `ExecuteReader()` — Executes the command and returns a typed `IDataReader`
- `ExecuteScalar()` — Executes the command and returns the value from the first column of the first row of any result set

In addition to these methods, the `SqlCommand` class exposes the following method:

- `ExecuteXmlReader()` — Executes the command and returns an `XmlReader` object, which can be used to traverse the XML fragment returned from the database

ExecuteNonQuery()

The `ExecuteNonQuery()` method is commonly used for `UPDATE`, `INSERT`, or `DELETE` statements, where the only returned value is the number of records affected. This method can, however, return results if you call a stored procedure that has output parameters:

```
using System;
using System.Data.SqlClient;

public class ExecuteNonQueryExample
{
   public static void Main(string[] args)
   {
      string source = "server=(local);" +
                      "integrated security=SSPI;" +
                      "database=Northwind";
      string select = "UPDATE Customers " +
                      "SET ContactName = 'Bob' " +
                      "WHERE ContactName = 'Bill'";
         SqlConnection  conn = new SqlConnection(source);
         conn.Open();
         SqlCommand cmd = new SqlCommand(select, conn);
         int rowsReturned = cmd.ExecuteNonQuery();
         Console.WriteLine("{0} rows returned.", rowsReturned);
         conn.Close();
      }
   }
```

code download GetDatabaseConnection.txt

`ExecuteNonQuery()` returns the number of rows affected by the command as an `int`.

ExecuteReader()

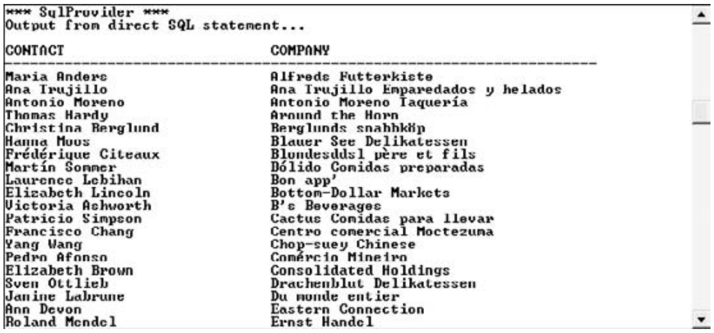
The `ExecuteReader()` method executes the command and returns a typed data reader object, depending on the provider in use. The object returned can be used to iterate through the record(s) returned, as shown in the following code:

```
using System;
using System.Data.SqlClient;

public class ExecuteReaderExample
{
   public static void Main(string[] args)
   {
      string source = "server=(local);" +
                      "integrated security=SSPI;" +
                      "database=Northwind";
      string select = "SELECT ContactName,CompanyName FROM Customers";
      SqlConnection conn = new SqlConnection(source);
      conn.Open();
      SqlCommand cmd = new SqlCommand(select, conn);
      SqlDataReader reader = cmd.ExecuteReader();
      while(reader.Read())
      {
         Console.WriteLine("Contact: {0,-20} Company: {1}",
                           reader[0], reader[1]);
      }
   }
}
```

code download ExecuteReaderExample.cs

Figure 30-2 shows the output of this code.



```

The `<provider>DataReader` objects are discussed later in this chapter.

ExecuteScalar()

On many occasions, it is necessary to return a single result from a SQL statement, such as the count of records in a given table, or the current date/time on the server. The `ExecuteScalar()` method can be used in such situations:

```
using System;
using System.Data.SqlClient;

public class ExecuteScalarExample
{
   public static void Main(string[] args)
   {
      string source = "server=(local);" +
                      "integrated security=SSPI;" +
                      "database=Northwind";
      string select = "SELECT COUNT(*) FROM Customers";
      SqlConnection conn = new SqlConnection(source);
      conn.Open();
      SqlCommand cmd = new SqlCommand(select, conn);
      object o = cmd.ExecuteScalar();
      Console.WriteLine(o);
   }
}
```

code download ExecuteReaderExample.cs

The method returns an object, which you can cast to the appropriate type if required. If the SQL you are calling returns only one column, it is preferable to use `ExecuteScalar()` over any other method of retrieving that column. That also applies to stored procedures that return a single value.

ExecuteXmlReader() (SqlClient Provider Only)

As its name implies, the `ExecuteXmlReader()` method executes the command and returns an `XmlReader` object to the caller. SQL Server permits a SQL `SELECT` statement to be extended with a `FOR XML` clause. This clause can take one of three options:

- `FOR XML AUTO` — Builds a tree based on the tables in the `FROM` clause
- `FOR XML RAW` — Maps result set rows to elements, with columns mapped to attributes
- `FOR XML EXPLICIT` — Requires that you specify the shape of the XML tree to be returned

For this example, use `AUTO`:

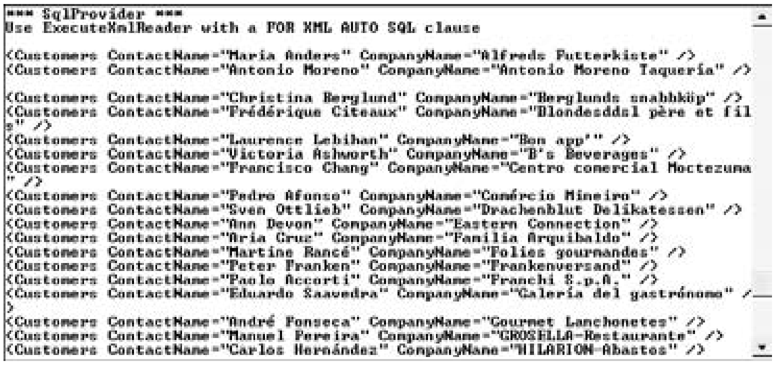
```
using System;
using System.Data.SqlClient;
using System.Xml;

public class ExecuteXmlReaderExample
{
   public static void Main(string[] args)
   {
      string source = "server=(local);" +
                      "integrated security=SSPI;" +
                      "database=Northwind";
      string select = "SELECT ContactName,CompanyName " +
                      "FROM Customers FOR XML AUTO";
      SqlConnection conn = new SqlConnection(source);
      conn.Open();
      SqlCommand cmd = new SqlCommand(select, conn);
      XmlReader xr = cmd.ExecuteXmlReader();
      xr.Read();
      string data;
      do
```

```
         {
            data = xr.ReadOuterXml();
            if (!string.IsNullOrEmpty(data))
               Console.WriteLine(data);
         } while (!string.IsNullOrEmpty(data));
         conn.Close();
      }
   }
```

code download ExecuteReaderExample.cs

Note that you have to import the `System.Xml` namespace in order to output the returned XML. This namespace and further XML capabilities of .NET Framework are explored in more detail in Chapter 33, "Manipulating XML." Here, you include the `FOR XML AUTO` clause in the SQL statement, then call the `ExecuteXmlReader()` method. Figure 30-3 shows the output of this code.



```
*** SqlProvider ***
Use ExecuteXmlReader with a FOR XML AUTO SQL clause

FIGURE 30-3

In the SQL clause, you specified `FROM Customers`, so an element of type `Customers` is shown in the output. To this are added attributes, one for each column selected from the database. This builds up an XML fragment for each row selected from the database.

Calling Stored Procedures

Calling a stored procedure with a command object is just a matter of defining the name of the stored procedure, adding a definition for each parameter of the procedure, and then executing the command with one of the methods presented in the previous section.

To make the examples in this section more useful, a set of stored procedures has been defined that can be used to insert, update, and delete records from the `Region` table in the Northwind sample database. Despite its small size, this is a good candidate to choose for the example because it can be used to define examples for each of the types of stored procedures you will commonly write.

Calling a Stored Procedure That Returns Nothing

The simplest example of calling a stored procedure is one that returns nothing to the caller. Two such procedures are defined in the following two subsections: one for updating a preexisting `Region` record and one for deleting a given `Region` record.

Record Update

Updating a `Region` record is fairly trivial because there is only one column that can be modified (assuming primary keys cannot be updated). You can type these examples directly into the SQL Server Query

Analyzer, or run the `StoredProcs.sql` file that is part of the downloadable code for this chapter. This file installs each of the stored procedures in this section:

```
CREATE PROCEDURE RegionUpdate (@RegionID INTEGER,
                              @RegionDescription NCHAR(50)) AS
   SET NOCOUNT OFF
   UPDATE Region
      SET RegionDescription = @RegionDescription
      WHERE RegionID = @RegionID
GO
```

code download StoredProcs.sql

An update command on a more real-world table might need to reselect and return the updated record in its entirety. This stored procedure takes two input parameters (`@RegionID` and `@RegionDescription`), and issues an `UPDATE` statement against the database.

To run this stored procedure from within .NET code, you need to define a SQL command and execute it:

```
SqlCommand cmd = new SqlCommand("RegionUpdate", conn);

cmd.CommandType = CommandType.StoredProcedure;
cmd.Parameters.AddWithValue ( "@RegionID", 23 );
cmd.Parameters.AddWithValue ( "@RegionDescription", "Something" );
```

code download StoredProcs.sql

This code creates a new `SqlCommand` object named `aCommand`, and defines it as a stored procedure. You then add each parameter in turn, using the `AddWithValue` method. This constructs a parameter and also sets its value — you can also manually construct `SqlParameter` instances and add these to the `Parameters` collection if appropriate.

The stored procedure takes two parameters: the unique primary key of the `Region` record being updated and the new description to be given to this record. After the command has been created, it can be executed by issuing the following command:

```
cmd.ExecuteNonQuery();
```

Because the procedure returns nothing, `ExecuteNonQuery()` will suffice. Command parameters can be set directly, using the `AddWithValue()` method, or by constructing `SqlParameter` instances. Note that the parameter collection is indexable by position or parameter name.

Record Deletion

The next stored procedure required is one that can be used to delete a `Region` record from the database:

```
CREATE PROCEDURE RegionDelete (@RegionID INTEGER) AS
   SET NOCOUNT OFF
   DELETE FROM Region
   WHERE       RegionID = @RegionID
GO
```

code download StoredProcs.sql

This procedure requires only the primary key value of the record. The code uses a `SqlCommand` object to call this stored procedure as follows:

```
SqlCommand cmd = new SqlCommand("RegionDelete", conn);
cmd.CommandType = CommandType.StoredProcedure;
cmd.Parameters.Add(new SqlParameter("@RegionID", SqlDbType.Int, 0,
                                     "RegionID"));
cmd.UpdatedRowSource = UpdateRowSource.None;
```

code download StoredProcs.cs

This command accepts only a single parameter, as shown in the following code, which will execute the `RegionDelete` stored procedure; here, you see an example of setting the parameter by name. If you have many similar calls to make to the same stored procedure, constructing `SqlParameter` instances and setting the values as in the following code may lead to better performance than reconstructing the entire `SqlCommand` for each call.

```
cmd.Parameters["@RegionID"].Value= 999;
cmd.ExecuteNonQuery();
```

Calling a Stored Procedure That Returns Output Parameters

Both of the previous examples execute stored procedures that return nothing. If a stored procedure includes output parameters, these need to be defined within the .NET client so that they can be filled when the procedure returns. The following example shows how to insert a record into the database and return the primary key of that record to the caller.

Record Insertion

The `Region` table consists of only a primary key (`RegionID`) and description field (`RegionDescription`). To insert a record, this numeric primary key must be generated, and then a new row needs to be inserted into the database. The primary key generation in this example has been simplified by creating one within the stored procedure. The method used is exceedingly crude, which is why there is a section on key generation later in this chapter. For now, this primitive example suffices:

```
CREATE PROCEDURE RegionInsert(@RegionDescription NCHAR(50),
                              @RegionID INTEGER OUTPUT)AS
   SET NOCOUNT OFF
   SELECT @RegionID = MAX(RegionID)+ 1
   FROM Region
   INSERT INTO Region(RegionID, RegionDescription)
   VALUES(@RegionID, @RegionDescription)
GO
```

code download StoredProcs.sql

The insert procedure creates a new `Region` record. Because the primary key value is generated by the database itself, this value is returned as an output parameter from the procedure (`@RegionID`). This is sufficient for this simple example, but for a more complex table (especially one with default values), it is more common not to use output parameters, and instead select the entire inserted row and return this to the caller. The .NET classes can cope with either scenario.

```
SqlCommand  cmd = new SqlCommand("RegionInsert", conn);
cmd.CommandType = CommandType.StoredProcedure;
cmd.Parameters.Add(new SqlParameter("@RegionDescription",
                                    SqlDbType.NChar,
                                    50,
                                    "RegionDescription"));
cmd.Parameters.Add(new SqlParameter("@RegionID",
                                    SqlDbType.Int,
                                    0,
                                    ParameterDirection.Output,
                                    false,
                                    0,
                                    0,
                                    "RegionID",
                                    DataRowVersion.Default,
                                    null));
cmd.UpdatedRowSource = UpdateRowSource.OutputParameters;
```

code download StoredProcs.cs

Here, the definition of the parameters is much more complex. The second parameter, `@RegionID`, is defined to include its parameter direction, which in this example is `Output`. In addition to this flag, on the last line of the code, the `UpdateRowSource` enumeration is used to indicate that data will be returned from this stored procedure via output parameters. This flag is mainly used when issuing stored procedure calls from a `DataTable` (which is discussed later in this chapter).

Calling this stored procedure is similar to the previous examples, except in this instance the output parameter is read after executing the procedure:

```
cmd.Parameters["@RegionDescription"].Value = "South West";
cmd.ExecuteNonQuery();
int newRegionID = (int) cmd.Parameters["@RegionID"].Value;
```

After executing the command, the value of the `@RegionID` parameter is read and cast to an integer. A shorthand version of the preceding is the `ExecuteScalar()` method, which will return (as an object) the first value returned from the stored procedure.

You might be wondering what to do if the stored procedure you call returns output parameters and a set of rows. In this instance, define the parameters as appropriate, and rather than calling `ExecuteNonQuery()`, call one of the other methods (such as `ExecuteReader()`) that will permit you to traverse any record(s) returned.

FAST DATA ACCESS: THE DATA READER

A data reader is the simplest and fastest way of selecting some data from a data source, but it is also the least capable. You cannot directly instantiate a data reader object — an instance is returned from the appropriate database's command object (such as `SqlCommand`) after having called the `ExecuteReader()` method.

The following code demonstrates how to select data from the `Customers` table in the Northwind database. The example connects to the database, selects a number of records, loops through these selected records, and outputs them to the console.

This example uses the OLE DB provider as a brief respite from the SQL provider. In most cases, the classes have a one-to-one correspondence with their `SqlClient` cousins; for example, there is the `OleDbConnection` object, which is similar to the `SqlConnection` object used in the previous examples.

To execute commands against an OLE DB data source, the `OleDbCommand` class is used. The following code shows an example of executing a simple SQL statement and reading the records by returning an `OleDbDataReader` object.

Note the second `using` directive, which makes the `OleDb` classes available:

```
using System;
using System.Data.OleDb;
```

Most of the data providers currently available are shipped within the same assembly, so it is only necessary to reference the `System.Data.dll` assembly to import all classes used in this section.

```
public class DataReaderExample
{
   public static void Main(string[] args)
   {
      string source = "Provider=SQLOLEDB;" +
                      "server=(local);" +
                      "integrated security=SSPI;" +
                      "database=northwind";
      string select = "SELECT ContactName,CompanyName FROM Customers";
      OleDbConnection conn = new OleDbConnection(source);
      conn.Open();
```

```
        OleDbCommand cmd = new OleDbCommand(select, conn);
        OleDbDataReader aReader = cmd.ExecuteReader();
        while(aReader.Read())
           Console.WriteLine("'{0}' from {1}",
                             aReader.GetString(0), aReader.GetString(1));
        aReader.Close();
        conn.Close();
     }
  }
```

code download DataReaderExample.cs

The preceding code includes many familiar aspects of C# already covered in this chapter. To compile the example, issue the following command:

```
csc /t:exe /debug+ DataReaderExample.cs /r:System.Data.dll
```

The following code from the previous example creates a new OLE DB .NET database connection, based on the source connection string:

```
OleDbConnection conn = new OleDbConnection(source);
conn.Open();
OleDbCommand cmd = new OleDbCommand(select, conn);
```

The third line creates a new `OleDbCommand` object, based on a particular `SELECT` statement, and the database connection to be used when the command is executed. When you have a valid command, you need to execute it, which returns an initialized `OleDbDataReader`:

```
OleDbDataReader aReader = cmd.ExecuteReader();
```

An `OleDbDataReader` is a forward-only "connected" reader. In other words, you can only traverse the records returned in one direction, and the database connection used is kept open until the data reader has been closed.

An OleDbDataReader keeps the database connection open until it is explicitly closed.

The `OleDbDataReader` class cannot be instantiated directly — it is always returned by a call to the `ExecuteReader()` method of the `OleDbCommand` class. Once you have an open data reader, there are various ways to access the data contained within the reader.

When the `OleDbDataReader` object is closed (via an explicit call to `Close()`, or the object being garbage collected), the underlying connection may also be closed, depending on which of the `ExecuteReader()` methods is called. If you call `ExecuteReader()` and pass `CommandBehavior.CloseConnection`, you can force the connection to be closed when the reader is closed.

The `OleDbDataReader` class has an indexer that permits access (although not type-safe access) to any field using the familiar array style syntax:

```
   object o = aReader[0];
or
   object o = aReader["CategoryID"];
```

Assuming that the `CategoryID` field was the first in the `SELECT` statement used to populate the reader, these two lines are functionally equivalent, although the second is slower than the first; to verify this, a test application was written that performed a million iterations of accessing the same column from an open data reader, just to get some numbers that were big enough to read. You probably don't read the same column a million times in a tight loop, but every (micro) second counts, so you should write code that is as optimal as possible.

As an aside, the numeric indexer took on average 0.09 seconds for the million accesses, and the textual one 0.63 seconds. The reason for this difference is that the textual method looks up the column number internally from the schema and then accesses it using its ordinal. If you know this information beforehand, you can do a better job of accessing the data.

So, should you use the numeric indexer? Maybe, but there is a better way. In addition to the indexers just presented, `OleDbDataReader` has a set of type-safe methods that can be used to read columns. These are fairly self-explanatory, and all begin with `Get`. There are methods to read most types of data, such as `GetInt32`, `GetFloat`, `GetGuid`, and so on.

The million iterations using `GetInt32` took 0.06 seconds. The overhead in the numeric indexer is incurred while getting the data type, calling the same code as `GetInt32`, then boxing (and in this instance unboxing) an integer. So, if you know the schema beforehand, are willing to use cryptic numbers instead of column names, and can be bothered to use a type-safe function for each and every column access, you stand to gain somewhere in the region of a tenfold speed increase over using a textual column name (when selecting those million copies of the same column).

Needless to say, there is a tradeoff between maintainability and speed. If you must use numeric indexers, define constants within class scope for each of the columns that you will be accessing. The preceding code can be used to select data from any OLE DB database; however, there are a number of SQL Server–specific classes that can be used with the obvious portability tradeoff.

The following example is the same as the previous one, except that in this instance the OLE DB provider and all references to OLE DB classes have been replaced with their SQL counterparts. The example is located in the `04_DataReaderSql` directory:

```
using System;
using System.Data.SqlClient;

public class DataReaderSql
{
   public static int Main(string[] args)
   {
      string source = "server=(local);" +
                      "integrated security=SSPI;" +
                      "database=northwind";
      string select = "SELECT ContactName,CompanyName FROM Customers";
      SqlConnection conn = new SqlConnection(source);
      conn.Open();
      SqlCommand cmd = new SqlCommand(select, conn);
      SqlDataReader aReader = cmd.ExecuteReader();
      while(aReader.Read())
         Console.WriteLine("'{0}' from {1}", aReader.GetString(0),
                           aReader.GetString(1));
      aReader.Close();
      conn.Close();
      return 0;
   }
}
```

code download DataReaderSql.cs

Notice the difference? If you're typing this, do a global replace on `OleDb` with `Sql`, change the data source string, and recompile. It's that easy!

The same performance tests were run on the indexers for the SQL provider, and this time the numeric indexers were both exactly the same at 0.13 seconds for the million accesses, and the string-based indexer ran at about 0.65 seconds.

MANAGING DATA AND RELATIONSHIPS: THE DATASET CLASS

The `DataSet` class has been designed as an offline container of data. It has no notion of database connections. In fact, the data held within a `DataSet` does not necessarily need to have come from a database — it could just as easily be records from a CSV file, an XML file, or points read from a measuring device.

A `DataSet` class consists of a set of data tables, each of which will have a set of data columns and data rows (see Figure 30-4). In addition to defining the data, you can also define *links* between tables within the `DataSet` class. One common scenario would be defining a parent-child relationship (commonly known as master/detail). One record in a table (say `Order`) links to many records in another table (say `Order_Details`). This relationship can be defined and navigated within the `DataSet`.

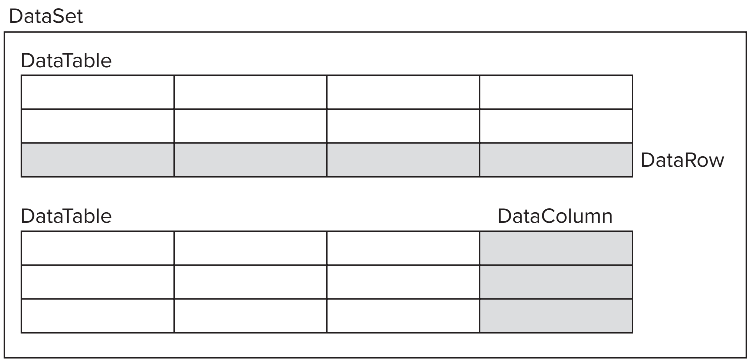

FIGURE 30-4

It is important to remember that basically, the `DataSet` class is an in-memory database that includes all the tables, relationships, and constraints. The following sections describe the classes that are used with a `DataSet` class.

Data Tables

A data table is very similar to a physical database table — it consists of a set of columns with particular properties and might have zero or more rows of data. A data table might also define a primary key, which can be one or more columns, and might also contain constraints on columns. The generic term for this information used throughout the rest of the chapter is *schema*.

Several ways exist to define the schema for a particular data table (and indeed the `DataSet` class as a whole). These are discussed after introducing data columns and data rows. Figure 30-5 shows some of the objects that are accessible through the data table.

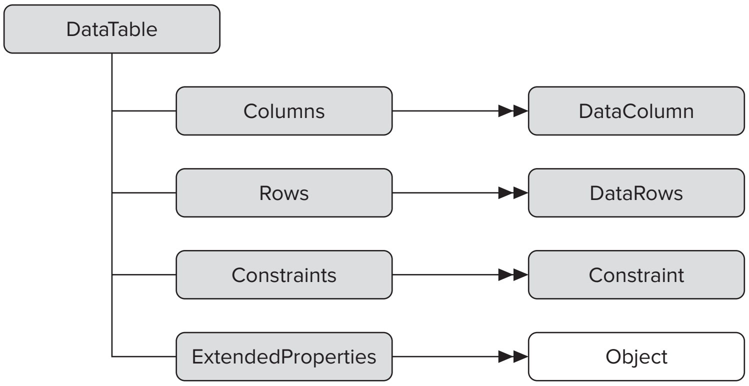

FIGURE 30-5

A `DataTable` object (and also a `DataColumn`) can have an arbitrary number of extended properties associated with it. This collection can be populated with any user-defined information pertaining to the object. For example, a given column might have an input mask used to validate the contents of that column — a typical example is the U.S. Social Security number. Extended properties are especially useful when the data is constructed within a middle tier and returned to the client for some processing. You could, for example, store validation criteria (such as `min` and `max`) for numeric columns in extended properties and use this in the UI tier when validating user input.

When a data table has been populated — by selecting data from a database, reading data from a file, or manually populating within code — the `Rows` collection will contain this retrieved data.

The `Columns` collection contains `DataColumn` instances that have been added to this table. These define the schema of the data, such as the data type, nullability, default values, and so on. The `Constraints` collection can be populated with either unique or primary key constraints.

One example of where the schema information for a data table is used is when displaying that data in a `DataGrid`. The `DataGrid` control uses properties such as the data type of the column to decide what control to use for that column. A bit field within the database will be displayed as a check box within the `DataGrid`. If a column is defined within the database schema as `NOT NULL`, this fact will be stored within the `DataColumn` so that it can be tested when the user attempts to move off a row.

Data Columns

A `DataColumn` object defines properties of a column within the `DataTable`, such as the data type of that column, whether the column is read-only, and various other facts. A column can be created in code, or it can be automatically generated by the runtime.

When creating a column, it is also useful to give it a name; otherwise, the runtime will generate a name for you in the form `Column`*`n`* where *`n`* is an incrementing number.

The data type of the column can be set either by supplying it in the constructor or by setting the `DataType` property. Once you have loaded data into a data table you cannot alter the type of a column — you will just receive an `ArgumentException`.

Data columns can be created to hold the following .NET Framework data types:

`Boolean`	`Decimal`
`Int64`	`TimeSpan`
`Byte`	`Double`
`Sbyte`	`UInt16`
`Char`	`Int16`
`Single`	`UInt32`
`DateTime`	`Int32`
`String`	`UInt64`

Once it is created, the next thing to do with a `DataColumn` object is to set up other properties, such as the nullability of the column or the default value. The following code fragment shows a few of the more common options that can be set on a `DataColumn` object:

```
DataColumn customerID = new DataColumn("CustomerID", typeof(int));
customerID.AllowDBNull = false;
customerID.ReadOnly = false;
customerID.AutoIncrement = true;
customerID.AutoIncrementSeed = 1000;
DataColumn name = new DataColumn("Name", typeof(string));
name.AllowDBNull = false;
name.Unique = true;
```

The following table shows the properties that can be set on a `DataColumn` object.

PROPERTY	DESCRIPTION
`AllowDBNull`	If `true`, permits the column to be set to `DBNull`.
`AutoIncrement`	Defines that this column value is automatically generated as an incrementing number.
`AutoIncrementSeed`	Defines the initial seed value for an `AutoIncrement` column.
`AutoIncrementStep`	Defines the step between automatically generated column values, with a default of one.
`Caption`	Can be used for displaying the name of the column onscreen.
`ColumnMapping`	Defines how a column is mapped into XML when a `DataSet` class is saved by calling `DataSet.WriteXml`.
`ColumnName`	The name of the column; this is auto-generated by the runtime if not set in the constructor.
`DataType`	Defines the `System.Type` value of the column.
`DefaultValue`	Can define a default value for a column.
`Expression`	Defines the expression to be used in a computed column.

Data Rows

This class makes up the other part of the `DataTable` class. The columns within a data table are defined in terms of the `DataColumn` class. The actual data within the table is accessed by using the `DataRow` object. The following example shows how to access rows within a data table. First, the connection details:

```
string source = "server=(local);" +
                " integrated security=SSPI;" +
                "database=northwind";
string select = "SELECT ContactName,CompanyName FROM Customers";
SqlConnection  conn = new SqlConnection(source);
```

The following code introduces the `SqlDataAdapter` class, which is used to place data into a `DataSet` class. `SqlDataAdapter` issues the SQL clause and fills a table in the `DataSet` class called `Customers` with the output of the following query. (For more details on the `SqlDataAdapter` class, see the section "Populating a DataSet" later in this chapter.)

```
SqlDataAdapter da = new SqlDataAdapter(select, conn);
DataSet ds = new DataSet();
da.Fill(ds, "Customers");
```

In the following code, you might notice the use of the `DataRow` indexer to access values from within that row. The value for a given column can be retrieved by using one of the several overloaded indexers. These permit you to retrieve a value knowing the column number, name, or `DataColumn`:

```
foreach(DataRow row in ds.Tables["Customers"].Rows)
   Console.WriteLine("'{0}' from {1}", row[0],row[1]);
```

One of the most appealing aspects of `DataRow` is that it is versioned. This permits you to receive various values for a given column in a particular row. The versions are described in the following table.

DATAROW VERSION VALUE	DESCRIPTION
`Current`	The value existing at present within the column. If no edit has occurred, this will be the same as the original value. If an edit (or edits) has occurred, the value will be the last valid value entered.
`Default`	The default value (in other words, any default set up for the column).
`Original`	The value of the column when originally selected from the database. If the `DataRow`'s `AcceptChanges()` method is called, this value will update to the `Current` value.
`Proposed`	When changes are in progress for a row, it is possible to retrieve this modified value. If you call `BeginEdit()` on the row and make changes, each column will have a proposed value until either `EndEdit()` or `CancelEdit()` is called.

The version of a given column could be used in many ways. One example is when updating rows within the database, in which instance it is common to issue a SQL statement such as the following:

```
UPDATE Products
SET    Name = Column.Current
WHERE  ProductID = xxx
AND    Name = Column.Original;
```

Obviously, this code would never compile, but it shows one use for original and current values of a column within a row.

To retrieve a versioned value from the `DataRow` indexer, use one of the indexer methods that accepts a `DataRowVersion` value as a parameter. The following snippet shows how to obtain all values of each column in a `DataTable` object:

```
foreach (DataRow row in ds.Tables["Customers"].Rows )
{
  foreach ( DataColumn dc in ds.Tables["Customers"].Columns )
  {
    Console.WriteLine ("{0} Current  = {1}", dc.ColumnName,
                                              row[dc,DataRowVersion.Current]);
    Console.WriteLine ("    Default  = {0}", row[dc,DataRowVersion.Default]);
    Console.WriteLine ("    Original = {0}",
                       row[dc,DataRowVersion.Original]);
  }
}
```

The whole row has a state flag called `RowState`, which can be used to determine what operation is needed on the row when it is persisted back to the database. The `RowState` property is set to keep track of all the changes made to the `DataTable`, such as adding new rows, deleting existing rows, and changing columns within the table. When the data is reconciled with the database, the row state flag is used to determine what SQL operations should occur. The following table provides an overview of the flags that are defined by the `DataRowState` enumeration.

DATAROWSTATE VALUE	DESCRIPTION
`Added`	Indicates that the row has been newly added to a `DataTable`'s `Rows` collection. All rows created on the client are set to this value and will ultimately issue SQL `INSERT` statements when reconciled with the database.
`Deleted`	Indicates that the row has been marked as deleted from the `DataTable` by means of the `DataRow.Delete()` method. The row still exists within the `DataTable` but will not normally be viewable onscreen (unless a `DataView` has been explicitly set up). `DataView`s are discussed in the next chapter. Rows marked as deleted in the `DataTable` will be deleted from the database when reconciled.
`Detached`	Indicates that a row is in this state immediately after it is created, and can also be returned to this state by calling `DataRow.Remove()`. A detached row is not considered to be part of any data table, thus no SQL for rows in this state will be issued.
`Modified`	Indicates that a row will be `Modified` if the value in any column has been changed.
`Unchanged`	Indicates that the row has not been changed since the last call to `AcceptChanges()`.

The state of the row depends also on what methods have been called on the row. The `AcceptChanges()` method is generally called after successfully updating the data source (that is, after persisting changes to the database).

The most common way to alter data in a `DataRow` is to use the indexer; however, if you have a number of changes to make, you also need to consider the `BeginEdit()` and `EndEdit()` methods.

When an alteration is made to a column within a DataRow, the ColumnChanging event is raised on the row's DataTable. This permits you to override the ProposedValue property of the DataColumnChangeEventArgs class and change it as required. This is one way of performing some data validation on column values. If you call BeginEdit() before making changes, the ColumnChanging event will not be raised. This permits you to make multiple changes and then call EndEdit() to persist these changes. If you want to revert to the original values, call CancelEdit().

A DataRow can be linked in some way to other rows of data. This permits the creation of navigable links between rows, which is common in master/detail scenarios. The DataRow contains a GetChildRows() method that will return an array of associated rows from another table in the same DataSet as the current row. These are discussed in the "Data Relationships" section later in this chapter.

Schema Generation

You can create the schema for a DataTable in three ways:

- ➤ Let the runtime do it for you.
- ➤ Write code to create the table(s).
- ➤ Use the XML schema generator.

The following sections describe these three alternatives.

Runtime Schema Generation

The DataRow example shown earlier presented the following code for selecting data from a database and populating a DataSet class:

```
SqlDataAdapter da = new SqlDataAdapter(select, conn);
DataSet ds = new DataSet();
da.Fill(ds, "Customers");
```

This is obviously easy to use, but it has a few drawbacks as well. For example, you have to make do with the default column names, which might work for you, but in certain instances, you might want to rename a physical database column (say PKID) to something more user-friendly.

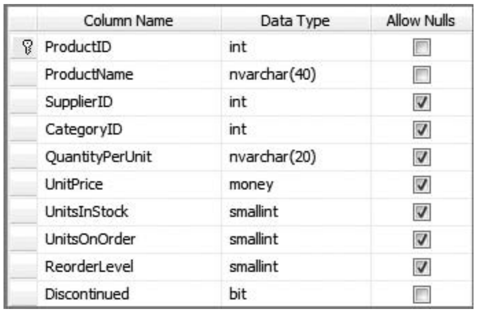
You could naturally alias columns within your SQL clause, as in SELECT PID AS PersonID FROM PersonTable; it's best to not rename columns within SQL, though, because a column only really needs to have a "pretty" name onscreen.

Another potential problem with automated DataTable/DataColumn generation is that you have no control over the column types that the runtime chooses for your data. It does a fairly good job of deciding the correct data type for you, but as usual there are instances where you need more control. For example, you might have defined an enumerated type for a given column to simplify user code written against your class. If you accept the default column types that the runtime generates, the column will likely be an integer with a 32-bit range, as opposed to an enum with your predefined options.

Last, and probably most problematic, is that when using automated table generation, you have no type-safe access to the data within the DataTable — you are at the mercy of indexers, which return instances of object rather than derived data types. If you like sprinkling your code with typecast expressions, skip the following sections.

Hand-Coded Schema

Generating the code to create a DataTable, replete with associated DataColumns, is fairly easy. The examples within this section access the Products table from the Northwind database, shown in Figure 30-6.



Column Name	Data Type	Allow Nulls
ProductID	int	☐
ProductName	nvarchar(40)	☐
SupplierID	int	✓
CategoryID	int	✓
QuantityPerUnit	nvarchar(20)	✓
UnitPrice	money	✓
UnitsInStock	smallint	✓
UnitsOnOrder	smallint	✓
ReorderLevel	smallint	✓
Discontinued	bit	☐

FIGURE 30-6

The following code manufactures a `DataTable`, which corresponds to the schema shown in Figure 30-6 (but does not cover the nullability of columns):

```
public static void ManufactureProductDataTable(DataSet ds)
{
   DataTable   products = new DataTable("Products");
   products.Columns.Add(new DataColumn("ProductID", typeof(int)));
   products.Columns.Add(new DataColumn("ProductName", typeof(string)));
   products.Columns.Add(new DataColumn("SupplierID", typeof(int)));
   products.Columns.Add(new DataColumn("CategoryID", typeof(int)));
   products.Columns.Add(new DataColumn("QuantityPerUnit", typeof(string)));
   products.Columns.Add(new DataColumn("UnitPrice", typeof(decimal)));
   products.Columns.Add(new DataColumn("UnitsInStock", typeof(short)));
   products.Columns.Add(new DataColumn("UnitsOnOrder", typeof(short)));
   products.Columns.Add(new DataColumn("ReorderLevel", typeof(short)));
   products.Columns.Add(new DataColumn("Discontinued", typeof(bool)));
   ds.Tables.Add(products);
}
```

code download ManufacturedDataSet.cs

You can alter the code in the `DataRow` example to use this newly generated table definition as follows:

```
string source = "server=(local);" +
                "integrated security=sspi;" +
                "database=Northwind";
string select = "SELECT * FROM Products";
SqlConnection conn = new SqlConnection(source);
SqlDataAdapter cmd = new SqlDataAdapter(select, conn);
DataSet ds = new DataSet();
ManufactureProductDataTable(ds);
cmd.Fill(ds, "Products");
foreach(DataRow row in ds.Tables["Products"].Rows)
   Console.WriteLine("'{0}' from {1}", row[0], row[1]);
```

The `ManufactureProductDataTable()` method creates a new `DataTable`, adds each column in turn, and finally appends this to the list of tables within the `DataSet`. The `DataSet` has an indexer that takes the name of the table and returns that `DataTable` to the caller.

The previous example is still not really type-safe because indexers are being used on columns to retrieve the data. What would be better is a class (or set of classes) derived from `DataSet`, `DataTable`, and `DataRow` that defines type-safe accessors for tables, rows, and columns. You can generate this code yourself; it is not particularly tedious and you end up with truly type-safe data access classes.

If you don't like generating these type-safe classes yourself, help is at hand. The .NET Framework includes support for the third method listed at the start of this section: using XML schemas to define a `DataSet` class, a `DataTable` class, and the other classes that we have described here. (For more details on this method, see the section "XML Schemas: Generating Code with XSD" later in this chapter.)

Data Relationships

When writing an application, it is often necessary to obtain and cache various tables of information. The `DataSet` class is the container for this information. With regular OLE DB, it was necessary to provide a strange SQL dialect to enforce hierarchical data relationships, and the provider itself was not without its own subtle quirks.

The `DataSet` class, however, has been designed from the start to establish relationships between data tables with ease. The code in this section shows how to generate data manually and populate two tables with data. So, if you don't have access to SQL Server or the Northwind database, you can run this example anyway:

```
DataSet ds = new DataSet("Relationships");
ds.Tables.Add(CreateBuildingTable());
ds.Tables.Add(CreateRoomTable());
ds.Relations.Add("Rooms",
                 ds.Tables["Building"].Columns["BuildingID"],
                 ds.Tables["Room"].Columns["BuildingID"]);
```

code download DataRelationships.cs

The tables used in this example are shown in Figure 30-7. They contain a primary key and name field, with the `Room` table having `BuildingID` as a foreign key.

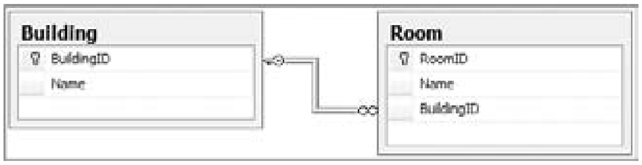


FIGURE 30-7

These tables have been kept deliberately simple. The following code shows how to iterate through the rows in the `Building` table and traverse the relationship to list all of the child rows from the `Room` table:

```
foreach(DataRow theBuilding in ds.Tables["Building"].Rows)
{
   DataRow[] children = theBuilding.GetChildRows("Rooms");
   int roomCount = children.Length;
   Console.WriteLine("Building {0} contains {1} room{2}",
                     theBuilding["Name"],
                     roomCount,
                     roomCount > 1 ? "s": "");
   // Loop through the rooms
   foreach(DataRow theRoom in children)
      Console.WriteLine("Room: {0}", theRoom["Name"]);
}
```

The key difference between the `DataSet` class and the old-style hierarchical `Recordset` object is in the way the relationship is presented. In a hierarchical `Recordset` object, the relationship was presented as a pseudo-column within the row. This column itself was a `Recordset` object that could be iterated through. Under ADO.NET, however, a relationship is traversed simply by calling the `GetChildRows()` method:

```
DataRow[] children = theBuilding.GetChildRows("Rooms");
```

This method has a number of forms, but the preceding simple example uses just the name of the relationship to traverse between parent and child rows. It returns an array of rows that can be updated as appropriate by using the indexers, as shown in earlier examples.

What's more interesting with data relationships is that they can be traversed both ways. Not only can you go from a parent to the child rows, but you can also find a parent row (or rows) from a child record simply by using the `ParentRelations` property on the `DataTable` class. This property returns a `DataRelationCollection`, which can be indexed by using the `[]` array syntax (for example, `ParentRelations["Rooms"]`), or as an alternative, the `GetParentRows()` method can be called, as shown here:

```
foreach(DataRow theRoom in ds.Tables["Room"].Rows)
{
   DataRow[] parents = theRoom.GetParentRows("Rooms");
   foreach(DataRow theBuilding in parents)
      Console.WriteLine("Room {0} is contained in building {1}",
                        theRoom["Name"],
                        theBuilding["Name"]);
}
```

Two methods with various overrides are available for retrieving the parent row(s): `GetParentRows()` (which returns an array of zero or more rows) and `GetParentRow()` (which retrieves a single parent row given a relationship).

Data Constraints

Changing the data type of columns created on the client is not the only thing a `DataTable` is good for. ADO.NET permits you to create a set of constraints on a column (or columns), which are then used to enforce rules within the data.

The following table lists the constraint types that are currently supported by the runtime, embodied as classes in the `System.Data` namespace.

CONSTRAINT	DESCRIPTION
`ForeignKeyConstraint`	Enforces a link between two `DataTables` within a `DataSet`.
`UniqueConstraint`	Ensures that entries in a given column are unique.

Setting a Primary Key

As is common with a table in a relational database, you can supply a primary key, which can be based on one or more columns from the `DataTable`.

The following code creates a primary key for the `Products` table, whose schema was constructed by hand earlier. Note that a primary key on a table is just one form of constraint. When a primary key is added to a `DataTable`, the runtime also generates a unique constraint over the key column(s). This is because there isn't actually a constraint type of `PrimaryKey` — a primary key is simply a unique constraint over one or more columns.

```
public static void ManufacturePrimaryKey(DataTable dt)
{
   DataColumn[] pk = new DataColumn[1];
   pk[0] = dt.Columns["ProductID"];
   dt.PrimaryKey = pk;
}
```

code download ManufacturedDataSet.cs

Because a primary key can contain several columns, it is typed as an array of `DataColumns`.
A table's primary key can be set to those columns simply by assigning an array of columns to the property.

To check the constraints for a table, you can iterate through the `ConstraintCollection`. For the auto-generated constraint produced by the preceding code, the name of the constraint is `Constraint1`. That's not a very useful name, so to avoid this problem it is always best to create the constraint in code first, then define which column(s) make up the primary key.

The following code names the constraint before creating the primary key:

```
DataColumn[] pk = new DataColumn[1];
pk[0] = dt.Columns["ProductID"];
dt.Constraints.Add(new UniqueConstraint("PK_Products", pk[0]));
dt.PrimaryKey = pk;
```

Unique constraints can be applied to as many columns as you want.

Setting a Foreign Key

In addition to unique constraints, a `DataTable` class can also contain foreign key constraints. These are primarily used to enforce master/detail relationships but can also be used to replicate columns between tables if you set up the constraint correctly. A master/detail relationship is one where there is commonly one parent record (say an order) and many child records (order lines), linked by the primary key of the parent record.

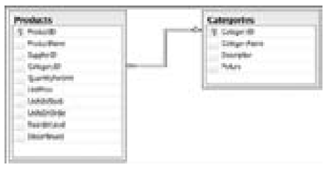

FIGURE 30-8

A foreign key constraint can operate only over tables within the same `DataSet`, so the following example uses the `Categories` table from the Northwind database (shown in Figure 30-8), and assigns a constraint between it and the `Products` table.

The first step is to generate a new data table for the `Categories` table:

```
DataTable categories = new DataTable("Categories");
categories.Columns.Add(new DataColumn("CategoryID", typeof(int)));
categories.Columns.Add(new DataColumn("CategoryName", typeof(string)));
categories.Columns.Add(new DataColumn("Description", typeof(string)));
categories.Constraints.Add(new UniqueConstraint("PK_Categories",
                               categories.Columns["CategoryID"]));
categories.PrimaryKey = new DataColumn[1]
                              {categories.Columns["CategoryID"]};
```

The last line of this code creates the primary key for the `Categories` table. The primary key in this instance is a single column; however, it is possible to generate a key over multiple columns using the array syntax shown.

Then the constraint can be created between the two tables:

```
DataColumn parent = ds.Tables["Categories"].Columns["CategoryID"];
DataColumn child = ds.Tables["Products"].Columns["CategoryID"];
ForeignKeyConstraint fk =
   new ForeignKeyConstraint("FK_Product_CategoryID", parent, child);
fk.UpdateRule = Rule.Cascade;
fk.DeleteRule = Rule.SetNull;
ds.Tables["Products"].Constraints.Add(fk);
```

This constraint applies to the link between `Categories.CategoryID` and `Products.CategoryID`. There are four different `ForeignKeyConstraints` — use those that permit you to name the constraint.

Setting Update and Delete Constraints

In addition to defining that there is some type of constraint between parent and child tables, you can define what should happen when a column in the constraint is updated.

The previous example sets the update rule and the delete rule. These rules are used when an action occurs to a column (or row) within the parent table, and the rule is used to decide what should happen to the row(s) within the child table that could be affected. Four different rules can be applied through the `Rule` enumeration:

- `Cascade` — If the parent key has been updated, copy the new key value to all child records. If the parent record has been deleted, delete the child records also. This is the default option.
- `None` — Takes no action whatsoever. This option leaves orphaned rows within the child data table.
- `SetDefault` — Each child record affected has the foreign key column(s) set to its default value, if one has been defined.
- `SetNull` — All child rows have the key column(s) set to DBNull. (Following the naming convention that Microsoft uses, this should really be SetDBNull.)

Constraints are enforced only within a DataSet *class if the* EnforceConstraints *property of the* DataSet *is* true*.*

This section has covered the main classes that make up the constituent parts of the DataSet class and has shown how to manually generate each of these classes in code. You can also define a DataTable, DataRow, DataColumn, DataRelation, and Constraint using the XML schema file(s) and the XSD tool that ships with .NET. The following section describes how to set up a simple schema and generate type-safe classes to access your data.

XML SCHEMAS: GENERATING CODE WITH XSD

XML is firmly entrenched in ADO.NET — indeed, the remoting format for passing data between objects is now XML. With the .NET runtime, it is possible to describe a DataTable class within an XML schema definition file (XSD). What's more, you can define an entire DataSet class, with a number of DataTable classes, and a set of relationships between these tables, and you can include various other details to fully describe the data.

When you have defined an XSD file, there is a tool in the runtime that will convert this schema to the corresponding data access class(es), such as the type-safe product DataTable class shown earlier. Let's start with a simple XSD file (Products.xsd) that describes the same information as the Products sample discussed earlier and then extend it to include some extra functionality:

```
<?xml version="1.0" encoding="utf-8" ?>
<xs:schema id="Products" targetNamespace="http://tempuri.org/XMLSchema1.xsd"
 xmlns:mstns="http://tempuri.org/XMLSchema1.xsd"
  xmlns:xs="http://www.w3.org/2001/XMLSchema"
  xmlns:msdata="urn:schemas-microsoft-com:xml-msdata">
  <xs:element name="Product">
    <xs:complexType>
      <xs:sequence>
        <xs:element name="ProductID" msdata:ReadOnly="true"
          msdata:AutoIncrement="true" type="xs:int" />
        <xs:element name="ProductName" type="xs:string" />
        <xs:element name="SupplierID" type="xs:int" minOccurs="0" />
        <xs:element name="CategoryID" type="xs:int" minOccurs="0" />
        <xs:element name="QuantityPerUnit" type="xs:string" minOccurs="0" />
        <xs:element name="UnitPrice" type="xs:decimal" minOccurs="0" />
        <xs:element name="UnitsInStock" type="xs:short" minOccurs="0" />
        <xs:element name="UnitsOnOrder" type="xs:short" minOccurs="0" />
        <xs:element name="ReorderLevel" type="xs:short" minOccurs="0" />
        <xs:element name="Discontinued" type="xs:boolean" />
      </xs:sequence>
    </xs:complexType>
  </xs:element>
</xs:schema>
```

code download Products.xsd

These options are covered in detail in Chapter 33; for now, this file basically defines a schema with the id attribute set to Products. A complex type called Product is defined, which contains a number of elements, one for each of the fields within the Products table.

These items map to data classes as follows. The Products schema maps to a class derived from DataSet. The Product complex type maps to a class derived from DataTable. Each subelement maps to a class derived from DataColumn. The collection of all columns maps to a class derived from DataRow.

Thankfully, there is a tool within the .NET Framework that produces the code for these classes with the help of the input XSD file. Because its sole job is to perform various functions on XSD files, the tool itself is called `XSD.EXE`.

Assuming that you saved the preceding file as `Product.xsd`, you would convert the file into code by issuing the following command in a command prompt:

```
xsd Product.xsd /d
```

This creates the file `Product.cs`.

Various switches can be used with XSD to alter the output generated. Some of the more commonly used switches are shown in the following table.

SWITCH	DESCRIPTION
`/dataset (/d)`	Enables you to generate classes derived from `DataSet`, `DataTable`, and `DataRow`.
`/language:<language>`	Permits you to choose which language the output file will be written in. C# is the default, but you can choose `VB` for a Visual Basic .NET file.
`/namespace:<namespace>`	Enables you to define the namespace that the generated code should reside within. The default is no namespace.

The following is an abridged version of the output from XSD for the `Products` schema. The output has been altered slightly to fit into a format appropriate for this book. To see the complete output, run `XSD.EXE` on the `Products` schema (or one of your own making) and look at the `.cs` file generated. The example includes the entire source code plus the `Product.xsd` file:

```
//------------------------------------
// <autogenerated>
//     This code was generated by a tool.
//     Runtime Version:4.0.21006.1
//
//     Changes to this file may cause incorrect behavior and will be lost if
//     the code is regenerated.
// </autogenerated>
//------------------------------------

//
// This source code was auto-generated by xsd, Version=4.0.21006.1
//

            base.Relations.CollectionChanged += schemaChangedHandler;
            this.EndInit();
    }
```

code download product.cs

All private and protected members have been removed to concentrate on the public interface. The `ProductDataTable` and `ProductRow` definitions show the positions of two nested classes, which will be implemented next. You review the code for these classes after a brief explanation of the `DataSet`-derived class.

The `Products()` constructor calls a private method, `InitClass()`, which constructs an instance of the `DataTable`-derived class `ProductDataTable`, and adds the table to the `Tables` collection of the `DataSet` class. The `Products` data table can be accessed by the following code:

```
DataSet ds = new Products();
DataTable products = ds.Tables["Products"];
```

Or, more simply by using the property `Product`, available on the derived `DataSet` object:

```
DataTable products = ds.Product;
```

Because the `Product` property is strongly typed, you could naturally use `ProductDataTable` rather than the `DataTable` reference shown in the previous code.

The `ProductDataTable` class includes far more code (note this is an abridged version of the code):

```
[global::System.Serializable()]
[global::System.Xml.Serialization.XmlSchemaProviderAttribute("GetTypedTableSchema")]
public partial class ProductDataTable : global::System.Data.DataTable,
   global::System.Collections.IEnumerable {

        private global::System.Data.DataColumn columnProductID;
        private global::System.Data.DataColumn columnProductName;
        private global::System.Data.DataColumn columnSupplierID;
        private global::System.Data.DataColumn columnCategoryID;
        private global::System.Data.DataColumn columnQuantityPerUnit;
        private global::System.Data.DataColumn columnUnitPrice;
        private global::System.Data.DataColumn columnUnitsInStock;
        private global::System.Data.DataColumn columnUnitsOnOrder;
        private global::System.Data.DataColumn columnReorderLevel;
        private global::System.Data.DataColumn columnDiscontinued;

[global::System.Diagnostics.DebuggerNonUserCodeAttribute()]
[global::System.CodeDom.Compiler.GeneratedCodeAttribute(
    "System.Data.Design.TypedDataSetGenerator", "4.0.0.0")]
        public ProductDataTable() {
            this.TableName = "Product";
            this.BeginInit();
            this.InitClass();
            this.EndInit();
        }
```

code download product.cs

The `ProductDataTable` class, derived from `DataTable` and implementing the `IEnumerable` interface, defines a private `DataColumn` instance for each of the columns within the table. These are initialized again from the constructor by calling the private `InitClass()` member. Each column is used by the `DataRow` class (which is described shortly):

```
[global::System.Diagnostics.DebuggerNonUserCodeAttribute()]
[global::System.CodeDom.Compiler.GeneratedCodeAttribute(
    "System.Data.Design.TypedDataSetGenerator", "4.0.0.0")]
[global::System.ComponentModel.Browsable(false)]
public int Count {
   get {
      return this.Rows.Count;
   }
}

// Other row accessors removed for clarity — there is one for each column
```

code download product.cs

Adding rows to the table is taken care of by the two overloaded (and significantly different) `AddProductRow()` methods. The first takes an already constructed `DataRow` and returns a void. The second takes a set of values, one for each of the columns in the `DataTable`, constructs a new row, sets the values within this new row, adds the row to the `DataTable` object, and returns the row to the caller. Such widely different functions shouldn't really have the same name!

```
[global::System.Diagnostics.DebuggerNonUserCodeAttribute()]
[global::System.CodeDom.Compiler.GeneratedCodeAttribute(
 "System.Data.Design.TypedDataSetGenerator", "4.0.0.0")]
        public ProductRow AddProductRow(string ProductName, int SupplierID,
           int CategoryID, string QuantityPerUnit, decimal UnitPrice,
           short UnitsInStock, short UnitsOnOrder, short ReorderLevel,
           bool Discontinued) {
            ProductRow rowProductRow = ((ProductRow)(this.NewRow()));
            object[] columnValuesArray = new object[] {
                    null,
                    ProductName,
                    SupplierID,
                    CategoryID,
                    QuantityPerUnit,
                    UnitPrice,
                    UnitsInStock,
                    UnitsOnOrder,
                    ReorderLevel,
                    Discontinued};
            rowProductRow.ItemArray = columnValuesArray;
            this.Rows.Add(rowProductRow);
            return rowProductRow;
        }
```

code download product.cs

Just like the `InitClass()` member in the `DataSet`-derived class, which added the table into the `DataSet` class, the `InitClass()` member in `ProductDataTable` adds columns to the `DataTable` class. Each column's properties are set as appropriate, and the column is then appended to the columns collection:

```
[global::System.Diagnostics.DebuggerNonUserCodeAttribute()]
[global::System.CodeDom.Compiler.GeneratedCodeAttribute(
    "System.Data.Design.TypedDataSetGenerator", "4.0.0.0")]
        private void InitClass() {
            this.columnProductID = new
global::System.Data.DataColumn("ProductID",
               typeof(int), null, global::System.Data.MappingType.Element);
            base.Columns.Add(this.columnProductID);
            this.columnProductName = new global::System.Data.DataColumn(
              "ProductName", typeof(string), null,
              global::System.Data.MappingType.Element);
            base.Columns.Add(this.columnProductName);
            this.columnSupplierID = new global::System.Data.DataColumn(
               "SupplierID", typeof(int), null,
               global::System.Data.MappingType.Element);
            base.Columns.Add(this.columnSupplierID);
            this.columnCategoryID = new global::System.Data.DataColumn("CategoryID",
               typeof(int), null, global::System.Data.MappingType.Element);
            base.Columns.Add(this.columnCategoryID);
            this.columnQuantityPerUnit = new
               global::System.Data.DataColumn("QuantityPerUnit", typeof(string), null,
               global::System.Data.MappingType.Element);
            base.Columns.Add(this.columnQuantityPerUnit);
            this.columnUnitPrice = new global::System.Data.DataColumn("UnitPrice",
               typeof(decimal), null, global::System.Data.MappingType.Element);
            base.Columns.Add(this.columnUnitPrice);
            this.columnUnitsInStock = new global::System.Data.DataColumn("UnitsInStock",
               typeof(short), null, global::System.Data.MappingType.Element);
            base.Columns.Add(this.columnUnitsInStock);
            this.columnUnitsOnOrder = new global::System.Data.DataColumn("UnitsOnOrder",
               typeof(short), null, global::System.Data.MappingType.Element);
            base.Columns.Add(this.columnUnitsOnOrder);
            this.columnReorderLevel = new global::System.Data.DataColumn("ReorderLevel",
               typeof(short), null, global::System.Data.MappingType.Element);
            base.Columns.Add(this.columnReorderLevel);
            this.columnDiscontinued = new global::System.Data.DataColumn("Discontinued",
               typeof(bool), null, global::System.Data.MappingType.Element);
            base.Columns.Add(this.columnDiscontinued);
            this.columnProductID.AutoIncrement = true;
            this.columnProductID.AllowDBNull = false;
            this.columnProductID.ReadOnly = true;
            this.columnProductName.AllowDBNull = false;
            this.columnDiscontinued.AllowDBNull = false;
        }

        [global::System.Diagnostics.DebuggerNonUserCodeAttribute()]
        [global::System.CodeDom.Compiler.GeneratedCodeAttribute(
           "System.Data.Design.TypedDataSetGenerator", "4.0.0.0")]
        public ProductRow NewProductRow() {
            return ((ProductRow)(this.NewRow()));
        }
```

code download product.cs

`NewRowFromBuilder()` is called internally from the `DataTable` class's `NewRow()` method. Here, it creates a new strongly typed row. The `DataRowBuilder` instance is created by the `DataTable` class, and its members are accessible only within the `System.Data` assembly:

```
[global::System.Diagnostics.DebuggerNonUserCodeAttribute()]
[global::System.CodeDom.Compiler.GeneratedCodeAttribute(
   "System.Data.Design.TypedDataSetGenerator", "4.0.0.0")]
        protected override global::System.Data.DataRow NewRowFromBuilder(
           global::System.Data.DataRowBuilder builder) {
             return new ProductRow(builder);
        }
```

The last class to discuss is the `ProductRow` class, derived from `DataRow`. This class is used to provide type-safe access to all fields in the data table. It wraps the storage for a particular row, and provides members to read (and write) each of the fields in the table.

In addition, for each nullable field, there are functions to set the field to `null` and to check if the field is `null`. The following example shows the functions for the `SupplierID` column:

```
public partial class ProductRow : global::System.Data.DataRow {

        private ProductDataTable tableProduct;

        [global::System.Diagnostics.DebuggerNonUserCodeAttribute()]
        [global::System.CodeDom.Compiler.GeneratedCodeAttribute(
           "System.Data.Design.TypedDataSetGenerator", "4.0.0.0")]
        internal ProductRow(global::System.Data.DataRowBuilder rb) :
                base(rb) {
            this.tableProduct = ((ProductDataTable)(this.Table));
        }

        [global::System.Diagnostics.DebuggerNonUserCodeAttribute()]
        [global::System.CodeDom.Compiler.GeneratedCodeAttribute(
           "System.Data.Design.TypedDataSetGenerator", "4.0.0.0")]
        public int ProductID {
            get {
                return ((int)(this[this.tableProduct.ProductIDColumn]));
            }
            set {
                this[this.tableProduct.ProductIDColumn] = value;
            }
        }

  // Other column accessors/mutators removed for clarity

        [global::System.Diagnostics.DebuggerNonUserCodeAttribute()]
        [global::System.CodeDom.Compiler.GeneratedCodeAttribute(
           "System.Data.Design.TypedDataSetGenerator", "4.0.0.0")]
        public bool IsSupplierIDNull() {
            return this.IsNull(this.tableProduct.SupplierIDColumn);
        }

        [global::System.Diagnostics.DebuggerNonUserCodeAttribute()]
        [global::System.CodeDom.Compiler.GeneratedCodeAttribute(
           "System.Data.Design.TypedDataSetGenerator", "4.0.0.0")]
        public void SetSupplierIDNull() {
            this[this.tableProduct.SupplierIDColumn] = global::System.Convert.DBNull;
        }
}
```

code download product.cs

The following code uses this class's output from the XSD tool to retrieve data from the `Products` table and display that data to the console:

```
using System;
using System.Data;
using System.Data.SqlClient;

public class XSD_DataSet
{
   public static void Main()
   {
      string source = "server=(local);" +
                      " integrated security=SSPI;" +
                      "database=northwind";
      string select = "SELECT * FROM Products";
      SqlConnection conn = new SqlConnection(source);
```

```
            SqlDataAdapter da = new SqlDataAdapter(select, conn);
            Products ds = new Products();
            da.Fill(ds, "Product");
            foreach(Products.ProductRow row in ds.Product )
            Console.WriteLine("'{0}' from {1}",
                              row.ProductID,
                              row.ProductName);
        }
    }
```

code download XSDDataSet.cs

The output of the XSD file contains a class derived from `DataSet`, `Products`, which is created and then filled by the use of the data adapter. The `foreach` statement uses the strongly typed `ProductRow` and also the `Product` property, which returns the `Product` data table.

To compile this example, issue the following commands:

```
xsd product.xsd /d
```

and

```
csc /recurse:*.cs
```

The first generates the `Products.cs` file from the `Products.XSD` schema, and then the `csc` command uses the `/recurse:*.cs` parameter to go through all files with the extension `.cs` and add these to the resulting assembly.

POPULATING A DATASET

After you have defined the schema of your data set, replete with `DataTable`, `DataColumn`, and `Constraint` classes, and whatever else is necessary, you need to be able to populate the `DataSet` class with some information. You have two main ways to read data from an external source and insert it into the `DataSet` class:

- Use a data adapter.
- Read XML into the `DataSet` class.

Populating a DataSet Class with a Data Adapter

The section on data rows briefly introduced the `SqlDataAdapter` class, as shown in the following code:

```
string select = "SELECT ContactName,CompanyName FROM Customers";
SqlConnection conn = new SqlConnection(source);
SqlDataAdapter da = new SqlDataAdapter(select, conn);
DataSet ds = new DataSet();
da.Fill(ds, "Customers");
```

The bold line shows the `SqlDataAdapter` class in use; the other data adapter classes are again virtually identical in functionality to the `Sql` equivalent.

To retrieve data into a `DataSet`, it is necessary to have some form of command that is executed to select that data. The command in question could be a SQL `SELECT` statement, a call to a stored procedure, or for the OLE DB provider, a `TableDirect` command. The preceding example uses one of the constructors available on `SqlDataAdapter` that converts the passed SQL `SELECT` statement into a `SqlCommand`, and issues this when the `Fill()` method is called on the adapter.

In the stored procedures example earlier in this chapter, the `INSERT`, `UPDATE`, and `DELETE` procedures were defined, but the `SELECT` procedure was not. That gap is filled in the next section, which also shows how to call a stored procedure from a `SqlDataAdapter` class to populate data in a `DataSet` class.

Using a Stored Procedure in a Data Adapter

The first step in this example is to define the stored procedure. The stored procedure to `SELECT` data is:

```
CREATE PROCEDURE RegionSelect AS
  SET NOCOUNT OFF
  SELECT * FROM Region
GO
```

code download StoredProcs.sql

You can type this stored procedure directly into the SQL Server Query Analyzer, or you can run the `StoredProc.sql` file that is provided for use by this example.

Next, you need to define the `SqlCommand` that executes this stored procedure. Again, the code is very simple, and most of it was already presented in the earlier section on issuing commands:

```
private static SqlCommand GenerateSelectCommand(SqlConnection conn)
{
   SqlCommand  aCommand = new SqlCommand("RegionSelect", conn);
   aCommand.CommandType = CommandType.StoredProcedure;
   aCommand.UpdatedRowSource = UpdateRowSource.None;
   return aCommand;
}
```

code download DataAdapter.cs

This method generates the `SqlCommand` that calls the `RegionSelect` procedure when executed. All that remains is to hook up this command to a `SqlDataAdapter` class and call the `Fill()` method:

```
DataSet ds = new DataSet();
// Create a data adapter to fill the DataSet
SqlDataAdapter da = new SqlDataAdapter();
// Set the data adapter's select command
da.SelectCommand = GenerateSelectCommand (conn);
da.Fill(ds, "Region");
```

code download DataAdapter.cs

Here, the `SqlDataAdapter` class is created, and the generated `SqlCommand` is then assigned to the `SelectCommand` property of the data adapter. Subsequently, `Fill()` is called, which will execute the stored procedure and insert all rows returned into the `Region DataTable` (which in this instance is generated by the runtime).

There is more to a data adapter than just selecting data by issuing a command, as discussed shortly in the "Persisting DataSet Changes" section.

Populating a DataSet from XML

In addition to generating the schema for a given `DataSet`, associated tables, and so on, a `DataSet` class can read and write data in native XML, such as a file on disk, a stream, or a text reader.

To load XML into a `DataSet` class, simply call one of the `ReadXML()` methods to read data from a disk file, as shown in this example:

```
DataSet ds = new DataSet();
ds.ReadXml(".\\MyData.xml");
```

The `ReadXml()` method attempts to load any inline schema information from the input XML. If a schema is found, the method uses this schema in the validation of any data loaded from that file. If no inline schema is found, the `DataSet` will extend its internal structure as data is loaded. This is similar to the behavior of `Fill()` in the previous example, which retrieves the data and constructs a `DataTable` based on the data selected.

PERSISTING DATASET CHANGES

After editing data within a `DataSet`, it is usually necessary to persist these changes. The most common example is selecting data from a database, displaying it to the user, and returning those updates to the database.

In a less "connected" application, changes might be persisted to an XML file, transported to a middle-tier application server, and then processed to update several data sources.

A `DataSet` class can be used for either of these examples; what's more, it's easy to do.

Updating with Data Adapters

In addition to the `SelectCommand` that a `SqlDataAdapter` most likely includes, you can also define an `InsertCommand`, `UpdateCommand`, and `DeleteCommand`. As the names imply, these objects are instances of the command object appropriate for your provider such as `SqlCommand` and `OleDbCommand`.

With this level of flexibility, you are free to tune the application by judicious use of stored procedures for frequently used commands (say `SELECT` and `INSERT`), and use straight SQL for less commonly used commands such as `DELETE`. In general, it is recommended to provide stored procedures for all database interaction because it is faster and easier to tune.

This example uses the stored procedure code from the "Calling Stored Procedures" section for inserting, updating, and deleting `Region` records, coupled with the `RegionSelect` procedure written previously, which produces an example that uses each of these commands to retrieve and update data in a `DataSet` class. The main body of code is shown in the following section.

Inserting a New Row

You can add a new row to a `DataTable` in two ways. The first way is to call the `NewRow()` method, which returns a blank row that you then populate and add to the `Rows` collection, as follows:

```
DataRow r = ds.Tables["Region"].NewRow();
r["RegionID"]=999;
r["RegionDescription"]="North West";
ds.Tables["Region"].Rows.Add(r);
```

The second way to add a new row would be to pass an array of data to the `Rows.Add()` method as shown in the following code:

```
DataRow r = ds.Tables["Region"].Rows.Add
             (new object [] { 999, "North West" });
```

Each new row within the `DataTable` will have its `RowState` set to `Added`. The example dumps out the records before each change is made to the database, so after adding a row (either way) to the `DataTable`, the rows will look something like the following. Note that the right-hand column shows the row's state:

```
New row pending inserting into database
  1   Eastern                                         Unchanged
  2   Western                                         Unchanged
  3   Northern                                        Unchanged
  4   Southern                                        Unchanged
  999 North West                                      Added
```

To update the database from the `DataAdapter`, call one of the `Update()` methods as shown here:

```
da.Update(ds, "Region");
```

For the new row within the `DataTable`, this executes the stored procedure (in this instance `RegionInsert`). The example then dumps the state of the data, so you can see that changes have been made to the database.

```
New row updated and new RegionID assigned by database
  1   Eastern                                            Unchanged
  2   Western                                            Unchanged
  3   Northern                                           Unchanged
  4   Southern                                           Unchanged
  5   North West                                         Unchanged
```

Look at the last row in the `DataTable`. The `RegionID` had been set in code to `999`, but after executing the `RegionInsert` stored procedure, the value has been changed to `5`. This is intentional — the database will often generate primary keys for you, and the updated data in the `DataTable` appears because the `SqlCommand` definition within the source code has the `UpdatedRowSource` property set to `UpdateRowSource.OutputParameters`:

```
SqlCommand aCommand = new SqlCommand("RegionInsert", conn);

aCommand.CommandType = CommandType.StoredProcedure;
aCommand.Parameters.Add(new SqlParameter("@RegionDescription",
                            SqlDbType.NChar,
                            50,
                            "RegionDescription"));
aCommand.Parameters.Add(new SqlParameter("@RegionID",
                            SqlDbType.Int,
                            0,
                            ParameterDirection.Output,
                            false,
                            0,
                            0,
                            "RegionID",   // Defines the SOURCE column
                            DataRowVersion.Default,
                            null));
aCommand.UpdatedRowSource = UpdateRowSource.OutputParameters;
```

code download DataAdapter2.cs

What this means is that whenever a data adapter issues this command, the output parameters should be mapped to the source of the row, which in this instance was a row in a `DataTable`. The flag states what data should be updated — the stored procedure has an output parameter that is mapped to the `DataRow`. The column it applies to is `RegionID` because this is defined within the command definition.

The following table shows the values for `UpdateRowSource`.

UPDATEROWSOURCE VALUE	DESCRIPTION
`Both`	A stored procedure might return output parameters and also a complete database record. Both of these data sources are used to update the source row.
`FirstReturnedRecord`	This implies that the command returns a single record, and that the contents of that record should be merged into the original source `DataRow`. This is useful where a given table has a number of default (or computed) columns because after an `INSERT` statement these need to be synchronized with the `DataRow` on the client. An example might be `'INSERT` (columns) `INTO` (table) `WITH` (primarykey)`'`, then `'SELECT` (columns) `FROM` (table) `WHERE` (primarykey)`'`. The returned record would then be merged into the original row.
`None`	All data returned from the command is discarded.
`OutputParameters`	Any output parameters from the command are mapped onto the appropriate column(s) in the `DataRow`.

Updating an Existing Row

Updating an existing row within the `DataTable` is just a case of using the `DataRow` class's indexer with either a column name or column number, as shown in the following code:

```
r["RegionDescription"]="North West England";
r[1] = "North West England";
```

Both of these statements are equivalent (in this example):

```
Changed RegionID 5 description
  1   Eastern                                           Unchanged
  2   Western                                           Unchanged
  3   Northern                                          Unchanged
  4   Southern                                          Unchanged
  5   North West England                                Modified
```

Prior to updating the database, the row updated has its state set to `Modified` as shown.

Deleting a Row

Deleting a row is a matter of calling the `Delete()` method:

```
r.Delete();
```

A deleted row has its row state set to `Deleted`, but you cannot read columns from the deleted `DataRow` because they are no longer valid. When the adaptor's `Update()` method is called, all deleted rows will use the `DeleteCommand`, which in this instance executes the `RegionDelete` stored procedure.

Writing XML Output

As you have seen already, the `DataSet` class has great support for defining its schema in XML, and just as you can read data from an XML document, you can also write data to an XML document.

The `DataSet.WriteXml()` method enables you to output various parts of the data stored within the `DataSet`. You can elect to output just the data, or the data and the schema. The following code shows an example of both for the `Region` example shown earlier:

```
ds.WriteXml(".\\WithoutSchema.xml");
ds.WriteXml(".\\WithSchema.xml", XmlWriteMode.WriteSchema);
```

The first file, `WithoutSchema.xml`, is shown here:

```
<?xml version="1.0" standalone="yes"?>
<NewDataSet>
   <Region>
      <RegionID>1</RegionID>
      <RegionDescription>Eastern                      </RegionDescription>
   </Region>
   <Region>
      <RegionID>2</RegionID>
      <RegionDescription>Western                      </RegionDescription>
   </Region>
   <Region>
      <RegionID>3</RegionID>
      <RegionDescription>Northern                     </RegionDescription>
   </Region>
   <Region>
      <RegionID>4</RegionID>
      <RegionDescription>Southern                     </RegionDescription>
   </Region>
</NewDataSet>
```

code download WithoutSchema.xml

The closing tag on `RegionDescription` is over to the right of the page because the database column is defined as `NCHAR(50)`, which is a 50-character string padded with spaces.

The output produced in the `WithSchema.xml` file includes the XML schema for the `DataSet` as well as the data itself:

```
<?xml version="1.0" standalone="yes"?>
<NewDataSet>
   <xs:schema id="NewDataSet" xmlns=""
              xmlns:xs="http://www.w3.org/2001/XMLSchema"
              xmlns:msdata="urn:schemas-microsoft-com:xml-msdata">
      <xs:element name="NewDataSet" msdata:IsDataSet="true">
         <xs:complexType>
            <xs:choice maxOccurs="unbounded">
               <xs:element name="Region">
                  <xs:complexType>
                     <xs:sequence>
                        <xs:element name="RegionID"
                                    msdata:AutoIncrement="true"
                                    msdata:AutoIncrementSeed="1"
                                    type="xs:int" />
                        <xs:element name="RegionDescription"
                                    type="xs:string" />
                     </xs:sequence>
                  </xs:complexType>
               </xs:element>
            </xs:choice>
         </xs:complexType>
      </xs:element>
   </xs:schema>
   <Region>
      <RegionID>1</RegionID>
      <RegionDescription>Eastern                       </RegionDescription>
   </Region>
   <Region>
      <RegionID>2</RegionID>
      <RegionDescription>Western                       </RegionDescription>
   </Region>
   <Region>
      <RegionID>3</RegionID>
      <RegionDescription>Northern                     </RegionDescription>
   </Region>
   <Region>
      <RegionID>4</RegionID>
      <RegionDescription>Southern                     </RegionDescription>
   </Region>
</NewDataSet>
```

code download WithoutSchema.xml

Note the use in this file of the `msdata` schema, which defines extra attributes for columns within a `DataSet`, such as `AutoIncrement` and `AutoIncrementSeed` — these attributes correspond directly to the properties definable on a `DataColumn` class.

WORKING WITH ADO.NET

This section addresses some common scenarios when developing data access applications with ADO.NET.

Tiered Development

Producing an application that interacts with data is often done by splitting up the application into tiers. A common model is to have an application tier (the front end), a data services tier, and the database itself.

One of the difficulties with this model is deciding what data to transport between your tiers as well as figuring out the format in which the data should be transported. With ADO.NET, you will be pleased to learn that these wrinkles have been ironed out, and support for this style of architecture is part of the design.

One of the things that is much better in ADO.NET than OLE DB is the support for copying an entire record set. In .NET, it is easy to copy a `DataSet`:

```
DataSet source = {some dataset};
DataSet dest = source.Copy();
```

This creates an exact copy of the source `DataSet` — each `DataTable`, `DataColumn`, `DataRow`, and `Relation` will be copied, and all data will be in exactly the same state as it was in the source. If all you want to copy is the schema of the `DataSet`, you can use the following code:

```
DataSet source = {some dataset};
DataSet dest = source.Clone();
```

This again copies all tables, relations, and so on. However, each copied `DataTable` will be empty. This process really could not be more straightforward.

A common requirement when writing a tiered system, whether based on a Windows client application or the Web, is to be able to ship as little data as possible between tiers. This reduces the amount of resources consumed.

To cope with this requirement, the `DataSet` class has the `GetChanges()` method. This simple method performs a huge amount of work, and returns a `DataSet` with only the changed rows from the source data set. This is ideal for passing data between tiers because only a minimal set of data has to be passed along.

The following example shows how to generate a “changes” `DataSet`:

```
DataSet source = {some dataset};
DataSet dest = source.GetChanges();
```

Again, this is trivial. Under the hood, things are a little more interesting. There are two overloads of the `GetChanges()` method. One overload takes a value of the `DataRowState` enumeration, and returns only rows that correspond to that state (or states). `GetChanges()` simply calls `GetChanges(Deleted | Modified | Added)`, and first checks to ensure that there are some changes by calling `HasChanges()`. If no changes have been made, `null` is returned to the caller immediately.

The next operation is to clone the current `DataSet`. Once this is done, the new `DataSet` is set up to ignore constraint violations (`EnforceConstraints = false`), and then each changed row for every table is copied into the new `DataSet`.

When you have a `DataSet` that just contains changes, you can then move these off to the data services tier for processing. After the data has been updated in the database, the “changes” `DataSet` can be returned to the caller (for example, there might be some output parameters from the stored procedures that have updated values in the columns). These changes can then be merged into the original `DataSet` using the `Merge()` method. Figure 30-9 depicts this sequence of operations.

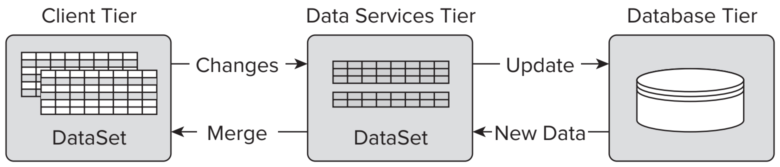

FIGURE 30-9

Key Generation with SQL Server

The RegionInsert stored procedure presented earlier in this chapter is one example of generating a primary key value on insertion into the database. The method for generating the key in this particular example is fairly crude and wouldn't scale well, so for a real application you should use some other strategy for generating keys.

Your first instinct might be to define an identity column and return the @@IDENTITY value from the stored procedure. The following stored procedure shows how this might be defined for the Categories table in the Northwind example database. Type this stored procedure into the SQL Query Analyzer or run the StoredProcs.sql file that is part of the code download:

```
CREATE PROCEDURE CategoryInsert(@CategoryName NVARCHAR(15),
                                  @Description NTEXT,
                                  @CategoryID INTEGER OUTPUT) AS
   SET NOCOUNT OFF
   INSERT INTO Categories (CategoryName, Description)
      VALUES(@CategoryName, @Description)
   SELECT @CategoryID = @@IDENTITY
GO
```

code download StoredProcs.sql

This inserts a new row into the Category table and returns the generated primary key to the caller (the value of the CategoryID column). You can test the procedure by typing the following in the SQL Query Analyzer:

```
DECLARE @CatID int;
EXECUTE CategoryInsert 'Pasties', 'Heaven Sent Food', @CatID OUTPUT;
PRINT @CatID;
```

When executed as a batch of commands, this inserts a new row into the Categories table and returns the identity of the new record, which is then displayed to the user.

Suppose that some months down the line, someone decides to add a simple audit trail, which will record all insertions and modifications made to the category name. In that case, you define a table similar to the one shown in Figure 30-10, which will record the old and new value of the category.

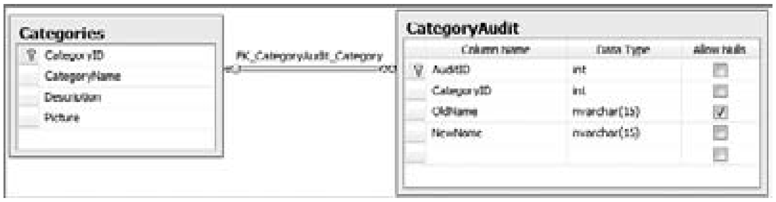

FIGURE 30-10

The script for this table is included in the StoredProcs.sql file. The AuditID column is defined as an IDENTITY column. You then construct a couple of database triggers that will record changes to the CategoryName field:

```
CREATE TRIGGER CategoryInsertTrigger
   ON Categories
   AFTER UPDATE
AS
   INSERT INTO CategoryAudit(CategoryID, OldName, NewName )
      SELECT old.CategoryID, old.CategoryName, new.CategoryName
      FROM Deleted AS old,
            Categories AS new
        WHERE old.CategoryID = new.CategoryID;
    GO
```

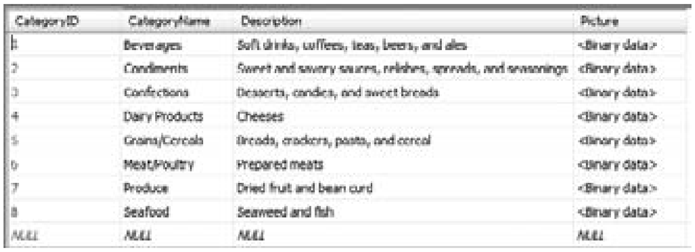
code download StoredProcs.sql

If you are used to Oracle stored procedures, SQL Server doesn't exactly have the concept of `OLD` and `NEW` rows; instead, for an insert trigger there is an in-memory table called `Inserted`, and for deletes and updates the old rows are available within the `Deleted` table.

This trigger retrieves the `CategoryID` of the record(s) affected and stores this together with the old and new value of the `CategoryName` column.

Now, when you call your original stored procedure to insert a new `CategoryID`, you receive an identity value; however, this is no longer the identity value from the row inserted into the `Categories` table — it is now the new value generated for the row in the `CategoryAudit` table. Ouch!

To view the problem first-hand, open a copy of SQL Server Enterprise Manager, and view the contents of the `Categories` table (see Figure 30-11).



CategoryID	CategoryName	Description	Picture
1	Beverages	Soft drinks, coffees, teas, beers, and ales	<Binary data>
2	Condiments	Sweet and savory sauces, relishes, spreads, and seasonings	<Binary data>
3	Confections	Desserts, candies, and sweet breads	<Binary data>
4	Dairy Products	Cheeses	<Binary data>
5	Grains/Cereals	Breads, crackers, pasta, and cereal	<Binary data>
6	Meat/Poultry	Prepared meats	<Binary data>
7	Produce	Dried fruit and bean curd	<Binary data>
8	Seafood	Seaweed and fish	<Binary data>
NULL	NULL	NULL	NULL

FIGURE 30-11

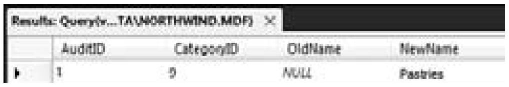
This lists all the categories in the Northwind database.

The next identity value for the `Categories` table should be `9`, so a new row can be inserted by executing the following code, to see what `ID` is returned:

```
DECLARE @CatID int;
EXECUTE CategoryInsert 'Pastries', 'Heaven Sent Food', @CatID OUTPUT;
PRINT @CatID;
```

The output value of this on a test PC was `1`. If you look at the `CategoryAudit` table shown in Figure 30-12, you will find that this is the identity of the newly inserted audit record, not the identity of the category record created.

The problem lies in the way that `@@IDENTITY` actually works. It returns the `LAST` identity value created by your session, so as shown in Figure 30-12, it isn't completely reliable.



Results: Query(v...TA\NORTHWIND.MDF)

AuditID	CategoryID	OldName	NewName
1	9	NULL	Pastries

FIGURE 30-12

Two other identity functions can be used instead of `@@IDENTITY`, but neither is free from possible problems. The first, `SCOPE_IDENTITY()`, returns the last identity value created within the current *scope*. SQL Server defines scope as a stored procedure, trigger, or function. This may work most of the time, but if for some reason someone adds another `INSERT` statement to the stored procedure, you can receive this value rather than the one you expected.

The other identity function, `IDENT_CURRENT()`, returns the last identity value generated for a given table in any scope. For example, if two users were accessing SQL Server at exactly the same time, it might be possible to receive the other user's generated identity value.

As you might imagine, tracking down a problem of this nature is not easy. The moral of the story is to beware when using `IDENTITY` columns in SQL Server.

Naming Conventions

The following tips and conventions are not directly .NET-related. However, they are worth sharing and following, especially when naming constraints. Feel free to skip this section if you already have your own views on this subject.

Conventions for Database Tables

- **Always use singular names** — For example, `Product` rather than `Products`. This one is largely due to having to explain a database schema to customers; it is much better grammatically to say, “The `Product` table contains products” than “The `Products` table contains products.” Check out the Northwind database to see an example of how not to do this.
- **Adopt some form of naming convention for the fields that go into a table** — Ours is `<Table>_Id` for the primary key of a table (assuming that the primary key is a single column), Name for the field considered to be the user-friendly name of the record, and Description for any textual information about the record itself. Having a good table convention means that you can look at virtually any table in the database and instinctively know what the fields are used for.

Conventions for Database Columns

- Use singular rather than plural names.
- Any columns that link to another table should be given the same name as the primary key of that table. For example, a link to the `Product` table would be `Product_Id`, and one to the `Sample` table `Sample_Id`. This is not always possible, especially if one table has multiple references to another. In that case, use your own judgment.
- Date fields should have a suffix of `_On`, as in `Modified_On` and `Created_On`. That makes it is easy to read some SQL output and infer what a column means just by its name.
- Fields that record activities from the user should be suffixed with `_By`, as in `Modified_By` and `Created_By`. Again, this aids comprehension.

Conventions for Constraints

- If possible, include in the name of the constraint the table and column name, as in `CK_<Table>_<Field>`. For example, use `CK_Person_Sex` for a check constraint on the `Sex` column of the `Person` table. A foreign key example would be `FK_Product_Supplier_Id`, for the foreign key relationship between product and supplier.
- Show the type of constraint with a prefix, such as `CK` for a check constraint or `FK` for a foreign key constraint. Feel free to be more specific, as in `CK_Person_Age_GT0` for a constraint on the age column indicating that the age should be greater than zero.
- If you have to trim the length of the constraint, do this on the table name part rather than the column name. When you get a constraint violation, it is usually easy to infer which table was in error, but sometimes not so easy to check which column caused the problem. Oracle has a 30-character limit on names, which is easy to surpass.

Stored Procedures

Just like the obsession many have developed over the past few years with putting a `C` in front of each and every class they declare (you know you have!), many SQL Server developers feel compelled to prefix every stored procedure with `sp_` or something similar. This is not a good idea.

SQL Server uses the `sp_` prefix for all (well, most) system stored procedures. So, you risk confusing your users into thinking that `sp_widget` is something that comes as standard with SQL Server. In addition, when looking for a stored procedure, SQL Server treats procedures with the `sp_` prefix differently from those without it.

If you use this prefix and do not qualify the database/owner of the stored procedure, SQL Server will look in the current scope and then jump into the master database and look up the stored procedure there. Without the sp_ prefix, your users would get an error a little earlier. What's worse, and also possible to do, is to create a local stored procedure (one within your database) that has the same name and parameters as a system stored procedure. Avoid this at all costs — if in doubt, do not prefix.

When calling stored procedures, always prefix them with the owner of the procedure, as in dbo.selectWidgets. This is slightly faster than not using the prefix, because SQL Server has less work to do to find the stored procedure. Something like this is not likely to have a huge impact on the execution speed of your application, but it is a tuning trick that is essentially available for free.

Above all, when naming entities, whether within the database or within code, *be consistent*.

SUMMARY

The subject of data access is a large one, especially in .NET, because there is an abundance of material to cover. This chapter has provided an outline of the main classes in the ADO.NET namespaces and has shown how to use the classes when manipulating data from a data source.

First, the Connection object was explored, using both SqlConnection (SQL Server–specific) and OleDbConnection (for any OLE DB data sources). The programming model for these two classes is so similar that one can normally be substituted for the other, and the code will continue to run.

This chapter also discussed how to use connections properly, so that these scarce resources could be closed as early as possible. All of the connection classes implement the IDisposable interface, called when the object is placed within a using clause. If there is one thing you should take away from this chapter, it is the importance of closing database connections as early as possible.

In addition, this chapter discussed database commands using examples that executed with no returned data, and examples that that called stored procedures with input and output parameters. It described various execute methods, including the ExecuteXmlReader() method available only on the SQL Server provider. This vastly simplifies the selection and manipulation of XML-based data.

The generic classes within the System.Data namespace were all described in detail, from the DataSet class through DataTable, DataColumn, DataRow, and on to relationships and constraints. The DataSet class is an excellent container of data, and various methods make it ideal for cross-tier data flow. The data within a DataSet is represented in XML for transport, and in addition, methods are available that pass a minimal amount of data between tiers. The ability to have many tables of data within a single DataSet can greatly increase its usability.

Having the schema stored within a DataSet is one thing, but .NET also includes the data adapter that, along with various Command objects, can be used to select data for a DataSet and subsequently update data in the data store. One of the beneficial aspects of a data adapter is that a distinct command can be defined for each of the four actions: SELECT, INSERT, UPDATE, and DELETE. The system can create a default set of commands based on database schema information and a SELECT statement. For the best performance, however, a set of stored procedures can be used, with the DataAdapter's commands defined appropriately to pass only the necessary information to these stored procedures.

The XSD tool (XSD.EXE) was described, using an example that showed how to work with classes based on an XML schema from within .NET. The classes produced are ready to be used within an application, and their automatic generation can save many hours of laborious typing.

Finally, this chapter discussed some best practices and naming conventions for database development.

Further information about accessing SQL Server databases is provided in Chapter 34, ".NET Programming with SQL Server."

31 ADO.NET Entity Framework

WHAT'S IN THIS CHAPTER?

- The ADO.NET Entity Framework
- Mapping between database tables and entity classes
- Creating entity classes and their features
- Object contexts
- Relationships
- Object queries
- Updates
- LINQ to Entities

The ADO.NET Entity Framework is an object-relational mapping framework that offers an abstraction of ADO.NET to get an object model based on the referential databases. This chapter gives information on the mappings between the database and the entity classes using the Conceptual Schema Definition Language (CSDL), Storage Schema Definition Language (SSDL), and the Mapping Schema Language (MSL). Different relationships between entities are covered, such as one Table-per-Hierarchy of objects, one Table-per-Type, and n-to-n relationships.

This chapter also describes different ways to access the database from the code directly with the Entity Client, using Entity SQL or helper methods that create Entity SQL, and using LINQ to Entities. Object tracking and how the data context holds change information for updating data is also shown.

OVERVIEW OF THE ADO.NET ENTITY FRAMEWORK

The ADO.NET Entity Framework provides a mapping from the relational database schema to objects. Relational databases and object-oriented languages define associations differently. For example, the Microsoft sample database Northwind contains the Customers and Orders tables. To access all the Orders rows for a customer, you need to do a SQL join statement. With object-oriented languages, it is more common to define a `Customer` and an `Order` class and access the orders of a customer by using an `Orders` property from the `Customer` class.

For object-relational mapping since .NET 1.0, it was possible to use the `DataSet` class and typed datasets. Datasets are very similar to the structure of a database containing `DataTable`, `DataRow`, `DataColumn`, and `DataRelation` classes instead of offering object-support. The ADO.NET Entity Framework gives support to directly define entity classes that are completely independent of a database structure and map them to tables and associations of the database. Using objects with the application, the application is shielded from changes in the database.

The ADO.NET Entity Framework makes use of Entity SQL to define entity-based queries to the store. LINQ to Entities makes it possible to use the LINQ syntax to query data. An object context keeps knowledge about entities that are changed, to have information when the entities should be written back to the store.

The namespaces that contain classes from the ADO.NET Entity Framework are listed in the following table.

NAMESPACE	DESCRIPTION
`System.Data`	This is a main namespace for ADO.NET. With the ADO.NET Entity Framework. This namespace contains exception classes related to entities — for example `MappingException` and `QueryException`.
`System.Data.Common`	This namespace contains classes shared by .NET data providers. The class `DbProviderServices` is an abstract base class that must be implemented by an ADO.NET Entity Framework provider.
`System.Data.Common.CommandTrees`	This namespace contains classes to build an expression tree.
`System.Data.Entity.Design`	This namespace contains classes used by the designer to create Entity Data Model (EDM) files.
`System.Data.EntityClient`	This namespace specifies classes for the .NET Framework Data Provider to access the Entity Framework. `EntityConnection`, `EntityCommand`, and `EntityDataReader` can be used to access the Entity Framework.
`System.Data.Objects`	This namespace contains classes to query and update databases. The class `ObjectContext` encapsulates the connection to the database and serves as a gateway for create, read, update, and delete methods. The class `ObjectQuery` represents a query against the store. `CompiledQuery` is a cached query.
`System.Data.Objects.DataClasses`	This namespace contains classes and interfaces required for entities.

ENTITY FRAMEWORK MAPPING

The ADO.NET Entity Framework offers several layers to map database tables to objects. You can start with a database schema and use a Visual Studio item template to create the complete mapping. You can also start designing entity classes with the designer and map it to the database where the tables and associations between the tables can have a very different structure.

The layers that need to be defined are as follows:

- *Logical* — This layer defines the relational data.
- *Conceptual* — This layer defines the .NET classes.
- *Mapping* — This layer defines the mapping from .NET classes to relational tables and associations.

Let's start with a simple database schema, as shown in Figure 31-1, with the tables `Books` and `Authors`, and an association table `BookAuthors` that maps the authors to books.

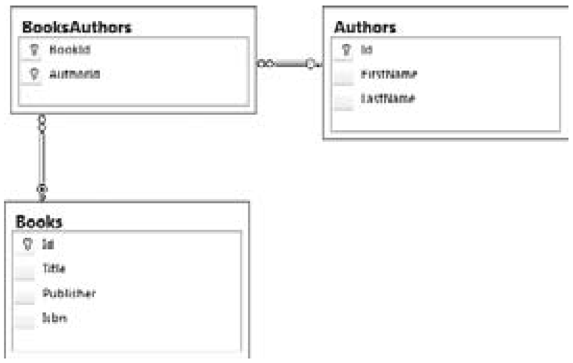


FIGURE 31-1

Logical Layer

The logical layer is defined by the Store Schema Definition Language (SSDL) and describes the structure of the database tables and their relations.

The following code uses SSDL to describe the three tables: `Books`, `Authors`, and `BooksAuthors`. The `EntityContainer` element describes all the tables with `EntitySet` elements, and associations with `AssociationSet` elements. The parts of a table are defined with the `EntityType` element. With `EntityType Books` you can see the columns `Id`, `Title`, `Publisher`, and `ISBN` defined by the `Property` element. The `Property` element contains XML attributes to define the data type. The `Key` element defines the key of the table:

```
<edmx:StorageModels>
    <Schema Namespace="BooksModel.Store" Alias="Self" Provider="System.Data.SqlClient"
            ProviderManifestToken="2008"
            xmlns:store=
              "http://schemas.microsoft.com/ado/2007/12/edm/EntityStoreSchemaGenerator"
            xmlns="http://schemas.microsoft.com/ado/2009/02/edm/ssdl">
      <EntityContainer Name="BooksModelStoreContainer">
        <EntitySet Name="Authors" EntityType="BooksModel.Store.Authors" store:Type="Tables"
                   Schema="dbo" />
        <EntitySet Name="Books" EntityType="BooksModel.Store.Books" store:Type="Tables"
                   Schema="dbo" />
        <EntitySet Name="BooksAuthors" EntityType="BooksModel.Store.BooksAuthors"
                   store:Type="Tables" Schema="dbo" />
        <AssociationSet Name="FK_BooksAuthors_Authors"
                        Association="BooksModel.Store.FK_BooksAuthors_Authors">
          <End Role="Authors" EntitySet="Authors" />
          <End Role="BooksAuthors" EntitySet="BooksAuthors" />
        </AssociationSet>
        <AssociationSet Name="FK_BooksAuthors_Books"
                        Association="BooksModel.Store.FK_BooksAuthors_Books">
          <End Role="Books" EntitySet="Books" />
          <End Role="BooksAuthors" EntitySet="BooksAuthors" />
        </AssociationSet>
      </EntityContainer>
      <EntityType Name="Authors">
        <Key>
          <PropertyRef Name="Id" />
        </Key>
        <Property Name="Id" Type="int" Nullable="false" StoreGeneratedPattern="Identity" />
        <Property Name="FirstName" Type="nvarchar" Nullable="false" MaxLength="50" />
        <Property Name="LastName" Type="nvarchar" Nullable="false" MaxLength="50" />
      </EntityType>
      <EntityType Name="Books">
        <Key>
          <PropertyRef Name="Id" />
        </Key>
        <Property Name="Id" Type="int" Nullable="false" StoreGeneratedPattern="Identity" />
        <Property Name="Title" Type="nvarchar" Nullable="false" MaxLength="50" />
      <Property Name="Publisher" Type="nvarchar" Nullable="false" MaxLength="50" />
      <Property Name="Isbn" Type="nchar" MaxLength="18" />
    </EntityType>
    <EntityType Name="BooksAuthors">
      <Key>
        <PropertyRef Name="BookId" />
        <PropertyRef Name="AuthorId" />
      </Key>
      <Property Name="BookId" Type="int" Nullable="false" />
      <Property Name="AuthorId" Type="int" Nullable="false" />
    </EntityType>
    <Association Name="FK_BooksAuthors_Authors">
      <End Role="Authors" Type="BooksModel.Store.Authors" Multiplicity="1" />
      <End Role="BooksAuthors" Type="BooksModel.Store.BooksAuthors" Multiplicity="*" />
      <ReferentialConstraint>
        <Principal Role="Authors">
          <PropertyRef Name="Id" />
        </Principal>
        <Dependent Role="BooksAuthors">
          <PropertyRef Name="AuthorId" />
        </Dependent>
      </ReferentialConstraint>
    </Association>
    <Association Name="FK_BooksAuthors_Books">
      <End Role="Books" Type="BooksModel.Store.Books" Multiplicity="1" />
      <End Role="BooksAuthors" Type="BooksModel.Store.BooksAuthors" Multiplicity="*" />
      <ReferentialConstraint>
        <Principal Role="Books">
          <PropertyRef Name="Id" />
        </Principal>
        <Dependent Role="BooksAuthors">
          <PropertyRef Name="BookId" />
        </Dependent>
      </ReferentialConstraint>
    </Association>
  </Schema>
</edmx:StorageModels>
```

code snippet BooksDemo/BooksModel.edmx

The file BooksModel.edmx contains SSDL, CSDL, and MSL. You can open this file with an XML editor to see its contents.

Conceptual Layer

The conceptual layer defines .NET classes. This layer is created with the Conceptual Schema Definition Language (CSDL).

Figure 31-2 shows the entities `Author` and `Book` defined with the ADO.NET Entity Data Model Designer.

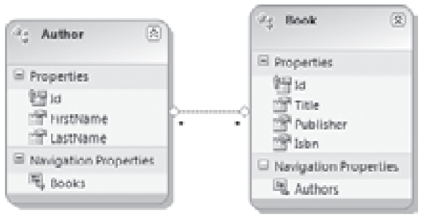

FIGURE 31-2

The following is the CSDL content that defines the entity types `Book` and `Author`. This was created from the Books database:

```
<edmx:ConceptualModels>
     <Schema Namespace="BooksModel" Alias="Self"
             xmlns:annotation="http://schemas.microsoft.com/ado/2009/02/edm/annotation"
             xmlns="http://schemas.microsoft.com/ado/2008/09/edm">
       <EntityContainer Name="BooksEntities" annotation:LazyLoadingEnabled="true">
         <EntitySet Name="Authors" EntityType="BooksModel.Author" />
```

```
        <EntitySet Name="Books" EntityType="BooksModel.Book" />
        <AssociationSet Name="BooksAuthors" Association="BooksModel.BooksAuthors">
          <End Role="Authors" EntitySet="Authors" />
          <End Role="Books" EntitySet="Books" />
        </AssociationSet>
      </EntityContainer>
      <EntityType Name="Author">
        <Key>
          <PropertyRef Name="Id" />
        </Key>
        <Property Name="Id" Type="Int32" Nullable="false"
                  annotation:StoreGeneratedPattern="Identity" />
        <Property Name="FirstName" Type="String" Nullable="false" MaxLength="50"
                  Unicode="true" FixedLength="false" />
        <Property Name="LastName" Type="String" Nullable="false" MaxLength="50"
                  Unicode="true" FixedLength="false" />
        <NavigationProperty Name="Books" Relationship="BooksModel.BooksAuthors"
                            FromRole="Authors" ToRole="Books" />
      </EntityType>
      <EntityType Name="Book">
        <Key>
          <PropertyRef Name="Id" />
        </Key>
        <Property Name="Id" Type="Int32" Nullable="false"
                  annotation:StoreGeneratedPattern="Identity" />
        <Property Name="Title" Type="String" Nullable="false" MaxLength="50" Unicode="true"
                  FixedLength="false" />
        <Property Name="Publisher" Type="String" Nullable="false" MaxLength="50"
                  Unicode="true" FixedLength="false" />
        <Property Name="Isbn" Type="String" MaxLength="18" Unicode="true"
                  FixedLength="true" />
        <NavigationProperty Name="Authors" Relationship="BooksModel.BooksAuthors"
                            FromRole="Books" ToRole="Authors" />
      </EntityType>
      <Association Name="BooksAuthors">
        <End Role="Authors" Type="BooksModel.Author" Multiplicity="*" />
        <End Role="Books" Type="BooksModel.Book" Multiplicity="*" />
      </Association>
    </Schema>
  </edmx:ConceptualModels>
```

code snippet BooksDemo/BooksModel.edmx

The entity is defined by an `EntityType` element that contains `Key`, `Property`, and `NavigationProperty` elements to describe the properties of the created class. The `Property` element contains attributes to describe the name and type of the .NET properties of the classes that are generated by the designer. The `Association` element connects the types `Author` and `Book`. `Multiplicity="*"` means that one `Author` can write multiple `Books`, and one `Book` can be written by multiple `Authors`.

Mapping Layer

The mapping layer maps the entity type definition from the CSDL to the SSDL by using the Mapping Specification Language (MSL). The following specification includes a `Mapping` element that contains the `EntityTypeMapping` element to reference the `Book` type of the CSDL and defines the `MappingFragment` to reference the `Authors` table from the SSDL. The `ScalarProperty` maps the property of the .NET class with the `Name` attribute to the column of the database table with the `ColumnName` attribute:

```
<edmx:Mappings>
  <Mapping Space="C-S" xmlns="http://schemas.microsoft.com/ado/2008/09/mapping/cs">
    <EntityContainerMapping StorageEntityContainer="BooksModelStoreContainer"
                            CdmEntityContainer="BooksEntities">
```

```
        <EntitySetMapping Name="Authors">
          <EntityTypeMapping TypeName="BooksModel.Author">
            <MappingFragment StoreEntitySet="Authors">
              <ScalarProperty Name="Id" ColumnName="Id" />
              <ScalarProperty Name="FirstName" ColumnName="FirstName" />
              <ScalarProperty Name="LastName" ColumnName="LastName" />
            </MappingFragment>
          </EntityTypeMapping>
        </EntitySetMapping>
        <EntitySetMapping Name="Books">
          <EntityTypeMapping TypeName="BooksModel.Book">
            <MappingFragment StoreEntitySet="Books">
              <ScalarProperty Name="Id" ColumnName="Id" />
              <ScalarProperty Name="Title" ColumnName="Title" />
              <ScalarProperty Name="Publisher" ColumnName="Publisher" />
              <ScalarProperty Name="Isbn" ColumnName="Isbn" />
            </MappingFragment>
          </EntityTypeMapping>
        </EntitySetMapping>
        <AssociationSetMapping Name="BooksAuthors" TypeName="BooksModel.BooksAuthors"
                               StoreEntitySet="BooksAuthors">
          <EndProperty Name="Authors">
            <ScalarProperty Name="Id" ColumnName="AuthorId" />
          </EndProperty>
          <EndProperty Name="Books">
            <ScalarProperty Name="Id" ColumnName="BookId" />
          </EndProperty>
        </AssociationSetMapping>
      </EntityContainerMapping>
    </Mapping>
  </edmx:Mappings>
```

code snippet BooksDemo/BooksModel.edmx

ENTITY CLIENT

A low-level API to access the Entity Framework is in the namespace `System.Data.SqlClient`. This namespace contains an ADO.NET provider that accesses the database by using an Entity Data Model (EDM). This ADO.NET provider defines classes, as you know from Chapter 30, "Core ADO.NET." These classes derive from the base classes `DbConnection`, `DbCommand`, `DbParameter`, and `DbDataReader`. Here, the classes are known as `EntityConnection`, `EntityCommand`, `EntityParameter`, and `EntityDataReader`.

You can use these classes in the same way that we described in Chapter 30, except that a special connection string is required and Entity SQL is used instead of T-SQL to access the EDM.

The connection to the database is done with the `EntityConnection` that requires an entity connection string. This string is read from the configuration file with help of the `ConfigurationManager` class from the `System.Configuration` namespace. The `CreateCommand` method of the `EntityConnection` class returns an `EntityCommand`. The command text for the `EntityCommand` is assigned with the `CommandText` property and requires an Entity SQL command. `BooksEntities.Books` is made from the `EntityContainer` element in the `BooksEntities` CSDL definition, and the `Books EntitySet` gets all books from the Books table. `command.ExecuteReader` returns an `EntityDataReader` that reads row by row:

```
string connectionString = ConfigurationManager.ConnectionStrings["BooksEntities"].
                              ConnectionString;
var connection = new EntityConnection(connectionString);
connection.Open();

EntityCommand command = connection.CreateCommand();
command.CommandText = "[BooksEntities].[Books]";
```

```
EntityDataReader reader = command.ExecuteReader(
    CommandBehavior.CloseConnection | CommandBehavior.SequentialAccess);
while (reader.Read())
{
    Console.WriteLine("{0}, {1}", reader["Title"], reader["Publisher"]);
}
reader.Close();
```

code snippet BooksDemo/Program.cs

The code is done in the same way as in Chapter 30. The only real difference is the connection string and the Entity SQL statements; that's why we look at these now.

Connection String

With the earlier code snippet, the connection string is read from the configuration file. The connection string is required for EDM and is different from the normal ADO.NET connection string because mapping information is required. The mapping is defined with the keyword `metadata`. `metadata` requires three things: a delimited list of mapping files, `Provider` for the invariant provider name to access the data source, and a `Provider connection string` to assign the provider-dependent connection string.

The delimited list of mapping files references the files `BooksModel.csdl`, `BooksModel.ssdl`, and `BooksModel.msl`, which are contained within resources in the assembly as defined with the `res:` prefix. Within Visual Studio, the designer uses just one file, `BooksModel.edmx`, which contains CSDL, SSDL, and MSL. Setting the property Custom Tool to `EntityModelCodeGenerator` creates three files that are contained within resources.

Within the `connectionString` setting you can find the connection string to the database with the connection string setting. This part is the same as a simple ADO.NET connection string and depends on the provider that is set with the `provider` setting:

```
<connectionStrings>
  <add name="BooksEntities"
    connectionString="metadata=res://*/BooksModel.csdl|res://*/BooksModel.ssdl|
      res://*/BooksModel.msl;provider=System.Data.SqlClient;
      provider connection string=&quot;Data Source=(local);Initial Catalog=Books;
        Integrated Security=True;Pooling=False;MultipleActiveResultSets=True&quot;"
    providerName="System.Data.EntityClient" />
</connectionStrings>
```

Entity SQL

For querying data with the Entity Client, Entity SQL is used. Entity SQL enhances T-SQL by adding types. This syntax doesn't require joins because associations of entities can be used instead.

Here, just a few syntax options are shown that help you start with Entity SQL. In the MSDN documentation you can find the complete reference.

The previous example showed how Entity SQL uses definitions from the CSDL in the `EntityContainer` and `EntitySet` — for example, `BooksEntities.Books` to get all the books from the table Books because the `Books EntitySet` maps to the `Books EntitySet` in the SSDL.

Instead of retrieving all columns, you can also use the `Property` elements of an `EntityType`. This might look very similar to the T-SQL queries used in the previous chapter:

```
command.CommandText = "SELECT Books.Title, Books.Publisher FROM " +
                      "BooksEntities.Books";
```

code snippet BooksDemo/Program.cs

There's no `SELECT *` with Entity SQL. All the columns were retrieved earlier by requesting the `EntitySet`. Using `SELECT VALUE` you can also get all the columns, as is shown in the next snippet. It also uses a filter with WHERE that only gets specific publishers with the query. Pay attention that the `CommandText` specifies the parameter with the `@` character — however, the parameter that is added to the `Parameters` collection does not use the `@` character to write a value to the same parameter:

```
command.CommandText = "SELECT VALUE it FROM BooksEntities.Books AS it WHERE " +
                      "it.Publisher = @Publisher";
command.Parameters.AddWithValue("Publisher", "Wrox Press");
```

ENTITIES

Entity classes that are created with the designer and are created by CSDL typically derive from the base class `EntityObject`, as shown with the `Book` class in the code that follows.

The `Book` class derives from the base class `EntityObject` and defines properties for its data such as `Title` and `Publisher`. The set accessors of these properties fire change information in two different ways. One way is by invoking the methods `ReportPropertyChanging()` and `ReportPropertyChanged()` of the base class `EntityObject`. Invoking these methods uses the `INotifyPropertyChanging` and `INotifyPropertyChanged` interfaces to inform every client that registers with the events about these interfaces.

The other way is by using partial methods such as `OnTitleChanging()` and `OnTitleChanged()` that have no implementation by default, but can be implemented in custom extensions of this class. The `Authors` property uses the `RelationshipManager` class to return the `Books` for an author:

```
[EdmEntityTypeAttribute(NamespaceName="BooksModel", Name="Book")]
[Serializable()]
[DataContractAttribute(IsReference=true)]
public partial class Book : EntityObject
{
    public static Book CreateBook(int id, string title, string publisher)
    {
        Book book = new Book();
        book.Id = id;
        book.Title = title;
        book.Publisher = publisher;
        return book;
    }

    [EdmScalarPropertyAttribute(EntityKeyProperty=true, IsNullable=false)]
    [DataMemberAttribute()]
    public int Id
    {
        get
        {
            return _Id;
        }
        set
        {
            if (_Id != value)
            {
                OnIdChanging(value);
                ReportPropertyChanging("Id");
                _Id = StructuralObject.SetValidValue(value);
                ReportPropertyChanged("Id");
                OnIdChanged();
            }
        }
    }
    private int _Id;
    partial void OnIdChanging(int value);
    partial void OnIdChanged();

    [EdmScalarPropertyAttribute(EntityKeyProperty=false, IsNullable=false)]
    [DataMemberAttribute()]
    public string Title
    {
        get
        {
            return _Title;
        }
        set
        {
            OnTitleChanging(value);
            ReportPropertyChanging("Title");
            _Title = StructuralObject.SetValidValue(value, false);
            ReportPropertyChanged("Title");
            OnTitleChanged();
        }
    }
    private string _Title;
    partial void OnTitleChanging(string value);
    partial void OnTitleChanged();

    [EdmScalarPropertyAttribute(EntityKeyProperty=false, IsNullable=false)]
    [DataMemberAttribute()]
    public string Publisher
    {
        get
        {
            return _Publisher;
        }
        set
        {
            OnPublisherChanging(value);
            ReportPropertyChanging("Publisher");
            _Publisher = StructuralObject.SetValidValue(value, false);
            ReportPropertyChanged("Publisher");
            OnPublisherChanged();
        }
    }
    private string _Publisher;
    partial void OnPublisherChanging(string value);
    partial void OnPublisherChanged();

    [EdmScalarPropertyAttribute(EntityKeyProperty=false, IsNullable=true)]
    [DataMemberAttribute()]
    public string Isbn
    {
        get
        {
            return _Isbn;
        }
        set
```

```
                {
                    OnIsbnChanging(value);
                    ReportPropertyChanging("Isbn");
                    _Isbn = StructuralObject.SetValidValue(value, true);
                    ReportPropertyChanged("Isbn");
                    OnIsbnChanged();
                }
            }
            private string _Isbn;
            partial void OnIsbnChanging(string value);
            partial void OnIsbnChanged();

            [XmlIgnoreAttribute()]
            [SoapIgnoreAttribute()]
            [DataMemberAttribute()]
            [EdmRelationshipNavigationPropertyAttribute("BooksModel", "BooksAuthors", "Authors")]
            public EntityCollection<Author> Authors
            {
                get
                {
                    return ((IEntityWithRelationships)this).RelationshipManager.
                             GetRelatedCollection<Author>("BooksModel.BooksAuthors", "Authors");
                }
                set
                {
                    if ((value != null))
                    {
                        ((IEntityWithRelationships)this).RelationshipManager.
                          InitializeRelatedCollection<Author>("BooksModel.BooksAuthors",
                                                                          "Authors", value);
                    }
                }
            }
        }
```

code snippet BooksDemo/BooksModel.Designer.cs

The classes and interfaces important in regard to entity classes are explained in the following table. With the exception of `INotifyPropertyChanging` and `INotifyPropertyChanged`, the types are defined in the namespace `System.Data.Objects.DataClasses`.

CLASS OR INTERFACE	DESCRIPTION
`StructuralObject`	`StructuralObject` is the base class of the classes `EntityObject` and `ComplexObject`. This class implements the interfaces `INotifyPropertyChanging` and `INotifyPropertyChanged`.
`INotifyPropertyChanging` `INotifyPropertyChanged`	These interfaces define the `PropertyChanging` and `PropertyChanged` events to allow subscribing to information when the state of the object changes. Different from the other classes and interfaces here, these interfaces are defined in the namespace `System.ComponentModel`.
`EntityObject`	This class derives from `StructuralObject` and implements the interfaces `IEntityWithKey`, `IEntityWithChangeTracker`, and `IEntityWithRelationships`. `EntityObject` is a commonly used base class for objects mapped to database tables that contain a key and relationships to other objects.
`ComplexObject`	This class can be used as a base class for entity objects that do not have a key. It derives from `StructuralObject` but does not implement other interfaces as the `EntityObject` class does.

CLASS OR INTERFACE	DESCRIPTION
`IEntityWithKey`	This interface defines an `EntityKey` property that allows fast access to the object.
`IEntityWithChangeTracker`	This interface defi nes the method `SetChangeTracker()` where a change tracker that implements the interface `IChangeTracker` can be assigned to get information about state change from the object.
`IEntityWithRelationships`	This interface defines the read-only property `RelationshipManager`, which returns a `RelationshipManager` object that can be used to navigate between objects.

For an entity class, it's not necessary to derive from the base classes `EntityObject` *or* `ComplexObject`. *Instead, an entity class can implement the required interfaces.*

The `Book` entity class can easily be accessed by using the object context class `BooksEntities`. The `Books` property returns a collection of `Book` objects that can be iterated:

```
using (var data = new BooksEntities())
{
    foreach (var book in data.Books)
    {
        Console.WriteLine("{0}, {1}", book.Title, book.Publisher);
    }
}
```

code snippet BooksDemo/Program.cs

OBJECT CONTEXT

To retrieve data from the database, the `ObjectContext` class is needed. This class defines the mapping from the entity objects to the database. With core ADO.NET, you can compare this class to the data adapter that fills a `DataSet`.

The `BooksEntities` class created by the designer derives from the base class `ObjectContext`. This class adds constructors to pass a connection string. With the default constructor, the connection string is read from the configuration file. It is also possible to pass an already opened connection to the constructor in the form of an `EntityConnection` instance. If you pass a connection to the constructor that is not opened, the object context opens and closes the connection; if you pass an opened connection you also need to close it.

The created class defines `Books` and `Authors` properties, which return an `ObjectSet<TEntity>`. `ObjectSet<TEntity>` that is new with .NET 4 and derives from `ObjectQuery<TEntity>`:

```
public partial class BooksEntities : ObjectContext
{
    public BooksEntities() : base("name=BooksEntities", "BooksEntities")
    {
        this.ContextOptions.LazyLoadingEnabled = true;
        OnContextCreated();
    }

    public BooksEntities(string connectionString) : base(connectionString, "BooksEntities")
    {
        this.ContextOptions.LazyLoadingEnabled = true;
        OnContextCreated();
    }
```

```
            public BooksEntities(EntityConnection connection) : base(connection, "BooksEntities")
            {
                this.ContextOptions.LazyLoadingEnabled = true;
                OnContextCreated();
            }

            partial void OnContextCreated();

            public ObjectSet<Author> Authors
            {
                get
                {
                    if ((_Authors == null))
                    {
                        _Authors = base.CreateObjectSet<Author>("Authors");
                    }
                    return _Authors;
                }
            }
            private ObjectSet<Author> _Authors;

            public ObjectSet<Book> Books
            {
                get
                {
                    if ((_Books == null))
                    {
                        _Books = base.CreateObjectSet<Book>("Books");
                    }
                    return _Books;
                }
            }
            private ObjectSet<Book> _Books;
        }
```

code snippet BooksDemo/BooksModel.Designer.cs

The `ObjectContext` class provides several services to the caller:

- ➤ It keeps track of entity objects that are already retrieved. If the object is queried again, it is taken from the object context.
- ➤ It keeps state information about the entities. You can get information about added, modified, and deleted objects.
- ➤ You can update the entities from the object context to write the changes to the underlying store.

Methods and properties of the `ObjectContext` class are listed in the following table.

OBJECTCONTEXT METHODS AND PROPERTIES	DESCRIPTION
`Connection`	Returns a `DbConnection` object that is associated with the object context.
`MetadataWorkspace`	Returns a `MetadataWorkspace` object that can be used to read the metadata and mapping information.
`QueryTimeout`	With this property you can get and set the timeout value for the queries of the object context.
`ObjectStateManager`	This property returns an `ObjectStateManager`. The `ObjectStateManager` keeps track of entity objects retrieved and object changes in the object context.

OBJECTCONTEXT METHODS AND PROPERTIES	DESCRIPTION
`CreateQuery()`	This method returns an `ObjectQuery` to get data from the store. The `Books` and `Authors` properties shown earlier use this method to return an `ObjectQuery`.
`GetObjectByKey()` `TryGetObjectByKey()`	These methods return the object by the key either from the object state manager or the underlying store. `GetObjectByKey()` throws an exception of type `ObjectNotFoundException` if the key does not exist. `TryGetObjectByKey()` returns `false`.
`AddObject()`	This method adds a new entity object to the object context.
`DeleteObject()`	This method deletes an object from the object context.
`Detach()`	This method detaches an entity object from the object context, so it is no longer tracked if changes occur.
`Attach()` `AttachTo()`	The `Attach()` method attaches a detached object to the store. Attaching objects back to the object context requires that the entity object implements the interface `IEntityWithKey`. The `AttachTo()` method does not have the requirement for a key with the object, but it requires the entity set name where the entity object needs to be attached.
`ApplyPropertyChanges()`	If an object was detached from the object context, then the detached object is modified, and afterward the changes should be applied to the object within the object context, you can invoke the `ApplyPropertyChanges()` method to apply the changes. This is useful in a scenario where a detached object was returned from a Web service, changed from a client, and passed to the Web service in a modified way.
`Refresh()`	The data in the store can change while entity objects are stored inside the object context. To make a refresh from the store, the `Refresh()` method can be used. With this method you can pass a `RefreshMode` enumeration value. If the values for the objects are not the same between the store and the object context, passing the value `ClientWins` changes the data in the store. The value `StoreWins` changes the data in the object context.
`SaveChanges()`	Adding, modifying, and deleting objects from the object context does not change the object from the underlying store. Use the `SaveChanges()` method to persist the changes to the store.
`AcceptAllChanges()`	This method changes the state of the objects in the context to unmodified. `SaveChanges()` invokes this method implicitly.

RELATIONSHIPS

The entity types `Book` and `Author` are related to each other. A book is written by one or more authors, and an author can write one or more books. Relationships are based on the count of types they relate and the multiplicity. The ADO.NET Entity Framework supports several kinds of relationships, some of which are shown here, including Table-per-Hierarchy (TPH) and Table-per-Type (TPT). Multiplicity can be one-to-one, one-to-many, or many-to-many.

Table per Hierarchy

With TPH, there's one table in the database that corresponds to a hierarchy of entity classes. The database table `Payments` (see Figure 31-3) contains columns for a hierarchy of entity types. Some of the columns are common to all entities in the hierarchy, such as `Id` and `Amount`. The `CreditCardNumber` column is only used by a credit card payment.

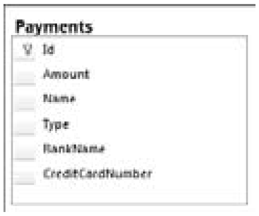

FIGURE 31-3

The entity classes that all map to the same `Payments` table are shown in Figure 31-4. `Payment` is an abstract base class to contain properties common for all types in the hierarchy. Concrete classes that derive from `Payment` are `CreditCardPayment`, `CashPayment`, and `ChequePayment`. `CreditCardPayment` has a `CreditCard` property in addition to the properties of the base class; `ChequePayment` has a `BankName` property.

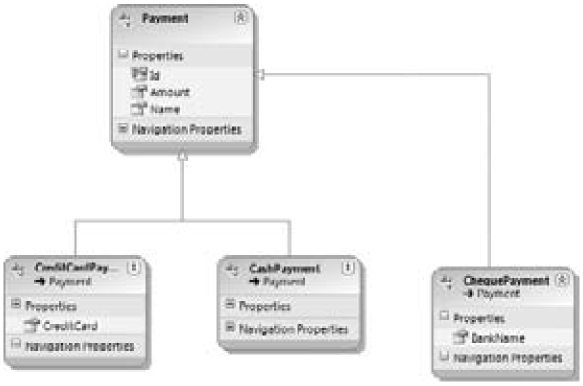

FIGURE 31-4

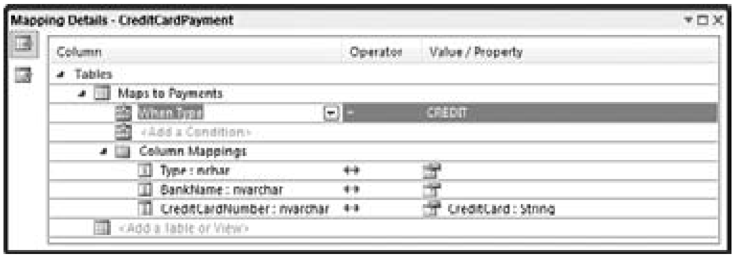
All this mapping can be defined with the designer. The mapping details can be configured with the Mapping Details window as shown in Figure 31-5. The selection of the type of the concrete class is done based on a `Condition` element as defined with the Maps to Payments When Type = CREDIT. The type is selected based on the value of the `Type` column. Other options to select the type are also possible; for example, you can verify if a column is not null.



Mapping Details - CreditCardPayment

Column	Operator	Value / Property
Tables		
Maps to Payments		
When Type	=	CREDIT
<Add a Condition>		
Column Mappings		
Type : nchar	↔	
BankName : nvarchar	↔	
CreditCardNumber : nvarchar	↔	CreditCard : String
<Add a Table or View>		

FIGURE 31-5

Now it's possible to iterate the data from the `Payments` table, and different types are returned based on the mapping:

```
using (var data = new PaymentsEntities())
{
    foreach (var p in data.Payments)
    {
        Console.WriteLine("{0}, {1} - {2:C}", p.GetType().Name, p.Name, p.Amount);
    }
}
```

code snippet PaymentsDemo/Program.cs

Running the application returns two `CashPayment` and one `CreditCardPayment` objects from the database:

```
CreditCardPayment, Gladstone - $22.00
CashPayment, Donald - $0.50
CashPayment, Scrooge - $80,000.00
```

Table per Type

With TPT, one table maps to one type. The Northwind database has a schema with the tables `Customers`, `Orders`, and `Order Details`. The `Orders` table has a relation with the `Customers` table with the foreign key `CustomerId`; the `Order Details` relates to the `Orders` table with the foreign key `OrderID`.

Figure 31-6 shows the entity types `Customer`, `Order`, and `Order_Detail`. `Customer` and `Order` have a zero or one-to-many relationship; `Order` to `Order_Detail` has a one-to-many relationship. There is a zero or one-to-many relationship with `Customer` and `Order` because the `CustomerID` with the `Order` table is defined as `Nullable` in the database schema.

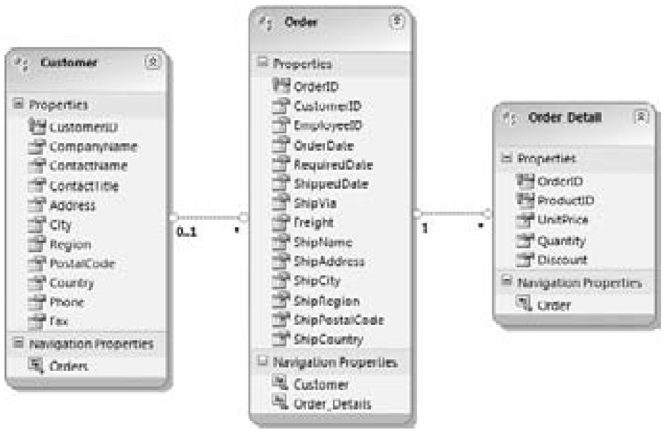


FIGURE 31-6

You access the customers and their orders with two iterations shown here. First the `Customer` objects are accessed, and the value of the `CompanyName` property is written to the console. Then all orders are accessed by using the `Orders` property of the `Customer` class. The related orders are lazy loaded to access the property because with the `ObjectContext` the `ContextOptions.LazyLoadingEnabled` property is set to `true`:

```
using (var data = new NorthwindEntities())
{
    foreach (Customer customer in data.Customers)
    {
        Console.WriteLine("{0}", customer.CompanyName);

        foreach (Order order in customer.Orders)
        {
            Console.WriteLine("\t{0} {1:d}", order.OrderID, order.OrderDate);
        }
    }
}
```

code snippet NorthwindDemo/Program.cs

Behind the scenes, the `RelationshipManager` class is used to access the relationship. The `RelationShipManager` instance can be accessed by casting the entity object to the interface `IEntityWithRelationships` as you can see in the designer-generated property `Orders` from the class `Customer`. This interface is explicitly implemented by the class `EntityObject`. The `RelationshipManager` property returns a `RelationshipManager` that is associated with the entity object at one end. The other end is defined by invoking the method `GetRelatedCollection()`. The first parameter `NorthwindModel.FK_Orders_Customers` is the name of the relationship: the second parameter `Orders` defines the name of the target role:

```
public EntityCollection<Order> Orders
{
    get
    {
        return ((IEntityWithRelationships)this).RelationshipManager.
            GetRelatedCollection<Order>("NorthwindModel.FK_Orders_Customers",
                                                  "Orders");
    }
    set
```

```
            {
                if ((value != null))
                {
                    ((IEntityWithRelationships)this).RelationshipManager.
                        InitializeRelatedCollection<Order>(
                            "NorthwindModel.FK_Orders_Customers", "Orders", value);
                }
            }
        }
```

code snippet NorthwindDemo/NorthwindModel.Designer.cs

Lazy, Delayed, and Eager Loading

By default, relationships are lazy loaded on request when the property `LazyLoadingEnabled` from the `ContextOptions` is set to `true`. You have other options as well. Relationships can also be *eager loaded* or *delayed loaded*.

Eager loading means that the relationship is loaded at the same time the parent objects are loaded. The orders are loaded immediately after adding a call to the `Include()` method. It passes the relationship name with `ObjectSet<TEntity>`, as shown with the `Customers` property:

```
foreach (Customer customer in data.Customers.Include("Orders"))
{
    Console.WriteLine("{0}", customer.CompanyName);

    foreach (Order order in customer.Orders)
    {
        Console.WriteLine("\t{0} {1:d}", order.OrderID, order.OrderDate);
    }
}
```

Eager loading has the advantage that if all related objects are needed, then fewer requests to the database are done. Of course, if not all related objects are needed, lazy or delayed loading is preferred.

Delayed loading needs an explicit call to the `Load()` method of the `EntityCollection<T>` class. Using this method, the option `LazyLoadingEnabled` can be set to `false`. With the following code snippet, the orders are loaded with the `Load()` method if they are not loaded with the `IsLoaded` property:

```
    if (!customer.Orders.IsLoaded)
        customer.Orders.Load();
```

One overload of the `Load()` method accepts a `MergeOption` enumeration. The possible values are explained in the following table.

MERGEOPTION VALUE	DESCRIPTION
`AppendOnly`	This is the default value. New entities are appended; existing entities in the object context are not modified.
`NoTracking`	The `ObjectStateManager` that tracks changes to entity objects is not modified.
`OverwriteChanges`	The current values of the entity objects are replaced with the values from the store.
`PreserveChanges`	The original values of the entity objects in the object context are replaced with the values from the store.

OBJECT QUERY

Querying objects is one of the services offered by the ADO.NET Entity Framework. Queries can be done using LINQ to Entities, Entity SQL, and Query Builder methods that create Entity SQL. LINQ to Entities is covered in the last section of this chapter; let's get into the other two options first.

The following sections of this book make use of a Formula1 database where you can see the entities created from the designer in Figure 31-7.

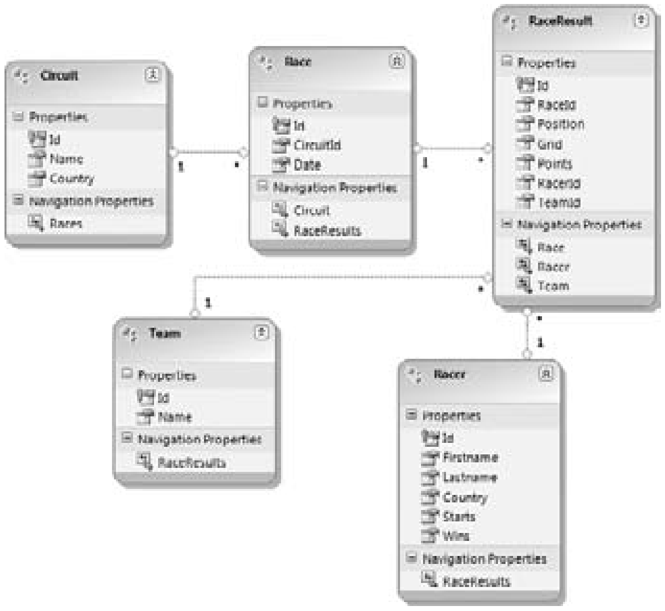

FIGURE 31-7

Queries can be defined with the `ObjectQuery<T>` class, or the class that derives from it: `ObjectSet<T>`. Let's start with a simple query to access all `Racer` entities. The `Racers` property of the generated `Formula1Entities` class returns a `ObjectSet<Racer>`:

```
using (Formula1Entities data = new Formula1Entities(connection))
{
   ObjectSet<Racer> racers = data.Racers;
   Console.WriteLine(racers.CommandText);
   Console.WriteLine(racers.ToTraceString());
}
```

code snippet Formula1Demo/Program.cs

The Entity SQL statement that is returned from the `CommandText` property is shown here:

```
[Formula1Entities].[Racers]
```

And this is the generated `SELECT` statement to retrieve the records from the database that is shown by the `ToTraceString()` method:

```
SELECT
[Extent1].[Id] AS [Id],
[Extent1].[Firstname] AS [Firstname],
[Extent1].[Lastname] AS [Lastname],
[Extent1].[Country] AS [Country],
[Extent1].[Starts] AS [Starts],
[Extent1].[Wins] AS [Wins]
FROM [dbo].[Racers] AS [Extent1]
```

Instead of accessing the `Racers` property from the object context, you can also create a query with the `CreateQuery()` method:

```
ObjectQuery<Racer> racers = data.CreateQuery<Racer>("[Formula1Entities].[Racers]");
```

This is similar to using the `Racers` property.

Now it would be interesting to filter the racers based on a condition. This can be done by using the `Where()` method of the `ObjectQuery<T>` class. `Where()` is one of the Query Builder methods that create Entity SQL. This method requires a predicate as a string, and optional parameters of type `ObjectParameter`. The predicate shown here specifies that only the racers from Brazil are returned. The `it` specifies the item of the result and Country is the column `Country`. The first parameter of the `ObjectParameter` constructor references the `@Country` parameter of the predicate, but doesn't list the `@` sign:

```
            string country = "Brazil";
            ObjectQuery<Racer> racers = data.Racers.Where("it.Country = @Country",
                  new ObjectParameter("Country", country));
```

The magic behind `it` can be seen immediately by accessing the `CommandText` property of the query. With Entity SQL, `SELECT VALUE it` declares `it` to access the columns:

```
SELECT VALUE it
FROM (
[Formula1Entities].[Racers]
) AS it
WHERE
it.Country = @Country
```

The method `ToTraceString()` shows the generated SQL statement:

```
SELECT
[Extent1].[Id] AS [Id],
[Extent1].[Firstname] AS [Firstname],
[Extent1].[Lastname] AS [Lastname],
[Extent1].[Country] AS [Country],
[Extent1].[Starts] AS [Starts],
[Extent1].[Wins] AS [Wins]
FROM [dbo].[Racers] AS [Extent1]
WHERE [Extent1].[Country] = @Country
```

Of course, you can also specify the complete Entity SQL:

```
            string country = "Brazil";
            ObjectQuery<Racer> racers = data.CreateQuery<Racer>(
               "SELECT VALUE it FROM ([Formula1Entities].[Racers]) AS " +
               "it WHERE it.Country = @Country",
               new ObjectParameter("Country", country));
```

The class `ObjectQuery<T>` offers several Query Builder methods as explained in the following table. Many of these methods are very similar to the LINQ extension methods that you learned about in Chapter 11, "Language Integrated Query." An important difference with the methods here is that instead of parameters of type delegate or `Expression<T>`, the parameter type with `ObjectQuery<T>` is usually of type `string`.

OBJECTQUERY<T> QUERY BUILDER METHODS	DESCRIPTION
`Where()`	This method allows you to filter the results based on a condition.
`Distinct()`	This method creates a query with unique results.
`Except()`	This method returns the result without the items that meet the condition with the `except` filter.
`GroupBy()`	This method creates a new query to group entities based on a specified criteria.
`Include()`	With relations, you saw earlier that related items are delay loaded. It is required to invoke the `Load()` method of the `EntityCollection<T>` class to get related entities into the object context. Instead of using the `Load()` method, you can specify a query with the `Include()` method to eager fetch-related entities.

OBJECTQUERY<T> QUERY BUILDER METHODS	DESCRIPTION
`OfType()`	This method specifies to return only those entities of a specific type. This is very helpful with TPH relations.
`OrderBy()`	This method is for defining the sort order of the entities.
`Select() SelectValue()`	These methods return a projection of the results. `Select()` returns the result items in the form of a `DbDataRecord`; `SelectValue()` returns the values as scalars or complex types as defined by the generic parameter `TResultType`.
`Skip() Top()`	These methods are useful for paging. Skip a number of items with the `Skip()` method and take a specified number as defined by the `Top()` method.
`Intersect() Union() UnionAll()`	These methods are used to combine two queries. `Intersect()` returns a query containing only the results that are available in both of the queries. `Union()` combines the queries and returns the complete result without duplicates. `UnionAll()` also includes duplicates.

Let's get into one example on how to use these Query Builder methods. With the next code snippet, the racers are filtered with the `Where()` method to return only racers from the USA; the `OrderBy()` method specifies descending sort order first based on the number of wins and next on the number of starts. Finally, only the first three racers are in the result using the `Top()` method:

```
using (var data = new Formula1Entities())
{
    string country = "USA";
    ObjectQuery<Racer> racers = data.Racers.Where("it.Country = @Country",
       new ObjectParameter("Country", country))
       .OrderBy("it.Wins DESC, it.Starts DESC")
       .Top("3");
    foreach (var racer in racers)
    {
        Console.WriteLine("{0} {1}, wins: {2}, starts: {3}",
              racer.Firstname, racer.Lastname, racer.Wins, racer.Starts);
    }
}
```

code snippet Formula1Demo/Program.cs

This is the result from this query:

```
Mario Andretti, wins: 12, starts: 128
Dan Gurney, wins: 4, starts: 87
Phil Hill, wins: 3, starts: 48
```

UPDATES

Reading, searching, and filtering data from the store are just one part of the work that usually needs to be done with data-intensive applications. Writing changed data back to the store is the other part you need to know.

The sections that follow cover these topics:

- ➤ Object tracking
- ➤ Change information
- ➤ Attaching and detaching entities
- ➤ Storing entity changes

Object Tracking

To allow data read from the store to be modified and saved, the entities must be tracked after they are loaded. This also requires that the object context be aware if an entity has already been loaded from the store. If multiple queries are accessing the same records, the object context needs to return already loaded entities.

The `ObjectStateManager` is used by the object context to keep track of entities that are loaded into the context.

The following example demonstrates that indeed if two different queries are done that return the same record from the database, the state manager is aware of that and does not create a new entity. Instead, the same entity is returned. The `ObjectStateManager` instance that is associated with the object context can be accessed with the `ObjectStateManager` property. The `ObjectStateManager` class defines an event named `ObjectStateManagerChanged` that is invoked every time a new object is added or removed from the object context. Here, the method `ObjectStateManager_ObjectStateManagerChanged` is assigned to the event to get information about changes.

Two different queries are used to return an entity object. The first query gets the first racer from the country Austria with the last name Lauda. The second query asks for the racers from Austria, sorts the racers by the number of races won, and gets the first result. As a matter of fact, that's the same racer. To verify that the same entity object is returned, the method `Object.ReferenceEquals()` is used to verify whether the two object references indeed reference the same instance:

```
  private static void TrackingDemo()
  {
      using (var data = new Formula1Entities())
      {
          data.ObjectStateManager.ObjectStateManagerChanged +=
              ObjectStateManager_ObjectStateManagerChanged;
          Racer niki1 = data.Racers.Where("it.Country='Austria' && it.Lastname='Lauda'").
                            First();
          Racer niki2 = data.Racers.Where("it.Country='Austria'").
                 OrderBy("it.Wins DESC").First();
          if (Object.ReferenceEquals(niki1, niki2))
          {
              Console.WriteLine("the same object");
          }
      }
  }

static void ObjectStateManager_ObjectStateManagerChanged(object sender,
      CollectionChangeEventArgs e)
{
   Console.WriteLine("Object State change — action: {0}", e.Action);
   Racer r = e.Element as Racer;
   if (r != null)
      Console.WriteLine("Racer {0}", r.Lastname);
}
```

code snippet Formula1Demo/Program.cs

Running the application, you can see that the event of the `ObjectStateManagerChanged` of the `ObjectStateManager` occurs only once, and the references niki1 and niki2 are indeed the same:

```
Object State change — action: Add
Racer Lauda
The same object
```

Change Information

The object context is also aware of changes with the entities. The following example adds and modifies a racer from the object context and gets information about the change. First, a new racer is added with the `AddObject()` method of the `ObjectSet<T>` class. This method adds a new entity with the `EntityState.Added` information. Next, a racer with the `Lastname` Alonso is queried. With this entity class, the `Starts` property is incremented and thus the entity is marked with the information `EntityState.Modified`. Behind the scenes, the `ObjectStateManager` is informed about a state change in the object based on the interface implementations `INotifyPropertyChanged`. This interface is implemented in the entity base class `StructuralObject`. The `ObjectStateManager` is attached to the `PropertyChanged` event, and this event is fired with every property change.

To get all added or modified entity objects, you can invoke the `GetObjectStateEntries()` method of the `ObjectStateManager` and pass an `EntityState` enumeration value as it is done here. This method returns a collection of `ObjectStateEntry` objects that keeps information about the entities. The helper method `DisplayState` iterates through this collection to give detail information.

You can also get state information about a single entity passing the `EntityKey` to the `GetObjectStateEntry()` method. The `EntityKey` property is available with entity objects implementing the interface `IEntityWithKey`, which is the case with the base class `EntityObject`. The `ObjectStateEntry` object returned offers the method `GetModifiedProperties()` where you can read all property values that have been changed, and also access the original and the current information about the properties with the `OriginalValues` and `CurrentValues` indexers:

```
private static void ChangeInformation()
{
    using (var data = new Formula1Entities())
    {
        var jaime = new Racer
        {
            Firstname = "Jaime",
            Lastname = "Alguersuari",
            Country = "Spain",
            Starts = 0
        };
        data.Racers.AddObject(jaime);
        Racer fernando = data.Racers.Where("it.Lastname='Alonso'").First();
        fernando.Starts++;
        DisplayState(EntityState.Added.ToString(),
            data.ObjectStateManager.GetObjectStateEntries(EntityState.Added));
        DisplayState(EntityState.Modified.ToString(),
              data.ObjectStateManager.GetObjectStateEntries(EntityState.Modified));
        ObjectStateEntry stateOfFernando =
              data.ObjectStateManager.GetObjectStateEntry(fernando.EntityKey);
        Console.WriteLine("state of Fernando: {0}",
              stateOfFernando.State.ToString());
        foreach (string modifiedProp in stateOfFernando.GetModifiedProperties())
        {
            Console.WriteLine("modified: {0}", modifiedProp);
            Console.WriteLine("original: {0}",
                                  stateOfFernando.OriginalValues[modifiedProp]);
            Console.WriteLine("current: {0}",
                                  stateOfFernando.CurrentValues[modifiedProp]);
        }
    }
}
static void DisplayState(string state, IEnumerable<ObjectStateEntry> entries)
{
    foreach (var entry in entries)
    {
```

```
                var r = entry.Entity as Racer;
                if (r != null)
                {
                    Console.WriteLine("{0}: {1}", state, r.Lastname);
                }
            }
        }
```

code snippet Formula1Demo/Program.cs

When you run the application, the added and modified racers are displayed, and the properties changed with their original and current values are shown:

```
Added: Alguersuari
Modified: Alonso
state of Fernando: Modified
modified: Starts
original: 138
current: 139
```

Attaching and Detaching Entities

When returning entity data to the caller, it might be important to detach the objects from the object context. This is necessary, for example, if an entity object is returned from a Web service. Here, if the entity object is changed on the client, the object context is not aware of the change.

With the sample code, the `Detach()` method of the `ObjectContext` detaches the entity named `fernando` and thus the object context is not aware of any change done on this entity. If a changed entity object is passed from the client application to the service, it can be attached again. Just attaching it to the object context might not be enough because it doesn't give the information that the object was modified. Instead, the original object must be available inside the object context. The original object can be accessed from the store by using the key with the method `GetObjectByKey()` or `TryGetObjectByKey()`. If the entity object is already inside the object context, the existing one is used; otherwise it is fetched newly from the database. Invoking the method `ApplyCurrentValues()` passes the modified entity object to the object context, and if there are changes, then the changes are done within the existing entity with the same key inside the object context, and the `EntityState` is set to `EntityState.Modified`. Remember that the method `ApplyCurrentValues()` requires the object to exist within the object context; otherwise the new entity object is added with `EntityState.Added`:

```
using (var data = new Formula1Entities())
{
    data.ObjectStateManager.ObjectStateManagerChanged +=
          ObjectStateManager_ObjectStateManagerChanged;
    ObjectQuery<Racer> racers = data.Racers.Where("it.Lastname='Alonso'");
    Racer fernando = racers.First();
    EntityKey key = fernando.EntityKey;
    data.Racers.Detach(fernando);

    // Racer is now detached and can be changed independent of the object context
    fernando.Starts++;
    Racer originalObject = data.GetObjectByKey(key) as Racer;
    data.Racers.ApplyCurrentValues(fernando);
}
```

code snippet Formula1Demo/Program.cs

Storing Entity Changes

Based on all the change information with the help of the `ObjectStateManager`, the added, deleted, and modified entity objects can be written to the store with the `SaveChanges()` method of the `ObjectContext` class. To verify changes within the object context, you can assign a handler method to the `SavingChanges` event of the ObjectContext class. This event is fired before the data is written to the store, so you can add some verification logic to see if the changes should be really done. SaveChanges() returns the number of entity objects that have been written.

What happens if the records in the database that are represented by the entity classes have been changed after reading the record? The answer depends on the ConcurrencyMode property that is set with the model. With every property of an entity object, you can configure the ConcurrencyMode to Fixed or None. The value Fixed means that the property is validated at write time to determine if the value was not changed in the meantime. None — which is the default — ignores any change. If some properties are configured to the Fixed mode, and data changed between reading and writing the entity objects, an OptimisticConcurrencyException occurs.

You can deal with this exception by invoking the Refresh() method to read the actual information from the database into the object context. This method accepts two refresh modes configured by a RefreshMode enumeration value: ClientWins or StoreWins. StoreWins means that the actual information is taken from the database and set to the current values of the entity objects. ClientWins means that the database information is set to the original values of the entity objects, and thus the database values will be overwritten with the next SaveChanges. The second parameter of the Refresh() method is either a collection of entity objects or a single entity object. You can decide the refresh behavior entity by entity:

```
private static void ChangeInformation()
{
    //...

        int changes = 0;
        try
        {
            changes += data.SaveChanges();
        }
        catch (OptimisticConcurrencyException ex)
        {
            data.Refresh(RefreshMode.ClientWins, ex.StateEntries);
            changes += data.SaveChanges();
        }
        Console.WriteLine("{0} entities changed", changes);
        //...
```

code snippet Formula1Demo/Program.cs

LINQ TO ENTITIES

In several chapters of this book, you've seen LINQ to Query objects, databases, and XML. Of course, LINQ is also available to query entities.

With LINQ to Entities, the source for the LINQ query is ObjectQuery<T>. Because ObjectQuery<T> implements the interface IQueryable, the extension methods selected for the query are defined with the class Queryable from the namespace System.Linq. The extension methods defined with this class have a parameter Expression<T>; that's why the compiler writes an expression tree to the assembly. You can read more about expression trees in Chapter 11. The expression tree is then resolved from the ObjectQuery<T> class to the SQL query.

You can use a simple LINQ query as shown here to return the racers that won more than 40 races:

```
using (var data = new Formula1Entities())
{
    var racers = from r in data.Racers
                 where r.Wins > 40
                 orderby r.Wins descending
                 select r;
```

```
            foreach (Racer r in racers)
            {
                Console.WriteLine("{0} {1}", r.Firstname, r.Lastname);
            }
        }
```

code snippet Formula1Demo/Program.cs

This is the result of accessing the Formula1 database:

```
Michael Schumacher
Alain Prost
Ayrton Senna
```

You can also define a LINQ query to access relations as shown here. Variable `r` references racers, variable `rr` references all race results. The filter is defined with the `where` clause to retrieve only racers from Switzerland who had a race position on the podium. To get the podium finishes, the result is grouped, and the podium count calculated. Sorting is done based on the podium finishes:

```
        using (var data = new Formula1Entities())
        {
            var query = from r in data.Racers
                        from rr in r.RaceResults
                        where rr.Position <= 3 && rr.Position >= 1 &&
                              r.Country == "Switzerland"
                        group r by r.Id into g
                        let podium = g.Count()
                        orderby podium descending
                        select new
                        {
                            Racer = g.FirstOrDefault(),
                            Podiums = podium
                        };
            foreach (var r in query)
            {
                Console.WriteLine("{0} {1} {2}", r.Racer.Firstname, r.Racer.Lastname,
                                  r.Podiums);
            }
        }
```

The names of three racers from Switzerland are returned when you run the application:

```
Clay Regazzoni 28
Jo Siffert 6
Rudi Fischer 2
```

SUMMARY

In this chapter, you've seen the features of the ADO.NET Entity Framework. The ADO.NET Entity Framework is based on mapping that is defined by CSDL, MSL, and SSDL — XML information that describes the entities, the mapping, and the database schema. Using this mapping technique, you can create different relation types to map entity classes to database tables.

You've seen how the object context keeps knowledge about entities retrieved and updated, and how the changes can be written to the store.

LINQ to Entities is just a facet of the ADO.NET Entity Framework that allows you to use the new query syntax to access entities.

32

Data Services

WHAT'S IN THIS CHAPTER?

- ➤ Overview of WCF Data Services
- ➤ WCF Data Services hosting with CLR objects
- ➤ HTTP client access to WCF Data Services
- ➤ URL queries to WCF Data Services
- ➤ WCF Data Services with the ADO.NET Entity Framework
- ➤ Using the WCF Data Services .NET Client Provider
- ➤ Tracking, Updates, and Batching

In the previous chapter you saw the ADO.NET Entity Framework used to easily create an object model to map to the database structures. The Entity Framework does not provide a way to get the objects across different tiers. This is where WCF Data Services come into play. WCF Data Services offers a WCF service to easily access data provided by an Entity Data Model or by simple CLR objects implementing the `IQueryable<T>` interface.

OVERVIEW

The ADO.NET Entity Framework offers mapping and creates entity classes representing databases. With the data context from the Entity Framework, the data context stays informed about changes to data so that it knows what should be updated. The Entity Framework does not help when creating solutions over multiple tiers.

Using WCF Data Services, you can use the Entity Framework (or a simple CLR object model) on the server side and send HTTP queries from the client to the service to retrieve and to update data. Figure 32-1 shows a typical scenario with a Windows client or a Web page using HTML and JavaScript to send an HTTP request to the server.

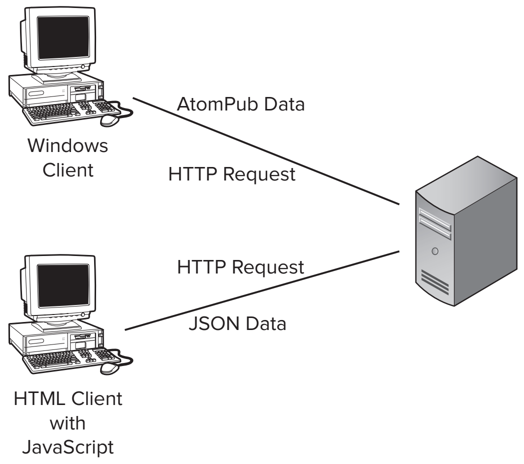

FIGURE 32-1

The returned information can be in AtomPub or JSON format. AtomPub is the Atom Publisher format based on XML. JSON (JavaScript Object Notation) is best accessed from JavaScript clients.

WCF Data Services makes use of WCF (Windows Communication Foundation) for the communication part and uses the `WebHttpBinding`.

For more information about the Atom protocol you can read Chapter 47, "Syndication." Chapter 43, "Windows Communication Foundation," provides details about WCF.

With WCF Data Services you not only get features on the server and the capability to use HTTP Web requests with AtomPub or JSON, there's also a client-side part of WCF Data Services. For the client, there's a data service context and the possibility to create queries that are transformed in the AtomPub or JSON format. While the HTTP protocol is stateless, the data service context for the client is stateful. With this context the client can remember what entities are changed, added, or removed, and send a request with all the change information to the service.

Let's get into the details of WCF Data Services first by creating a simple service that is accessed from a client using HTTP Web requests.

CUSTOM HOSTING WITH CLR OBJECTS

The heart of WCF Data Services is the `DataService<T>` class that is the implementation of a WCF service. `DataService<T>` implements the interface `IRequestHandler` that is defined as follows. The attribute `WebInvoke` is specified to accept any URI parameters and any HTTP methods. With the parameter and return type, the method `ProcessRequestForMessage()` is very flexible. It accepts any stream and returns a `Message`. This is a requirement for the flexibility of data supported.

```
 [ServiceContract]
public interface IRequestHandler
{
   [OperationContract]
   [WebInvoke(UriTemplate="*", Method="*")]
   Message ProcessRequestForMessage(Stream messageBody);
}
```

The WCF attributes `ServiceContract`, `OperationContract`, *and* `WebInvoke` *are explained in Chapter 43.*

The .NET 4 version of WCF Data Services supports the AtomPub and JSON formats for sending and receiving requests. Let's start with a simple example by using a console application to host a service that offers a list of CLR objects. This service will then be used from a client application that directly sends HTTP requests to retrieve the data.

CLR Objects

The sample defines two entity classes: `Category` and `Menu`. These classes are simple data holders. The `Menu` contains `Name`, `Price`, and a reference to `Category`. To make the different instances uniquely identifiable by Data Services, the attribute `DataServiceKey` must be added to reference the unique identifier. This attribute is defined in the namespace `System.Data.Services.Common`. Instead of defining a single property as the identity, it is also possible to assign a list of properties for unique identification.

```
    [DataServiceKey("Id")]
    public class Category
    {
        public int Id { get; set; }
        public string Name { get; set; }

        public Category() { }
        public Category(int id, string name)
        {
            this.Id = id;
            this.Name = name;
        }
    }
```

code snippet DataServicesHost/Category.cs

```
    [DataServiceKey("Id")]
    public class Menu
    {
        public int Id { get; set; }
        public string Name { get; set; }
        public decimal Price { get; set; }
        public Category Category { get; set; }

        public Menu() { }
        public Menu(int id, string name, decimal price, Category category)
        {
            this.Id = id;
            this.Name = name;
            this.Price = price;
            this.Category = category;
        }
    }
```

code snippet DataServicesHost/Menu.cs

The class `MenuCard` manages the collections of `Menu` and `Category` items. It contains a list of `Menu` and `Category` items that can be iterated from the public `Menus` and `Categories` properties. This class implements a singleton pattern, so only one list of each exists.

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Text;

namespace Wrox.ProCSharp.DataServices
{
    public class MenuCard
    {
        private static object sync = new object();
        private static MenuCard menuCard;
        public static MenuCard Instance
        {
            get
            {
                lock (sync)
                {
                    if (menuCard == null)
                        menuCard = new MenuCard();
                }
                return menuCard;
            }
            }

            private List<Category> categories;
            private List<Menu> menus;

            private MenuCard()
            {
                categories = new List<Category>
                {
                    new Category(1, "Main"),
                    new Category(2, "Appetizer")
                };

                menus = new List<Menu>() {
                    new Menu(1, "Roasted Chicken", 22, categories[0]),
                    new Menu(2, "Rack of Lamb", 32, categories[0]),
                    new Menu(3, "Pork Tenderloin", 23, categories[0]),
                    new Menu(4, "Fried Calamari", 9, categories[1])
                };
            }

            public IEnumerable<Menu> Menus
            {
                get
                {
                    return menus;
                }
            }

            public IEnumerable<Category> Categories
            {
                get
                {
                    return categories;
                }
            }
        }
    }
```

code snippet DataServicesHost/MenuCard.cs

Data Model

Now it gets really interesting with the class `MenuCardDataModel`. This class defines what entities are offered from the data service by specifying properties that return `IQueryable<T>`. `IQueryable<T>` is used by the `DataService<T>` class to pass expressions for querying in object lists.

```
        public class MenuCardDataModel
        {
            public IQueryable<Menu> Menus
            {
                get
                {
                    return MenuCard.Instance.Menus.AsQueryable();
                }
            }

            public IQueryable<Category> Categories
            {
                get
                {
```

```
                return MenuCard.Instance.Categories.AsQueryable();
            }
        }
    }
```

code snippet DataServicesHost/MenuCardDataModel.cs

Data Service

The implementation of the data service `MenuDataService` derives from the base class `DataService<T>`. The generic parameter of the `DataService<T>` class is the class `MenuCardDataModel`, with the `Menus` and `Categories` properties returning `IQueryable<T>`.

In the `IntializeService()` method, you need to configure the entity and service operations access rules by using the `DataServiceConfiguration` class. You can pass `*` for the entity and operations access rules to allow access to every entity and operation. With the enumerations `EntitySetRights` and `ServiceOperationsRights`, you can specify if read and/or write access should be enabled. The `MaxProtocolVersion` property of the `DataServiceBehavior` defines what version of the AtomPub protocol should be supported. Version 2 is supported with .NET 4 and supports some additional features such as getting the number of items from a list.

```
using System.Data.Services;
using System.Data.Services.Common;
using System.Linq;
using System.ServiceModel.Web;

namespace Wrox.ProCSharp.DataServices
{
    public class MenuDataService : DataService<MenuCardDataModel>
    {
        public static void InitializeService(DataServiceConfiguration config)
        {
            config.SetEntitySetAccessRule("Menus", EntitySetRights.All);
            config.SetEntitySetAccessRule("Categories", EntitySetRights.All);
            config.SetServiceOperationAccessRule("*", ServiceOperationRights.All);

            config.DataServiceBehavior.MaxProtocolVersion = DataServiceProtocolVersion.V2;
        }
    }
}
```

code snippet DataServicesHost/MenuDataService.cs

Hosting the Service

Finally, you need a process to host the application. Later in this chapter, a Web application is used for hosting. You can also host the service in any application type that's supported by WCF; this can be a simple console application or Windows Service. This sample uses a console application that you easily can change to any other hosting type.

In the `Main()` method of the console application, a `DataServiceHost` is instantiated. `DataServiceHost` derives from the base class `ServiceHost` to offer WCF functionality. You can also use the `DataServiceHostFactory` for creating the `DataServiceHost`. Calling the `Open()` method, `DataServiceHost` instantiates an instance from the `MenuDataService` class for offering the service functionality. The address of the service is defined with `http://localhost:9000/Samples`.

```
using System;
using System.Data.Services;

namespace Wrox.ProCSharp.DataServices
```

```
    {
        class Program
        {
            static void Main()
            {
                DataServiceHost host = new DataServiceHost(typeof(MenuDataService),
                        new Uri[] { new Uri("http://localhost:9000/Samples ") });

                host.Open();

                Console.WriteLine("service running");
                Console.WriteLine("Press return to exit");
                Console.ReadLine();

                host.Close();
            }
        }
    }
```

code snippet DataServicesHost/Program.cs

Now you can start the executable and request the service with the links `http://localhost:9000/Samples/Menus` and `http://localhost:9000/Samples/Categories` from within Internet Explorer. To use Internet Explorer to see the data returned from the service, you need to deselect the option "Turn on feed reading view."

Additional Service Operations

Instead of offering just the properties from the data model, you can add additional service operations to the data service. In the sample code, you can see the method `GetMenusByName()`, which gets a request parameter from the client and returns all menus starting with the requested string with an `IQueryable<Menu>` collection. Such operations need to be added to the service operation access rules in the `InitalizeService()` method in case you do not offer all service operations using the `*`.

```
public class MenuDataService : DataService<MenuCardDataModel>
{
    public static void InitializeService(DataServiceConfiguration config)
    {
        config.SetEntitySetAccessRule("Menus", EntitySetRights.All);
        config.SetEntitySetAccessRule("Categories", EntitySetRights.All);
        config.SetServiceOperationAccessRule("GetMenusByName",
                                             ServiceOperationRights.All);

        config.DataServiceBehavior.MaxProtocolVersion = DataServiceProtocolVersion.V2;
    }

    [WebGet(UriTemplate="GetMenusByName?name={name}",
            BodyStyle=WebMessageBodyStyle.Bare)]
    public IQueryable<Menu> GetMenusByName(string name)
    {
        return (from m in CurrentDataSource.Menus
                where m.Name.StartsWith(name)
                select m).AsQueryable();
    }
}
```

code snippet DataServicesHost/MenuDataService.cs

HTTP CLIENT APPLICATION

The client application can be a simple application to just send HTTP requests to the service and receive AtomPub or JSON responses. The first client application example is a WPF application that makes use of the `HttpWebRequest` class from the `System.Net` namespace.

Figure 32-2 shows the UI from the Visual Studio Designer. A `TextBox` named `textUrl` is used to enter the HTTP request with a default value of `http://localhost:9000/Samples/Menus`. The read-only `TextBox` named `textReturn` receives the answer from the service. You can also see a `CheckBox` `checkJSON`, where the response can be requested in the JSON format. The `Button` with the content Call Data Service has the `Click` event associated to the `OnRequest()` method.

In the implementation of the `OnRequest()` handler, an `HttpWebRequest` object is created with the `WebRequest.Create()` factory method. The HTTP request that is sent is defined by the `textUrl.Text` property. If the JSON checkbox is selected, the `Accept` property of the `HttpWebRequest` is set to `application/json`. This way, the data service returns a JSON response instead of the default AtomPub format. The request to the server is sent with the asynchronous method `BeginGetResponse`. When a response from the service is received, the method defined with the first parameter as a Lambda expression is invoked. The response is read from a stream associated with `HttpWebResponse`, converted to a `string`, and passed to the `textResult` `TextBox`.

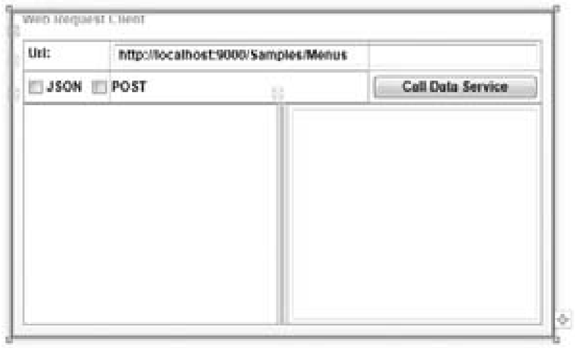

FIGURE 32-2

```
private void OnRequest(object sender, RoutedEventArgs e)
{
    HttpWebRequest request = WebRequest.Create(textUrl.Text)
                                 as HttpWebRequest;
    if (checkJSON.IsChecked == true)
    {
        request.Accept = "application/json";
    }

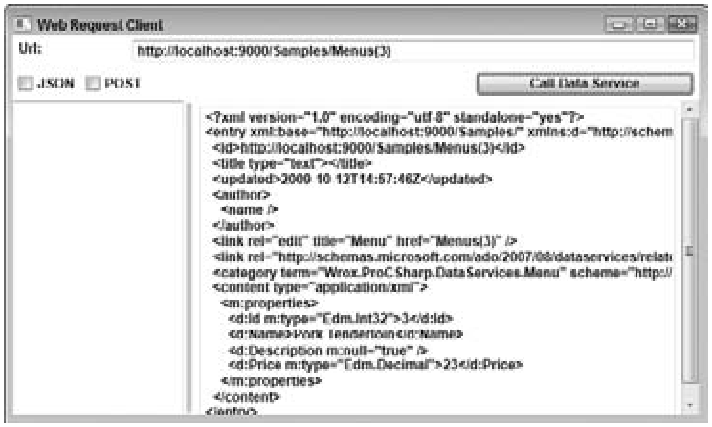
    request.BeginGetResponse((ar) =>
        {
            try
            {
                using (MemoryStream ms = new MemoryStream())
                {
                    const int bufferSize = 1024;
                    byte[] buffer = new byte[bufferSize];
                    HttpWebResponse response =
                        request.EndGetResponse(ar) as HttpWebResponse;

                    Stream responseStream = response.GetResponseStream();
                    int count;
                    while ((count = responseStream.Read(buffer, 0,
                                                bufferSize)) > 0)
                    {
                        ms.Write(buffer, 0, count);
                    }
                    responseStream.Close();
                    byte[] dataRead = ms.ToArray();
                    string data = UnicodeEncoding.ASCII.GetString(
                                             dataRead, 0, dataRead.Length);
                                Dispatcher.BeginInvoke(new Action<string>(s =>
                                    {
                                        textResult.Text = data;
                                    }), data);
                            }
                        }
                        catch (WebException ex)
                        {
                            Dispatcher.Invoke(new Action<string>(s =>
                                {
                                    textResult.Text = s;
                                }), ex.Message);
                        }

                    }, null);
            }
```

code snippet WebRequestClient/WebRequestClient.xaml.cs

Now you can use several HTTP requests to the service and see the data returned. The running application is shown in Figure 32-3.



```
<?xml version="1.0" encoding="utf-8" standalone="yes"?>
<entry xml:base="http://localhost:9000/Samples/" xmlns:d="http://schem
  <id>http://localhost:9000/Samples/Menus(3)</id>
  <title type="text"></title>
  <updated>2009-10-12T14:57:46Z</updated>
  <author>
    <name />
  </author>
  <link rel="edit" title="Menu" href="Menus(3)" />
  <link rel="http://schemas.microsoft.com/ado/2007/08/dataservices/relat
  <category term="Wrox.ProCSharp.DataServices.Menu" scheme="http://
  <content type="application/xml">
    <m:properties>
      <d:Id m:type="Edm.Int32">3</d:Id>
      <d:Name>Pork Tenderloin</d:Name>
      <d:Description m:null="true" />
      <d:Price m:type="Edm.Decimal">23</d:Price>
    </m:properties>
  </content>
</entry>
```

FIGURE 32-3

Using the request `http://localhost:9000/Samples/Menus(3)` to get the menu with the unique identifier 3, this AtomPub information is received:

```
<?xml version="1.0" encoding="utf-8" standalone="yes"?>
<entry xml:base="http://localhost:9000/Samples/"
       xmlns:d="http://schemas.microsoft.com/ado/2007/08/dataservices"
       xmlns:m="http://schemas.microsoft.com/ado/2007/08/dataservices/metadata"
       xmlns="http://www.w3.org/2005/Atom">
  <id>http://localhost:9000/Samples/Menus(3)</id>
  <title type="text"></title>
  <updated>2009-07-30T13:20:07Z</updated>
  <author>
    <name />
  </author>
  <link rel="edit" title="Menu" href="Menus(3)" />
  <link rel=
    "http://schemas.microsoft.com/ado/2007/08/dataservices/related/Category"
    type="application/atom+xml;type=entry" title="Category"
    href="Menus(3)/Category" />
    <category term="Wrox.ProCSharp.DataServices.Menu"
      scheme="http://schemas.microsoft.com/ado/2007/08/dataservices/scheme" />
    <content type="application/xml">
      <m:properties>
        <d:Id m:type="Edm.Int32">3</d:Id>
        <d:Name>Pork Tenderloin</d:Name>
        <d:Description m:null="true" />
        <d:Price m:type="Edm.Decimal">23</d:Price>
      </m:properties>
    </content>
  </entry>
```

If you select the JSON format, a response with the same information but a JSON representation that can be easily read from JavaScript is returned:

```
{ "d" :
   { "__metadata":
      { "uri": "http://localhost:9000/Samples/Menus(3)",
        "type": "Wrox.ProCSharp.DataServices.Menu"
      },
     "Id": 3, "Name": "Pork Tenderloin", "Price": "23",
     "Category":
        { "__deferred":
           { "uri": "http://localhost:9000/Samples/Menus(3)/Category"
           }
        }
   }
}
```

Let's have a look at all the addressing options you have to build the query.

QUERIES WITH URLS

With the flexibility of the data services interface, you can request all objects from the service or get into specific objects and also values for specific properties.

For better readability, in the following queries the address of the service `http://localhost:9000/Samples` *is omitted. This must be prefixed to all the queries.*

You've already seen that you can get a list of all entities in an entity set. The query

```
Menus
```

returns all menu entities, while

```
Categories
```

returns all category entities. According to the AtomPub protocol, the returned root element is `<feed>` and contains `<entry>` elements for every element. This query does not go across references; for example, getting all menus with `Menus` doesn't return the content of the category, only a reference to it. To get the category information within a menu, you can use the `$expand` query string:

```
Menus?$expand=Category
```

Passing the primary key value inside brackets returns just a single entity. Here, the menu with identifier 3 is accessed. This requires the definition of the `DataServiceKey` attribute that was used earlier:

```
Menus(3)
```

With a navigation property (using `/`), you can access a property of an entity:

```
Menus(3)/Price
```

The same syntax works for relations, accessing properties from related entities:

```
Menus(3)/Category/Name
```

To get just the value without the surrounding XML content of an entity, you can use the `$value` query function:

```
Menus(3)/Category/Name/$value
```

Getting back to complete lists, you can get the number of entities in a list with `$count`. `$count` is only available with V2 of the AtomPub protocol.

```
Menus/$count
```

Getting just the first entities of a list is done with the top query string option `$top`:

```
Menus?$top=2
```

You can skip a number of entities with `$skip`. `$skip` and `$top` can be combined for implementing paging functionality.

```
Menus?$skip=2
```

Filtering entities can be performed with the `$filter` query string option and by using the logical operators `eq` (equal), `ne` (not equal), and `gt` (greater than), `ge` (greater than or equal to):

```
Menus?$filter=Category/Name eq 'Appetizer'
```

The result can also be sorted with the `$orderby` query string option:

```
Menus?$filter=Category/Name eq 'Appetizer'&orderby=Price desc
```

For only getting a projection, a subset of the available properties, `$select` can be used to specify the properties that should be accessed:

```
Menus?$select=Name, Price
```

USING WCF DATA SERVICES WITH THE ADO.NET ENTITY FRAMEWORK

Now that you've learned the basic concept of Data Services, passing AtomPub or JSON data across simple HTTP requests, let's get into a more complex example, using the ADO.NET Entity Framework for the data model, a Web application for hosting, and clients performing LINQ queries across a network that make use of classes from the `System.Data.Services.Client` namespace.

ASP.NET Hosting and EDM

First you have to create a new project. This time a Web Application project named `RestaurantDataServiceWeb` is used to host the service. The new data model is created with the help of the ADO.NET Entity Data Model (EDM) template and uses the tables Menus and Categories from a Restaurant database, as shown in Figure 32-4, to create the entity classes `Menu` and `Category`.

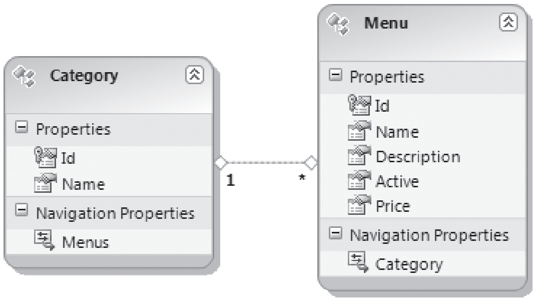


FIGURE 32-4

Now, use the Data Service template and create `RestaurantDataService.svc`. The `.svc` file contains the ASP.NET `ServiceHost` directive and uses the `DataServiceHostFactory` to instantiate the data service on request.

```
<%@ ServiceHost Language="C#" Factory="System.Data.Services.DataServiceHostFactory,
      System.Data.Services, Version=4.0.0.0, Culture=neutral,
      PublicKeyToken=b77a5c561934e089"
      Service="Wrox.ProCSharp.DataServices.RestaurantDataService" %>
```

code snippet RestaurantDataServiceWeb/RestaurantDataService.svc

With the code-behind, you need to change the template parameter of the `DataService<T>` class to reference the previously created entity data service context class, and change the entity set access rule and service operations access rule to allow access:

```
using System.Data.Services;
using System.Data.Services.Common;

namespace Wrox.ProCSharp.DataServices
{
    public class RestaurantDataService : DataService<RestaurantEntities>
    {
        // This method is called only once to initialize service-wide policies.
        public static void InitializeService(DataServiceConfiguration config)
        {
            config.SetEntitySetAccessRule("Menus", EntitySetRights.All);
            config.SetEntitySetAccessRule("Categories", EntitySetRights.All);

            config.DataServiceBehavior.MaxProtocolVersion = DataServiceProtocolVersion.V2;
        }
    }
}
```

code snippet RestaurantDataServiceWeb/RestaurantDataService.svc.cs

Now, you can use a web browser to invoke queries as before to this data service; for example, you can use `http://localhost:13617/RestaurantDataService.svc/Menus` to receive the AtomPub of all menus from the database. Next, you create a client application that makes use of the client part of Data Services.

.NET Applications Using System.Data.Service.Client

Earlier in this chapter, you read how a .NET client application can be created that simply sends HTTP requests by using the `HttpWebRequest` class. The client part of Data Services, with the namespace `System.Data.Services.Client`, offers functionality for the client to build HTTP requests. The two most important classes with this namespace are `DataServiceContext` and `DataServiceQuery<TElement>`. `DataServiceContext` represents the state that is managed on the client. This state keeps track of objects that are loaded from the server as well as all the changes made on the client. `DataServiceQuery<TElement>` represents an HTTP query to a data service.

To call the data service, create a WPF application. Figure 32-5 shows the design view of the WPF application. The top row contains a `ComboBox` control, which is used to display all categories. The second row contains a `StackPanel` with four `Button` controls. The third row contains a `DataGrid` control to display the menus, and the fourth row contains a `TextBlock` element to display some status information.

To create a client proxy and entity classes to be used on the client, you need metadata information. The Data Service offers metadata by using the `$metadata` query string: `http://localhost:13617/RestaurantDataService.svc/$metadata`.

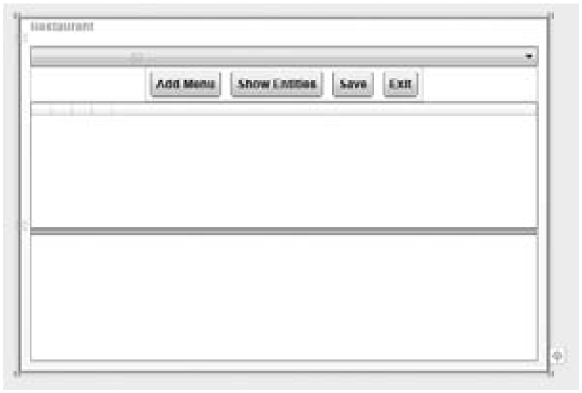

FIGURE 32-5

With this information a service reference can be added to the client application project to create a proxy class and entity classes. With the Restaurant data service, the class `RestaurantEntities` that derives from the base class `DataServiceContext` is created that can be used as a proxy. Entity classes `Menu` and `Category` to keep the data are created as well. The entity classes implement the interface `INotifyPropertyChanged`, which makes it easy to keep informed about changes from the UI.

Data Service Context

Now you can use the data service context `RestaurantEntities` to send a query to the data service. A variable of the service context is defined in the code-behind of the WPF window, in the class `MainWindow`. To avoid conflict with the `Menu` class that's generated for the data service and the `Menu` control from WPF, a namespace alias is defined with the alias name `R`, for *Restaurant*, to reference the generated classes from the service reference.

```
using System;
using System.Collections.Generic;
using System.Data.Services.Client;
using System.Linq;
using System.Text;
using System.Windows;
using System.Windows.Controls;
using R = Wrox.ProCSharp.DataServices.RestaurantService.RestaurantModel;

namespace Wrox.ProCSharp.DataServices
{
    public partial class MainWindow : Window
    {
        private R.RestaurantEntities data;
        private DataServiceCollection<R.Menu> trackedMenus;
```

code snippet ClientApp/MainWindow.xaml.cs

The instance of the `RestaurantEntities` is created in the constructor of the `MainWindow` class. The constructor of the data service context requires a link to the service root. This is defined within the application configuration file and accessed from the strongly typed settings.

```
        public MainWindow()
        {
            Uri serviceRoot = new Uri(Properties.Settings.Default.RestaurantServiceURL);
            data = new R.RestaurantEntities(serviceRoot);
            data.SendingRequest += data_SendingRequest;

            InitializeComponent();
            this.DataContext = this;
        }
```

The content of the application configuration file used to reference the data service is shown here:

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
    <configSections>
        <sectionGroup name="applicationSettings"
            type="System.Configuration.ApplicationSettingsGroup, System, Version=4.0.0.0,
                  Culture=neutral, PublicKeyToken=b77a5c561934e089" >
            <section name="Wrox.ProCSharp.DataServices.Properties.Settings"
                type="System.Configuration.ClientSettingsSection, System, Version=4.0.0.0,
                      Culture=neutral, PublicKeyToken=b77a5c561934e089"
                      requirePermission="false" />
        </sectionGroup>
    </configSections>
    <applicationSettings>
        <Wrox.ProCSharp.DataServices.Properties.Settings>
            <setting name="RestaurantServiceURL" serializeAs="String">
                <value>http://localhost:13617/RestaurantDataService.svc</value>
            </setting>
        </Wrox.ProCSharp.DataServices.Properties.Settings>
    </applicationSettings>
</configuration>
```

code snippet ClientApp/app.config

With the `SendingRequest` event, the data service context invokes the handler every time a request is sent to the service. The method `data_sendingRequest()` is associated with the `SendingRequest` event and receives information about the request in the `SendingRequestEventArgs` argument. With `SendingRequestEventArgs`, you can access request and header information. The request method and URI retrieved from the `Method` and `RequestUri` properties is written to the *textStatus* control in the UI.

```
void data_SendingRequest(object sender, SendingRequestEventArgs e)
{
    var sb = new StringBuilder();
    sb.AppendFormat("Method: {0}\n", e.Request.Method);
    sb.AppendFormat("Uri: {0}\n", e.Request.RequestUri.ToString());
    this.textStatus.Text = sb.ToString();
}
```

code snippet ClientApp/MainWindow.xaml.cs

The data service context `RestaurantEntities` allows you to retrieve entities from the service; tracks the entities that have been retrieved; allows you to add, delete, and change entities inside the data context; and keeps the state of the changes for sending update requests.

LINQ Query

The data service context implements a LINQ provider to convert LINQ requests to HTTP requests. The `Categories` property of the `MainWindow` class defines a LINQ query by using the data context to return all categories:

```
public IEnumerable<R.Category> Categories
{
    get
    {
        return from c in data.Categories
               orderby c.Name
               select c;
    }
}
```

code snippet ClientApp/MainWindow.xaml.cs

The `ComboBox` in the XAML code defines a binding to this property to display all categories:

```
            <ComboBox x:Name="comboCategories" Grid.Row="0"
                      ItemsSource="{Binding Path=Categories}" SelectedIndex="0"
                      SelectionChanged="OnCategorySelection">
                <ComboBox.ItemTemplate>
                    <DataTemplate>
                        <TextBlock Text="{Binding Path=Name}" />
                    </DataTemplate>
                </ComboBox.ItemTemplate>
            </ComboBox>
```

code snippet ClientApp/MainWindow.xaml

With the help of the `SendingRequest` event, it can easily be seen that the LINQ query to access all categories is converted to an HTTP `GET` Request with the following URI:

```
Method: GET
Uri: http://localhost:13617/RestaurantDataService.svc/Categories()?$orderby=Name
```

The `Categories` property of the `RestaurantEntities` class returns a `DataServiceQuery<Category>`. `DataServiceQuery<T>` implements `IQueryable`, and thus, the compiler creates expression trees from the LINQ query that are analyzed and converted to an HTTP `GET` request.

LINQ queries are covered in Chapter 11, "Language Integrated Query."

You can also create a LINQ query to only get the menus from the category `Soups`:

```
                var q = from m in data.Menus
                        where m.Category.Name == "Soups"
                        orderby m.Name
                        select m;
```

This translates the URI `Menus()?$filter=Category/Name eq 'Soups'&$orderby=Name`.

The query can be expanded by using data service query options. For example, to include the relation and get all categories with the selected menus, add `AddQueryOption()` with `$expand` and the parameter value `Category`:

```
                var q = from m in data.Menus.AddQueryOption("$expand", "Category")
                        where m.Category.Name == "Soups"
                        orderby m.Name
                        select m;
```

This modifies the query to `Menus()?$filter=Category/Name eq 'Soups'&$orderby=Name&$expand=Category`.

The `DataServiceQuery<T>` class also offers the `Expand()` method for this particular query option:

```
                var q = from m in data.Menus.Expand("Category")
                        where m.Category.Name == "Soups"
                        orderby m.Name
                        select m;
```

Observable Collections

To keep the user interface informed about collection changes, Data Services contains the collection class `DataServiceCollection<T>`. This collection class is based on `ObservableCollection<T>`, which implements the interface `INotifyCollectionChanged`. WPF controls register with the event of this interface to keep informed about changes in the collection so that the UI can be updated immediately.

To create a `DataServiceCollection<T>` instance the class `DataServiceCollection` defines the static methods `Create()` and `CreateTracked()`. `Create()` creates a list that is independent of the data service context. `CreateTracked()` keeps track of the objects returned from the data service context so that you can take advantage of saving the objects by sending the changes to the service.

The `Menus` property invokes the `DataServiceCollection.CreateTracked<T>()` method to fill a `DataServiceCollection<R.Menu>` list named `trackedMenus` and returns this list. The retrieved entities that are defined by the LINQ query are associated with the data service context `data`.

```
public IEnumerable<R.Menu> Menus
{
    get
    {
        if (trackedMenus == null)
            trackedMenus = DataServiceCollection.CreateTracked<R.Menu>(
                data,
                from m in data.Menus
                where m.CategoryId == (comboCategories.SelectedItem as R.Category).Id
                      && m.Active
                select m);
        return trackedMenus;
    }
}
```

code snippet ClientApp/MainWindow.xaml.cs

The `DataGrid` from the XAML code maps to the `Menus` property with the `Binding` markup extension:

```
<DataGrid Grid.Row="2" ItemsSource="{Binding Path=Menus}" AutoGenerateColumns="False">
    <DataGrid.Columns>
        <DataGridTextColumn Binding="{Binding Path=Name}" />
        <DataGridTextColumn Binding="{Binding Path=Description}" />
        <DataGridTextColumn Binding="{Binding Path=Price}" />
        <DataGridTextColumn Binding="{Binding Path=CategoryId}" />
    </DataGrid.Columns>
</DataGrid>
```

code snippet ClientApp/MainWindow.xaml

Using the `SelectionChanged` event from the `ComboBox` to select a new category, the menus are retrieved again with the newly selected category in the handler method `OnCategorySelection()`:

```
private void OnCategorySelection(object sender, SelectionChangedEventArgs e)
{

    var selectedCategory = comboCategories.SelectedItem as R.Category;
    if (selectedCategory != null && trackedMenus != null)
    {
        trackedMenus.Clear();
        trackedMenus.Load(from m in data.Menus
                          where m.CategoryId == selectedCategory.Id
                          select m);
    }
}
```

code snippet ClientApp/MainWindow.xaml.cs

For more information about observable collections and the class `ObservableCollection<T>` *please consult Chapter 10, "Collections."*

Object Tracking

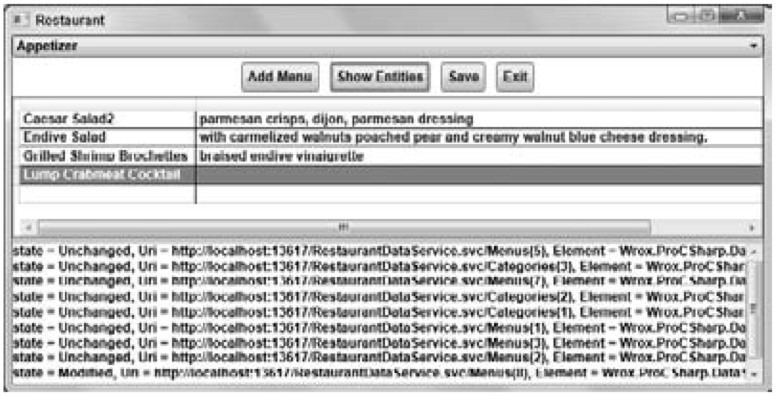
The data service context keeps track of all the objects that have been retrieved. You can get information about the objects by iterating through the return of the `Entities` property. `Entities` returns a read-only collection of `EntityDescriptor` objects. `EntityDescriptor` contains the entity itself that can be accessed via the `Entity` property, and also state information. The state of type `EntityStates` is an enumeration with the possible values `Added`, `Deleted`, `Detached`, `Modified`, and `Unchanged`. This information is used to keep track of changes and send a change request to the service.

To get information about the current entities associated with the data context, the handler method `OnShowEntities()` is associated with the `Click` event of the Show Entities button. Here, the `State`, `Identity`, and `Entity` properties are used to write status information to the UI.

```
private void OnShowEntities(object sender, RoutedEventArgs e)
{
    var sb = new StringBuilder();
    foreach (var entity in data.Entities)
    {
        sb.AppendFormat("state = {0}, Uri = {1}, Element = {2}\n",
                        entity.State, entity.Identity, entity.Entity);
    }
    this.textStatus.Text = sb.ToString();
}
```

code snippet ClientApp/MainWindow.xaml.cs

Figure 32-6 shows the running application with information about the objects tracked.



Caesar Salad2	parmesan crisps, dijon, parmesan dressing
Endive Salad	with carmelized walnuts poached pear and creamy walnut blue cheese dressing.
Grilled Shrimp Brochettes	braised endive vinaigrette
Lump Crabmeat Cocktail	

```
state = Unchanged, Uri = http://localhost:13617/RestaurantDataService.svc/Menus(5), Element = Wrox.ProCSharp.Da
state = Unchanged, Uri = http://localhost:13617/RestaurantDataService.svc/Categories(3), Element = Wrox.ProCShar
state = Unchanged, Uri = http://localhost:13617/RestaurantDataService.svc/Menus(7), Element = Wrox.ProCSharp.Da
state = Unchanged, Uri = http://localhost:13617/RestaurantDataService.svc/Categories(2), Element = Wrox.ProCShar
state = Unchanged, Uri = http://localhost:13617/RestaurantDataService.svc/Categories(1), Element = Wrox.ProCShar
state = Unchanged, Uri = http://localhost:13617/RestaurantDataService.svc/Menus(1), Element = Wrox.ProCSharp.Da
state = Unchanged, Uri = http://localhost:13617/RestaurantDataService.svc/Menus(3), Element = Wrox.ProCSharp.Da
state = Unchanged, Uri = http://localhost:13617/RestaurantDataService.svc/Menus(2), Element = Wrox.ProCSharp.Da
state = Modified, Uri = http://localhost:13617/RestaurantDataService.svc/Menus(8), Element = Wrox.ProCSharp.Data
```

FIGURE 32-6

Adding, Modifying, and Deleting Entities

To add new entities to the data service context and thus send the new objects later to the data service, you can add entities to the data service context with the `AddObject()` method, or strongly typed variants such as `AddToMenus()` and `AddToCategories()`. You just have to fill the mandatory properties; otherwise, saving the state will not succeed. Adding new objects sets the state to `Added`.

The `DeleteObject()` method of the data service context sets the state of an object to `Deleted`.

If properties of an object are modified, the state changes from `Unchanged` to `Modified`.

Now you can invoke the method `SaveChanges()`, which sends HTTP `MERGE` requests to update entities, HTTP `DELETE` requests to delete entities, and HTTP `POST` requests to add new entities.

```
        private void OnSave(object sender, RoutedEventArgs e)
        {
            try
            {
                DataServiceResponse response = data.SaveChanges();
            }
            catch (DataServiceRequestException ex)
            {
                textStatus.Text = ex.ToString();
            }
        }
```

code snippet ClientApp/MainWindow.xaml.cs

Operation Batching

Instead of sending `DELETE` and `MODIFY` requests for every entity in a collection, you can batch multiple change requests to a single network request. By default, every change is sent by using a single request when the `SaveChanges()` method is applied. Adding the parameter `SaveChangesOptions.Batch` to the `SaveChanges()` method combines all the change requests to a single network call with the `$batch` query option.

```
        private void OnSave(object sender, RoutedEventArgs e)
        {
            try
            {
                DataServiceResponse response = data.SaveChanges(SaveChangesOptions.Batch);
            }
            catch (DataServiceRequestException ex)
            {
                textStatus.Text = ex.ToString();
            }
        }
```

code snippet ClientApp/MainWindow.xaml.cs

As the transferred data demonstrate, multiple HTTP headers are combined inside a single HTTP `POST` request and are split again on the server side. With the following HTTP `POST` request, you can see that the `DELETE` and `MERGE` requests are combined. The `DELETE` request deletes the menu with `id 4`; the `MERGE` request contains AtomPub information to update the menu with `id 2`.

```
POST /RestaurantDataService.svc/$batch HTTP/1.1

SUMMARY

In this chapter, you've seen the features of WCF Data Services. WCF Data Services brings the data model from the ADO.NET Entity Framework across multiple tiers. The technology that this is based on is WCF, by using connectionless, stateless communication sending AtomPub or JSON queries.

You've not only seen the server-side part of this technology but also the client-side part, where change information is tracked inside a data service context. The client-side part of WCF Data Services implements a LINQ provider, so you can create simple LINQ requests that are converted to HTTP `GET`/`POST`/`PUT`/`DELETE` requests.

33 Manipulating XML

WHAT'S IN THIS CHAPTER?

- XML standards
- XmlReader and XmlWriter
- XmlDocument
- XPathDocument
- XmlNavigator
- LINQ to XML
- Working with objects in the `System.Xml.Linq` namespace
- Querying XML documents using LINQ
- Using LINQ to SQL and LINQ to XML together

XML plays a significant role in the .NET Framework. Not only does the .NET Framework allow you to use XML in your application, but the .NET Framework itself uses XML for configuration files and source code documentation, as do SOAP, web services, and ADO.NET, to name just a few.

To accommodate this extensive use of XML, the .NET Framework includes the `System.Xml` namespace. This namespace is loaded with classes that can be used for the processing of XML, and many of these classes are discussed in this chapter.

This chapter discusses how to use the `XmlDocument` class, which is the implementation of the Document Object Model (DOM), as well as what .NET offers as a replacement for SAX (the `XmlReader` and `XmlWriter` classes). It also discusses the class implementations of XPath and XSLT and demonstrates how XML and ADO.NET work together, as well as how easy it is to transform one to the other. You also learn how you can serialize your objects to XML and create an object from (or deserialize) an XML document by using classes in the `System.Xml.Serialization` namespace. More to the point, you learn how you can incorporate XML into your C# applications.

You should note that the XML namespace allows you to get similar results in a number of different ways. It is impossible to include all these variations in one chapter, so while exploring one possible way of doing things, we'll try our best to mention alternative routes that will yield the same or similar results.

Because it's beyond the scope of this book to teach you XML from scratch, we assume that you are already somewhat familiar with XML. For example, you should be familiar with elements, attributes, and nodes, and you should also know what we mean when we refer to a *well-formed* document. You should also be familiar with SAX and DOM.

> *If you want to learn more about XML, Wrox's* Professional XML *(Wiley Publishing, 2007, ISBN 978-0471-77777-9) is a great place to start.*

In addition to general XML usage, the .NET Framework also includes the ability to work with XML by using LINQ to XML. One of the available web downloads, Chapter 56, "LINQ to SQL," takes a look at using LINQ to query SQL Server databases. This chapter takes a quick look at using LINQ to query your XML data sources instead.

The discussion begins with a brief overview of the current status of XML standards.

XML STANDARDS SUPPORT IN .NET

The World Wide Web Consortium (W3C) has developed a set of standards that give XML its power and potential. Without these standards, XML would not have the impact on the development world that it does. The W3C web site (`www.w3.org`) is a valuable source for all things XML.

The .NET Framework supports the following W3C standards:

- XML 1.0 (`www.w3.org/TR/1998/REC-xml-19980210`), including DTD support
- XML namespaces (`www.w3.org/TR/REC-xml-names`), both stream level and DOM
- XML schemas (`www.w3.org/2001/XMLSchema`)
- XPath expressions (`www.w3.org/TR/xpath`)
- XSLT transformations (`www.w3.org/TR/xslt`)
- DOM Level 1 Core (`www.w3.org/TR/REC-DOM-Level-1`)
- DOM Level 2 Core (`www.w3.org/TR/DOM-Level-2-Core`)
- SOAP 1.1 (`www.w3.org/TR/SOAP`)

The level of standards support will change as the framework matures and the W3C updates the recommended standards. Because of this, you need to make sure that you stay up to date with the standards and the level of support provided by Microsoft.

INTRODUCING THE SYSTEM.XML NAMESPACE

Support for processing XML is provided by the classes in the `System.Xml` namespace in .NET. This section looks (in no particular order) at some of the more important classes that the `System.Xml` namespace provides. The following table lists the main XML reader and writer classes.

CLASS NAME	DESCRIPTION
`XmlReader`	An abstract reader class that provides fast, noncached XML data. `XmlReader` is forward-only, like the SAX parser.
`XmlWriter`	An abstract writer class that provides fast, noncached XML data in stream or file format.
`XmlTextReader`	Extends `XmlReader`. Provides fast forward-only stream access to XML data.
`XmlTextWriter`	Extends `XmlWriter`. Fast forward-only generation of XML streams.

The following table lists some other useful classes for handling XML.

CLASS NAME	DESCRIPTION
`XmlNode`	An abstract class that represents a single node in an XML document. Base class for several classes in the XML namespace.
`XmlDocument`	Extends `XmlNode`. This is the W3C DOM implementation. It provides a tree representation in memory of an XML document, enabling navigation and editing.
`XmlDataDocument`	Extends `XmlDocument`. This is a document that can be loaded from XML data or from relational data in an ADO.NET `DataSet`. Allows the mixing of XML and relational data in the same view.
`XmlResolver`	An abstract class that resolves external XML-based resources such as DTD and schema references. Also used to process `<xsl:include>` and `<xsl:import>` elements.
`XmlNodeList`	A list of `XmlNodes` that can be iterated through.
`XmlUrlResolver`	Extends `XmlResolver`. Resolves external resources named by a uniform resource identifier (URI).

Many of the classes in the `System.Xml` namespace provide a means to manage XML documents and streams, whereas others (such as the `XmlDataDocument` class) provide a bridge between XML data stores and the relational data stored in `DataSets`.

USING SYSTEM.XML CLASSES

The following examples use `books.xml` as the source of data. You can download this file and the other code samples for this chapter from the Wrox web site (`www.wrox.com`), but it is also included in several examples in the .NET SDK. The `books.xml` file is a book catalog for an imaginary bookstore. It includes book information such as genre, author name, price, and ISBN number.

This is what the `books.xml` file looks like:

```
<?xml version='1.0'?>
<!--This file represents a fragment of a book store inventory database-->
<bookstore>
   <book genre="autobiography" publicationdate="1991" ISBN="1-861003-11-0">
      <title>The Autobiography of Benjamin Franklin</title>
      <author>
         <first-name>Benjamin</first-name>
         <last-name>Franklin</last-name>
      </author>
      <price>8.99</price>
   </book>
   <book genre="novel" publicationdate="1967" ISBN="0-201-63361-2">
      <title>The Confidence Man</title>
      <author>
         <first-name>Herman</first-name>
         <last-name>Melville</last-name>
      </author>
      <price>11.99</price>
   </book>
   <book genre="philosophy" publicationdate="1991" ISBN="1-861001-57-6">
      <title>The Gorgias</title>
```

```
        <author>
           <name>Plato</name>
        </author>
        <price>9.99</price>
     </book>
  </bookstore>
```

code snippet books.xml

READING AND WRITING STREAMED XML

The `XmlReader` and `XmlWriter` classes will feel familiar if you have ever used SAX. `XmlReader`-based classes provide a very fast, forward-only, read-only cursor that streams the XML data for processing. Because it is a streaming model, the memory requirements are not very demanding. However, you don't have the navigation flexibility and the read or write capabilities that would be available from a DOM-based model. `XmlWriter`-based classes produce an XML document that conforms to the W3C's XML 1.0 Namespace Recommendations.

`XmlReader` and `XmlWriter` are both abstract classes. The following classes are derived from `XmlReader`:

- `XmlNodeReader`
- `XmlTextReader`
- `XmlValidatingReader`

The following classes are derived from `XmlWriter`:

- `XmlTextWriter`
- `XmlQueryOutput`

`XmlTextReader` and `XmlTextWriter` work with either a stream-based object from the `System.IO` namespace or `TextReader`/`TextWriter` objects. `XmlNodeReader` uses an `XmlNode` as its source instead of a stream. The `XmlValidatingReader` adds DTD and schema validation and therefore offers data validation. You look at these a bit more closely later in this chapter.

Using the XmlReader Class

`XmlReader` is a lot like SAX in the MSXML SDK. One of the biggest differences, however, is that whereas SAX is a *push* type of model (that is, it pushes data out to the application, and the developer has to be ready to accept it), the `XmlReader` is a *pull* model, where data is pulled into an application requesting it. This provides an easier and more intuitive programming model. Another advantage to this is that a pull model can be selective about the data that is sent to the application: if you don't want all of the data, you don't need to process it. In a push model, all of the XML data has to be processed by the application, whether it is needed or not.

The following is a very simple example of reading XML data, and later you will take a closer look at the `XmlReader` class. You'll find the code in the XmlReaderSample folder. Here is the code for reading in the `books.xml` document. As each node is read, the `NodeType` property is checked. If the node is a text node, the value is appended to the text box:

```
using System.Xml;

private void button3_Click(object sender, EventArgs e)
{
  richTextBox1.Clear();
  XmlReader rdr = XmlReader.Create("books.xml");
  while (rdr.Read())
  {
    if (rdr.NodeType == XmlNodeType.Text)
```

```
        richTextBox1.AppendText(rdr.Value + "\r\n");
      }
    }
```

code download XMLReaderSample.sln

As previously discussed, XmlReader is an abstract class. So in order to use the XmlReader class directly, a Create static method has been added. The Create method returns an XmlReader object. The overload list for the Create method contains nine entries. In the preceding example, a string that represents the filename of the XmlDocument is passed in as a parameter. Stream-based objects and TextReader-based objects can also be passed in.

An XmlReaderSettings object can also be used. XmlReaderSettings specifies the features of the reader. For example, a schema can be used to validate the stream. Set the Schemas property to a valid XmlSchemaSet object, which is a cache of XSD schemas. Then the XsdValidate property on the XmlReaderSettings object can be set to true.

You can use several Ignore properties to control the way the reader processes certain nodes and values. These properties include IgnoreComments, IgnoreIdentityConstraints, IgnoreInlineSchema, IgnoreProcessingInstructions, IgnoreSchemaLocation, and IgnoreWhitespace. These properties can be used to strip certain items from the document.

Read Methods

Several ways exist to move through the document. As shown in the previous example, Read() takes you to the next node. You can then verify whether the node has a value (HasValue()) or, as you will see shortly, whether the node has any attributes (HasAttributes()). You can also use the ReadStartElement() method, which verifies whether the current node is the start element and then positions you on the next node. If you are not on the start element, an XmlException is raised. Calling this method is the same as calling the IsStartElement() method followed by a Read() method.

ReadElementString() is similar to ReadString(), except that you can optionally pass in the name of an element. If the next content node is not a start tag, or if the Name parameter does not match the current node Name, an exception is raised.

Here is an example of how ReadElementString() can be used. Notice that this example uses FileStreams, so you will need to make sure that you include the System.IO namespace via a using statement:

```
private void button6_Click(object sender, EventArgs e)
{
  richTextBox1.Clear();
        XmlReader rdr = XmlReader.Create("books.xml");
  while (!rdr.EOF)
  {
    //if we hit an element type, try and load it in the listbox
    if (rdr.MoveToContent() == XmlNodeType.Element && rdr.Name == "title")
    {
      richTextBox1.AppendText(rdr.ReadElementString() + "\r\n");
    }
    else
    {
      //otherwise move on
      rdr.Read();
    }
  }
}
```

code download XMLReaderSample.sln

In the `while` loop, you use `MoveToContent()` to find each node of type `XmlNodeType.Element` with the name `title`. You use the `EOF` property of the `XmlTextReader` as the loop condition. If the node is not of type `Element` or not named `title`, the `else` clause will issue a `Read()` method to move to the next node. When you find a node that matches the criteria, you add the result of a `ReadElementString()` to the list box. This should leave you with just the book titles in the list box. Note that you don't have to issue a `Read()` call after a successful `ReadElementString()` because `ReadElementString()` consumes the entire `Element` and positions you on the next node.

If you remove `&& rdr.Name=="title"` from the `if` clause, you will have to catch the `XmlException` when it is thrown. If you look at the data file, you will see that the first element that `MoveToContent()` will find is the `<bookstore>` element. Because it is an element, it will pass the check in the `if` statement. However, because it does not contain a simple text type, it will cause `ReadElementString()` to raise an `XmlException`. One way to work around this is to put the `ReadElementString()` call in a function of its own. Then, if the call to `ReadElementString()` fails inside this function, you can deal with the error and return to the calling function.

Go ahead and do this; call this new method `LoadTextBox()` and pass in the `XmlTextReader` as a parameter. This is what the `LoadTextBox()` method looks like with these changes:

```
private void LoadTextBox(XmlReader reader)
{
   try
   {
      richTextBox1.AppendText (reader.ReadElementString() + "\r\n");
   }
   // if an XmlException is raised, ignore it.
   catch(XmlException er){}
}
```

This section from the previous example:

```
if (tr.MoveToContent() == XmlNodeType.Element && tr.Name == "title")
{
  richTextBox1.AppendText(tr.ReadElementString() + "\r\n");
}
else
{
  //otherwise move on
  tr.Read();
}
```

will have to be changed to the following:

```
if (tr.MoveToContent() == XmlNodeType.Element)
{
  LoadTextBox(tr);
}
else
{
  //otherwise move on
  tr.Read();
}
```

After running this example, the results should be the same as before. What you are seeing is that there is more than one way to accomplish the same goal. This is where the flexibility of the classes in the `System.Xml` namespace starts to become apparent.

The `XmlReader` can also read strongly typed data. There are several `ReadElementContentAs` methods, such as `ReadElementContentAsDouble`, `ReadElementContentAsBoolean`, and so on. The following example shows how to read in the values as a decimal and do some math on the value. In this case, the value from the price element is increased by 25 percent:

```
private void button5_Click(object sender, EventArgs e)
{
  richTextBox1.Clear();
  XmlReader rdr = XmlReader.Create("books.xml");
  while (rdr.Read())
  {
    if (rdr.NodeType == XmlNodeType.Element)
    {
      if (rdr.Name == "price")
      {
        decimal price = rdr.ReadElementContentAsDecimal();
        richTextBox1.AppendText("Current Price = " + price + "\r\n");
        price += price * (decimal).25;
        richTextBox1.AppendText("New Price = " + price + "\r\n\r\n");
      }
      else if(rdr.Name== "title")
        richTextBox1.AppendText(rdr.ReadElementContentAsString() + "\r\n");
    }
  }
}
```

code download XMLReaderSample.sln

If the value cannot be converted to a decimal value, a `FormatException` is raised. This is a much more efficient method than reading the value as a string and casting it to the proper data type.

Retrieving Attribute Data

As you play with the sample code, you might notice that when the nodes are read in, you don't see any attributes. This is because attributes are not considered part of a document's structure. When you are on an element node, you can check for the existence of attributes and optionally retrieve the attribute values.

For example, the `HasAttributes` property returns `true` if there are any attributes; otherwise, it returns `false`. The `AttributeCount` property tells you how many attributes there are, and the `GetAttribute()` method gets an attribute by name or by index. If you want to iterate through the attributes one at a time, you can use the `MoveToFirstAttribute()` and `MoveToNextAttribute()` methods.

The following is an example of iterating through the attributes of the `books.xml` document:

```
private void button7_Click(object sender, EventArgs e)
{
  richTextBox1.Clear();
  XmlReader tr = XmlReader.Create("books.xml");
  //Read in node at a time
  while (tr.Read())
  {
    //check to see if it's a NodeType element
    if (tr.NodeType == XmlNodeType.Element)
    {
      //if it's an element, then let's look at the attributes.
      for (int i = 0; i < tr.AttributeCount; i++)
      {
        richTextBox1.AppendText(tr.GetAttribute(i) + "\r\n");
      }
    }
  }
}
```

code download XMLReaderSample.sln

This time you are looking for element nodes. When you find one, you loop through all of the attributes and, using the `GetAttribute()` method, you load the value of the attribute into the list box. In this example, those attributes would be `genre`, `publicationdate`, and `ISBN`.

Validating with XmlReader

Sometimes it's important to know not only that the document is well formed but also that it is valid. An `XmlReader` can validate the XML according to an XSD schema by using the `XmlReaderSettings` class. The XSD schema is added to the `XmlSchemaSet` that is exposed through the `Schemas` property. The `XsdValidate` property must also be set to `true`; the default for this property is `false`.

The following example demonstrates the use of the `XmlReaderSettings` class. The following is the XSD schema that will be used to validate the `books.xml` document:

```
<?xml version="1.0" encoding="utf-8"?>
<xs:schema attributeFormDefault="unqualified"
        elementFormDefault="qualified" xmlns:xs="http://www.w3.org/2001/XMLSchema">
  <xs:element name="bookstore">
    <xs:complexType>
      <xs:sequence>
        <xs:element maxOccurs="unbounded" name="book">
          <xs:complexType>
            <xs:sequence>
              <xs:element name="title" type="xs:string" />
              <xs:element name="author">
                <xs:complexType>
                  <xs:sequence>
                    <xs:element minOccurs="0" name="name"
                                          type="xs:string" />
                    <xs:element minOccurs="0" name="first-name"
                                          type="xs:string" />
                    <xs:element minOccurs="0" name="last-name"
                                          type="xs:string" />
                  </xs:sequence>
                </xs:complexType>
              </xs:element>
              <xs:element name="price" type="xs:decimal" />
            </xs:sequence>
            <xs:attribute name="genre" type="xs:string" use="required" />
            <!--<xs:attribute name="publicationdate"
                                   type="xs:unsignedShort" use="required" />-->
            <xs:attribute name="ISBN" type="xs:string" use="required" />
          </xs:complexType>
        </xs:element>
      </xs:sequence>
    </xs:complexType>
  </xs:element>
</xs:schema>
```

code download books.xsd

This schema was generated from `books.xml` in Visual Studio. Notice that the `publicationdate` attribute has been commented out. This will cause the validation to fail.

The following is the code that uses the schema to validate the `books.xml` document:

```
private void button8_Click(object sender, EventArgs e)
{

 richTextBox1.Clear();
  XmlReaderSettings settings = new XmlReaderSettings();
  settings.Schemas.Add(null, "books.xsd");
```

```
        settings.ValidationType = ValidationType.Schema;
        settings.ValidationEventHandler +=
          new System.Xml.Schema.ValidationEventHandler(settings_ValidationEventHandler);
        XmlReader rdr = XmlReader.Create("books.xml", settings);
        while (rdr.Read())
        {
          if (rdr.NodeType == XmlNodeType.Text)
            richTextBox1.AppendText(rdr.Value + "\r\n");
        }
      }
```

code download XMLReaderSample.sln

After the `XmlReaderSettings` object setting is created, the schema `books.xsd` is added to the `XmlSchemaSet` object. The `Add` method for `XmlSchemaSet` has four overloads. One takes an `XmlSchema` object. The `XmlSchema` object can be used to create a schema on the fly, without having to create the schema file on disk. Another overload takes another `XmlSchemaSet` object as a parameter. Another takes two string values: the first is the target namespace and the other is the URL for the XSD document. If the target namespace parameter is null, the `targetNamespace` of the schema will be used. The last overload takes the `targetNamespace` as the first parameter as well, but it uses an `XmlReader`-based object to read in the schema. The `XmlSchemaSet` preprocesses the schema before the document to be validated is processed.

After the schema is referenced, the `XsdValidate` property is set to one of the `ValidationType` enumeration values. These valid values are `DTD`, `Schema`, or `None`. If the value selected is set to `None`, then no validation will occur.

Because the `XmlReader` object is being used, if there is a validation problem with the document, it will not be found until that attribute or element is read by the reader. When the validation failure does occur, an `XmlSchemaValidationException` is raised. This exception can be handled in a `catch` block; however, handling exceptions can make controlling the flow of the data difficult. To help with this, a `ValidationEvent` is available in the `XmlReaderSettings` class. This way, the validation failure can be handled without your having to use exception handling. The event is also raised by validation warnings, which do not raise an exception. The `ValidationEvent` passes in a `ValidationEventArgs` object that contains a `Severity` property. This property determines whether the event was raised by an error or a warning. If the event was raised by an error, the exception that caused the event to be raised is passed in as well. There is also a message property. In the example, the message is displayed in a `MessageBox`.

Using the XmlWriter Class

The `XmlWriter` class allows you write XML to a stream, a file, a `StringBuilder`, a `TextWriter`, or another `XmlWriter` object. Like `XmlTextReader`, it does so in a forward-only, noncached manner. `XmlWriter` is highly configurable, allowing you to specify such things as whether or not to indent content, the amount to indent, what quote character to use in attribute values, and whether namespaces are supported. Like the `XmlReader`, this configuration is done using an `XmlWriterSettings` object.

Here's a simple example that shows how the `XmlTextWriter` class can be used:

```
      private void button9_Click(object sender, EventArgs e)
      {
        XmlWriterSettings settings = new XmlWriterSettings();
        settings.Indent = true;
        settings.NewLineOnAttributes = true;
        XmlWriter writer = XmlWriter.Create("newbook.xml", settings);
        writer.WriteStartDocument();
        //Start creating elements and attributes
        writer.WriteStartElement("book");
        writer.WriteAttributeString("genre", "Mystery");
        writer.WriteAttributeString("publicationdate", "2001");
        writer.WriteAttributeString("ISBN", "123456789");
      writer.WriteElementString("title", "Case of the Missing Cookie");
      writer.WriteStartElement("author");
      writer.WriteElementString("name", "Cookie Monster");
      writer.WriteEndElement();
      writer.WriteElementString("price", "9.99");
      writer.WriteEndElement();
      writer.WriteEndDocument();
      //clean up
      writer.Flush();
      writer.Close();
    }
```

code download XMLReaderSample.sln

Here, you are writing to a new XML file called `newbook.xml`, adding the data for a new book. Note that `XmlWriter` will overwrite an existing file with a new one. You will look at inserting a new element or node into an existing document later in this chapter. You are instantiating the `XmlWriter` object by using the `Create` static method. In this example, a string representing a filename is passed as a parameter, along with an instance of an `XmlWriterSetting` class.

The `XmlWriterSettings` class has properties that control the way that the XML is generated. The `CheckedCharacters` property is a Boolean that will raise an exception if a character in the XML does not conform to the W3C XML 1.0 recommendation. The `Encoding` class sets the encoding used for the XML being generated; the default is Encoding.UTF8. The `Indent` property is a Boolean value that determines if elements should be indented. The `IndentChars` property is set to the character string that it is used to indent. The default is two spaces. The `NewLine` property is used to determine the characters for line breaks. In the preceding example, the `NewLineOnAttribute` is set to `true`. This will put each attribute in a separate line, which can make the XML generated a little easier to read.

`WriteStartDocument()` adds the document declaration. Now you start writing data. First comes the `book` element; next, you add the `genre`, `publicationdate`, and `ISBN` attributes. Then you write the `title`, `author`, and `price` elements. Note that the `author` element has a child element name.

When you click the button, you produce the `booknew.xml` file, which looks like this:

```
<?xml version="1.0" encoding="utf-8"?>
<book
  genre="Mystery"
  publicationdate="2001"
  ISBN="123456789">
  <title>Case of the Missing Cookie</title>
  <author>
    <name>Cookie Monster</name>
  </author>
  <price>9.99</price>
</book>
```

The nesting of elements is controlled by paying attention to when you start and finish writing elements and attributes. You can see this when you add the `name` child element to the `authors` element. Note how the `WriteStartElement()` and `WriteEndElement()` method calls are arranged and how that arrangement produces the nested elements in the output file.

To go along with the `WriteElementString()` and `WriteAttributeString()` methods, there are several other specialized write methods. `WriteCData()` outputs a `CData` section (`<!CDATA[.]]>`), writing out the text it takes as a parameter. `WriteComment()` writes out a comment in proper XML format. `WriteChars()` writes out the contents of a `char` buffer. This works in a similar fashion to the `ReadChars()` method that you looked at earlier; they both use the same type of parameters. `WriteChars()` needs a buffer (an array of characters), the starting position for writing (an integer), and the number of characters to write (an integer).

Reading and writing XML using the `XmlReader`- and `XmlWriter`-based classes are surprisingly flexible and simple to do. Next, you'll learn how the DOM is implemented in the `System.Xml` namespace through the `XmlDocument` and `XmlNode` classes.

USING THE DOM IN .NET

The DOM implementation in .NET supports the W3C DOM Level 1 and Core DOM Level 2 specifications. The DOM is implemented through the `XmlNode` class, which is an abstract class that represents a node of an XML document.

There is also an `XmlNodeList` class, which is an ordered list of nodes. This is a live list of nodes, and any changes to any node are immediately reflected in the list. `XmlNodeList` supports indexed access or iterative access.

The `XmlNode` and `XmlNodeList` classes make up the core of the DOM implementation in the .NET Framework. The following table lists some of the classes that are based on `XmlNode`.

CLASS NAME	DESCRIPTION
`XmlLinkedNode`	Returns the node immediately before or after the current node. Adds `NextSibling` and `PreviousSibling` properties to `XmlNode`.
`XmlDocument`	Represents the entire document. Implements the DOM Level 1 and Level 2 specifications.
`XmlDocumentFragment`	Represents a fragment of the document tree.
`XmlAttribute`	Represents an attribute object of an `XmlElement` object.
`XmlEntity`	Represents a parsed or unparsed entity node.
`XmlNotation`	Contains a notation declared in a DTD or schema.

The following table lists classes that extend `XmlCharacterData`.

CLASS NAME	DESCRIPTION
`XmlCDataSection`	Represents a `CData` section of a document.
`XmlComment`	Represents an XML comment object.
`XmlSignificantWhitespace`	Represents a node with whitespace. Nodes are created only if the `PreserveWhiteSpace` flag is `true`.
`XmlWhitespace`	Represents whitespace in element content. Nodes are created only if the `PreserveWhiteSpace` flag is `true`.
`XmlText`	Represents the textual content of an element or attribute.

The following table lists classes that extend the `XmlLinkedNode`.

CLASS NAME	DESCRIPTION
`XmlDeclaration`	Represents the declaration node (`<?xml version=`‘`1.0'.>`).
`XmlDocumentType`	Represents data relating to the document type declaration.
`XmlElement`	Represents an XML element object.
`XmlEntityReferenceNode`	Represents an entity reference node.
`XmlProcessingInstruction`	Contains an XML processing instruction.

As you can see, .NET makes available a class to fit just about any XML type that you might encounter. Because of this, you end up with a very flexible and powerful tool set. This section won't look at every class in detail, but you will see several examples to give you an idea of what you can accomplish.

Using the XmlDocument Class

`XmlDocument` and its derived class `XmlDataDocument` (discussed later in this chapter) are the classes that you will be using to represent the DOM in .NET. Unlike `XmlReader` and `XmlWriter`, `XmlDocument` gives you read and write capabilities as well as random access to the DOM tree. `XmlDocument` resembles the DOM implementation in MSXML. If you have experience programming with MSXML, you will feel comfortable using `XmlDocument`.

This section introduces an example that creates an `XmlDocument` object, loads a document from disk, and loads a text box with data from the title elements. This is similar to one of the examples that you constructed in the "Using the XmlReader Class" section. The difference here is that you will be selecting the nodes you want to work with, instead of going through the entire document as in the `XmlReader`-based example.

Here is the code to create an `XmlDocument` object. Notice how simple it looks in comparison to the `XmlReader` example:

```
private void button1_Click(object sender, System.EventArgs e)
{
      //doc is declared at the module level
      //change path to match your path structure
      _doc.Load("books.xml");
      //get only the nodes that we want.
      XmlNodeList nodeLst = _doc.GetElementsByTagName("title");
      //iterate through the XmlNodeList
      textBox1.Text = "";
      foreach (XmlNode node in nodeLst)
      {
          textBox1.Text += node.OuterXml + "\r\n";
      }
}
```

code snippet frmXMLDOM.cs

Note that you also add the following declaration at the module level for the examples in this section:

```
private XmlDocument doc=new XmlDocument();
```

If this is all that you wanted to do, using the `XmlReader` would have been a much more efficient way to load the text box, because you just go through the document once and then you are finished with it. This is exactly the type of work that `XmlReader` was designed for. However, if you want to revisit a node, using `XmlDocument` is a better way.

Here is an example of using the XPath syntax to retrieve a set of nodes from the document:

```
private void button2_Click(object sender, EventArgs e)
{
  //doc is declared at the module level
  //change path to match your path structure
  doc.Load("books.xml");
  //get only the nodes that we want.
  XmlNodeList nodeLst = _doc.SelectNodes("/bookstore/book/title");
  textBox1.Text = "";
  //iterate through the XmlNodeList
  foreach (XmlNode node in nodeLst)
  {
      textBox1.Text += node.OuterXml + "\r\n";
  }
}
```

code snippet frmXMLDOM.cs

SelectNodes() returns a NodeList, or a collection of XmlNodes. The list contains only nodes that match the XPath statement passed in as the parameter SelectNodes. In this example, all you want to see are the title nodes. If you had made the call to SelectSingleNode, then you would have received a single node object that contained the first node in the XmlDocument that matched the XPath criteria.

A quick comment regarding the SelectSingleNode() method: This is an XPath implementation in the XmlDocument class. Both the SelectSingleNode() and SelectNodes() methods are defined in XmlNode, which XmlDocument is based on. SelectSingleNode() returns an XmlNode and SelectNodes() returns an XmlNodeList. However, the System.Xml.XPath namespace contains a richer XPath implementation, which you will look at in a later section.

Inserting Nodes

Earlier, you looked at an example using XmlTextWriter that created a new document. The limitation was that it would not insert a node into a current document. With the XmlDocument class, you can do just that. Change the button1_Click() event handler from the last example to the following:

```
private void button4_Click(object sender, System.EventArgs e)
{
      //change path to match your structure
      _doc.Load("books.xml");
      //create a new 'book' element
      XmlElement newBook = _doc.CreateElement("book");
      //set some attributes
      newBook.SetAttribute("genre", "Mystery");
      newBook.SetAttribute("publicationdate", "2001");
      newBook.SetAttribute("ISBN", "123456789");
      //create a new 'title' element
      XmlElement newTitle = _doc.CreateElement("title");
      newTitle.InnerText = "Case of the Missing Cookie";
      newBook.AppendChild(newTitle);
      //create new author element
      XmlElement newAuthor = _doc.CreateElement("author");
      newBook.AppendChild(newAuthor);
      //create new name element
      XmlElement newName = _doc.CreateElement("name");
      newName.InnerText = "Cookie Monster";
      newAuthor.AppendChild(newName);
      //create new price element
      XmlElement newPrice = _doc.CreateElement("price");
      newPrice.InnerText = "9.95";
      newBook.AppendChild(newPrice);
      //add to the current document
      _doc.DocumentElement.AppendChild(newBook);
      //write out the doc to disk
      XmlTextWriter tr = new XmlTextWriter("booksEdit.xml", null);
      tr.Formatting = Formatting.Indented;
      _doc.WriteContentTo(tr);
      tr.Close();
      //load listBox1 with all of the titles, including new one
      XmlNodeList nodeLst = _doc.GetElementsByTagName("title");
      textBox1.Text = "";
      foreach (XmlNode node in nodeLst)
      {
          textBox1.Text += node.OuterXml + "\r\n";
      }
}
```

code snippet frmXMLDOM.cs

After executing this code, you end up with the same functionality as in the previous example, but there is one additional book in the text box, *The Case of the Missing Cookie* (a soon-to-be classic). If you look closely at the code, you can see that this is actually a fairly simple process. The first thing that you do is create a new `book` element:

```
XmlElement newBook = doc.CreateElement("book");
```

`CreateElement()` has three overloads that allow you to specify the following:

- ➤ The element name
- ➤ The name and namespace URI
- ➤ The prefix, localname, and namespace

Once the element is created, you need to add attributes:

```
newBook.SetAttribute("genre","Mystery");
newBook.SetAttribute("publicationdate","2001");
newBook.SetAttribute("ISBN","123456789");
```

Now that you have the attributes created, you need to add the other elements of a book:

```
XmlElement newTitle = doc.CreateElement("title");
newTitle.InnerText = "The Case of the Missing Cookie";
newBook.AppendChild(newTitle);
```

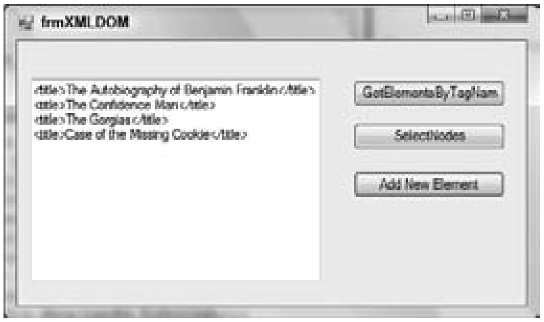
Once again, you create a new `XmlElement`-based object (`newTitle`). Then you set the `InnerText` property to the title of our new classic and append the element as a child to the `book` element. You repeat this for the rest of the elements in this `book` element. Note that you add the `name` element as a child to the `author` element. This will give you the proper nesting relationship, as in the other `book` elements.

Finally, you append the `newBook` element to the `doc.DocumentElement` node. This is the same level as all of the other `book` elements. You have now updated an existing document with a new element.

The last thing to do is to write the new XML document to disk. In this example, you create a new `XmlTextWriter` and pass it to the `WriteContentTo()` method. `WriteContentTo()` and `WriteTo()` both take an `XmlTextWriter` as a parameter. `WriteContentTo()` saves the current node and all of its children to the `XmlTextWriter`, whereas `WriteTo()` just saves the current node. Because `doc` is an `XmlDocument`-based object, it represents the entire document and so that is what is saved. You could also use the `Save()` method. It will always save the entire document. `Save()` has four overloads. You can specify a string with the filename and path, a `Stream`-based object, a `TextWriter`-based object, or an `XmlWriter`-based object.

You also call the `Close()` method on `XmlTextWriter` to flush the internal buffers and close the file.

Figure 33-1 shows what you get when you run this example. Notice the new entry at the bottom of the list.



```
<title>The Autobiography of Benjamin Franklin</title>
<title>The Confidence Man</title>
<title>The Gorgias</title>
<title>Case of the Missing Cookie</title>
```

FIGURE 33-1

Earlier in the chapter, you saw how to create a document using the `XmlTextWriter` class. You can also use `XmlDocument`. Why would you use one in preference to the other? If the data that you want streamed to XML is available and ready to write, then the `XmlTextWriter` class is the best choice. However, if you need to build the XML document a little at a time, inserting nodes into various places, then creating the document with `XmlDocument` might be the better choice. You can accomplish this by changing the following line:

```
doc.Load("books.xml");
```

to this:

```
      //create the declaration section
      XmlDeclaration newDec = doc.CreateXmlDeclaration("1.0",null,null);
      doc.AppendChild(newDec);
      //create the new root element
      XmlElement newRoot = doc.CreateElement("newBookstore");
      doc.AppendChild(newRoot);
```

First, you create a new `XmlDeclaration`. The parameters are the version (always `1.0` for now), the encoding, and the standalone flag. The encoding parameter should be set to a string that is part of the `System.Text.Encoding` class if `null` is not used (`null` defaults to UTF-8). The standalone flag can be either `yes`, `no`, or `null`. If it is `null`, the attribute is not used and will not be included in the document.

The next element that is created will become the `DocumentElement`. In this case, it is called `newBookstore` so that you can see the difference. The rest of the code is the same as in the previous example and works in the same way. This is `booksEdit.xml`, which is generated from the following code:

```
<?xml version="1.0"?>
<newBookstore>
   <book genre="Mystery" publicationdate="2001" ISBN="123456789">
      <title>The Case of the Missing Cookie</title>
      <author>
         <name>C. Monster</name>
      </author>
      <price>9.95</price>
   </book>
</newBookstore>
```

You will want to use the `XmlDocument` class when you want to have random access to the document, or the `XmlReader`-based classes when you want a streaming-type model instead. Remember that there is a cost for the flexibility of the `XmlNode`-based `XmlDocument` class — memory requirements are higher and the performance of reading the document is not as good as when using `XmlReader`. There is another way to traverse an XML document: the `XPathNavigator`.

USING XPATHNAVIGATORS

An `XPathNavigator` is used to select, iterate through, and sometimes edit data from an XML document. An `XPathNavigator` can be created from an `XmlDocument` to allow editing capabilities or from an `XPathDocument` for read-only use. Because the `XPathDocument` is read-only, it performs very well. Unlike the `XmlReader`, the `XPathNavigator` is not a streaming model, so the same document can be used without having to re-read and parse.

The `XPathNavigaor` is part of the `System.Xml.XPath` namespace. XPath is a query language used to select specific nodes or elements from an XML document for processing.

The System.Xml.XPath Namespace

The `System.Xml.XPath` namespace is built for speed. It provides a read-only view of your XML documents, so there are no editing capabilities. Classes in this namespace are built to do fast iteration and selections on the XML document in a cursory fashion.

The following table lists the key classes in `System.Xml.XPath` and gives a short description of the purpose of each class.

CLASS NAME	DESCRIPTION
`XPathDocument`	Provides a view of the entire XML document. Read-only.
`XPathNavigator`	Provides the navigational capabilities to an `XPathDocument`.
`XPathNodeIterator`	Provides iteration capabilities to a node set.
`XPathExpression`	Represents a compiled XPath expression. Used by `SelectNodes`, `SelectSingleNodes`, `Evaluate`, and `Matches`.
`XPathException`	An XPath exception class.

XPathDocument

`XPathDocument` does not offer any of the functionality of the `XmlDocument` class. Its sole purpose is to create `XPathNavigators`. In fact, that is the only method available on the `XPathDocument` class (other than those provided by `Object`).

An `XPathDocument` can be created in a number of different ways. You can pass in an `XmlReader`, a filename of an XML document, or a `Stream`-based object to the constructor. This allows a great deal of flexibility. For example, you can use the `XmlValidatingReader` to validate the XML and then use that same object to create the `XPathDocument`.

XPathNavigator

`XPathNavigator` contains all of the methods for moving and selecting elements that you need. The following table lists some of the "move" methods defined in this class.

METHOD NAME	DESCRIPTION
`MoveTo()`	Takes `XPathNavigator` as a parameter. Moves the current position to be the same as that passed in to `XPathNavigator`.
`MoveToAttribute()`	Moves to the named attribute. Takes the attribute name and namespace as parameters.
`MoveToFirstAttribute()`	Moves to the first attribute in the current element. Returns `true` if successful.
`MoveToNextAttribute()`	Moves to the next attribute in the current element. Returns `true` if successful.
`MoveToFirst()`	Moves to the first sibling in the current node. Returns `true` if successful.
`MoveToLast()`	Moves to the last sibling in the current node. Returns `true` if successful.
`MoveToNext()`	Moves to the next sibling in the current node. Returns `true` if successful.
`MoveToPrevious()`	Moves to the previous sibling in the current node. Returns `true` if successful.
`MoveToFirstChild()`	Moves to the first child of the current element. Returns `true` if successful.
`MoveToId()`	Moves to the element with the ID supplied as a parameter. There needs to be a schema for the document, and the data type for the element must be of type `ID`.
`MoveToParent()`	Moves to the parent of the current node. Returns `true` if successful.
`MoveToRoot()`	Moves to the root node of the document.

To select a subset of the document, you can use one of the `Select` methods listed in the following table.

METHOD NAME	DESCRIPTION
`Select()`	Selects a node set using an XPath expression.
`SelectAncestors()`	Selects all the ancestors of the current node based on an XPath expression.
`SelectChildren()`	Selects all the children of the current node based on an XPath expression.
`SelectDescendants()`	Selects all of the descendants of the current node based on an XPath expression.
`SelectSingleNode()`	Selects one node based on an XPath expression.

If the XPathNavigator was created from an XPathDocument, it is read-only. If it is created from an XmlDocument, the XPathNavigator can be used to edit the document. This can be verified by checking the CanEdit property. If it is true, you can use one of the Insert methods. InsertBefore and InsertAfter will create a new node either before or after the current node. The source of the new node can be from an XmlReader or a string. Optionally, an XmlWriter can be returned and used to write the new node information.

Strongly typed values can be read from the nodes by using the ValueAs properties. Notice that this is different from XmlReader, which used ReadValue methods.

XPathNodeIterator

XPathNodeIterator can be thought of as the equivalent of a NodeList or a NodeSet in XPath. This object has two properties and three methods:

- Clone() — Creates a new copy of itself
- Count — Number of nodes in the XPathNodeIterator object
- Current — Returns an XPathNavigator pointing to the current node
- CurrentPosition() — Returns an integer with the current position
- MoveNext() — Moves to the next node that matches the XPath expression that created the XPathNodeIterator

The XPathNodeIterator is returned by the XPathNavigator Select methods. You use it to iterate over the set of nodes returned by a Select method of the XPathNavigator. Using the MoveNext method of the XPathNodeIterator does not change the location of the XPathNavigator that created it.

Using Classes from the XPath Namespace

The best way to see how these classes are used is to look at some code that iterates through the books.xml document. This will allow you to see how the navigation works. In order to use the examples, you first add a reference to the System.Xml.Xsl and System.Xml.XPath namespaces:

```
using System.Xml.XPath;
using System.Xml.Xsl;
```

For this example, you use the file booksxpath.xml. It is similar to the books.xml file that you have been using, except that there are a couple of extra books added. Here's the form code, which is part of the XmlSample project:

```
private void button1_Click(object sender, EventArgs e)
{
  //modify to match your path structure
  XPathDocument doc = new XPathDocument("books.xml");
  //create the XPath navigator
  XPathNavigator nav = ((IXPathNavigable)doc).CreateNavigator();
  //create the XPathNodeIterator of book nodes
  // that have genre attribute value of novel
  XPathNodeIterator iter = nav.Select("/bookstore/book[@genre='novel']");
  textBox1.Text = "";
  while (iter.MoveNext())
  {
    XPathNodeIterator newIter =
       iter.Current.SelectDescendants(XPathNodeType.Element, false);
    while (newIter.MoveNext())
    {
      textBox1.Text += newIter.Current.Name + ": " +
          newIter.Current.Value + "\r\n";
    }
  }
}
```

code snippet frmNavigator.cs

The first thing you do in the `button1_Click()` method is create the `XPathDocument` (called `doc`), passing in the file and path string of the document you want opened. The next line is where the `XPathNavigator` is created:

```
XPathNavigator nav = doc.CreateNavigator();
```

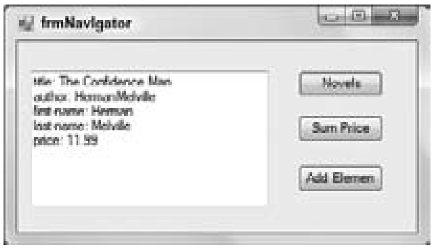
In the example, you can see that you use the `Select()` method to retrieve a set of nodes that all have `novel` as the value of the `genre` attribute. You then use the `MoveNext()` method to iterate through all of the novels in the book list.

To load the data into the list box, you use the `XPathNodeIterator.Current` property. This creates a new `XPathNavigator` object based on just the node that the `XPathNodeIterator` is pointing to. In this case, you are creating an `XPathNavigator` for one `book` node in the document.

The next loop takes this `XPathNavigator` and creates another `XPathNodeIterator` by issuing another type of select method, the `SelectDescendants()` method. This gives you an `XPathNodeIterator` of all of the child nodes and children of the child nodes of the `book` node.

Then, you do another `MoveNext()` loop on the `XPathNodeIterator` and load the text box with the element names and element values.

Figure 33-2 shows what the screen looks like after running the code. Note that novels are the only books listed now.



```
title: The Confidence Man
author: HermanMelville
first name: Herman
last name: Melville
price: 11.99
```

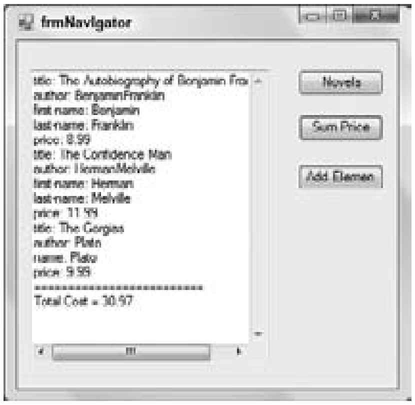
FIGURE 33-2

What if you wanted to add up the cost of these books? `XPathNavigator` includes the `Evaluate()` method for just this reason. `Evaluate()` has three overloads. The first one contains a string that is the XPath function call. The second overload uses the `XPathExpression` object as a parameter, and the third uses `XPathExpression` and an `XPathNodeIterator` as parameters. The following code is similar to the previous example, except that this time all of the nodes in the document are iterated through. The `Evaluate` method call at the end totals up the cost of all of the books:

```
private void button2_Click(object sender, EventArgs e)
{
  //modify to match your path structure
  XPathDocument doc = new XPathDocument("books.xml");
  //create the XPath navigator
  XPathNavigator nav = ((IXPathNavigable)doc).CreateNavigator();
  //create the XPathNodeIterator of book nodes
  XPathNodeIterator iter = nav.Select("/bookstore/book");
  textBox1.Text = "";
  while (iter.MoveNext())
  {
    XPathNodeIterator newIter =
       iter.Current.SelectDescendants(XPathNodeType.Element, false);
    while (newIter.MoveNext())
    {
      textBox1.Text += newIter.Current.Name + ": " + newIter.Current.Value +
          "\r\n";
    }
  }
  textBox1.Text += "========================" + "\r\n";
  textBox1.Text += "Total Cost = " +
      nav.Evaluate("sum(/bookstore/book/price)");
}
```

code snippet frmNavigator.cs

This time, you see the total cost of the books evaluated in the text box (see Figure 33-3).



```
title: The Autobiography of Benjamin Fra
author: BenjaminFranklin
first-name: Benjamin
last-name: Franklin
price: 8.99
title: The Confidence Man
author: HermanMelville
first-name: Herman
last-name: Melville
price: 11.99
title: The Gorgias
author: Plato
name: Plato
price: 9.99
==============================
Total Cost = 30.97
```

FIGURE 33-3

Now let's say that you need to add a node for discount. You can use the `InsertAfter` method to get this done fairly easily. Here is the code:

```
private void button3_Click(object sender, EventArgs e)
{
  XmlDocument doc = new XmlDocument();
  doc.Load("books.xml");
  XPathNavigator nav = doc.CreateNavigator();

  if (nav.CanEdit)
  {
    XPathNodeIterator iter =
       nav.Select("/bookstore/book/price");
    while (iter.MoveNext())
    {
      iter.Current.InsertAfter("<disc>5</disc>");
    }
  }
  doc.Save("newbooks.xml");
}
```

code snippet frmNavigator.cs

Here, you add the `<disc>5</disc>` element after the price elements. First, all of the price nodes are selected. The `XPathNodeIterator` is used to iterate over the nodes, and the new node is inserted. The modified document is saved with a new name, `newbooks.xml`. The new version looks like the following:

```
<?xml version="1.0"?>
<!--This file represents a fragment of a book store inventory database-->
<bookstore>
  <book genre="autobiography" publicationdate="1991" ISBN="1-861003-11-0">
    <title>The Autobiography of Benjamin Franklin</title>
    <author>
      <first-name>Benjamin</first-name>
      <last-name>Franklin</last-name>
    </author>
    <price>8.99</price>
    <disc>5</disc>
  </book>
  <book genre="novel" publicationdate="1967" ISBN="0-201-63361-2">
    <title>The Confidence Man</title>
    <author>
      <first-name>Herman</first-name>
      <last-name>Melville</last-name>
    </author>
    <price>11.99</price>
    <disc>5</disc>
  </book>
  <book genre="philosophy" publicationdate="1991" ISBN="1-861001-57-6">
    <title>The Gorgias</title>
    <author>
      <name>Plato</name>
    </author>
    <price>9.99</price>
    <disc>5</disc>
  </book>
</bookstore>
```

Nodes can be inserted before or after a selected node. The nodes can also be changed, and they can be deleted. If you have changes that have to be done to large numbers of nodes, using the `XPathNavigator` created from an `XmlDocument` may be your best choice.

The System.Xml.Xsl Namespace

The `System.Xml.Xsl` namespace contains the classes that the .NET Framework uses to support XSL transforms. The contents of this namespace are available to any store whose classes implement the `IXPathNavigable` interface. In the .NET Framework, that would currently include `XmlDocument`, `XmlDataDocument`, and `XPathDocument`. Again, just as with XPath, use the store that makes the most sense. If you plan to create a custom store, such as one using the file system and you want to be able to do transforms, be sure to implement the `IXPathNavigable` interface in your class.

XSLT is based on a streaming pull model. Because of this, you can chain several transforms together. You could even apply a custom reader between transforms if needed. This allows a great deal of flexibility in design.

Transforming XML

The first example you will look at takes the `books.xml` document and transforms it into a simple HTML document for display, using the XSLT file `books.xsl`. (This code is in the `XSLSample01` folder.) You will need to add the following `using` statements:

```
using System.IO;
using System.Xml.Xsl;
using System.Xml.XPath;
```

The following is the code to perform the transform:

```
private void button1_Click(object sender, EventArgs e)
{
  XslCompiledTransform trans = new XslCompiledTransform();
  trans.Load("books.xsl");
  trans.Transform("books.xml", "out.html");
  webBrowser1.Navigate(AppDomain.CurrentDomain.BaseDirectory + "out.html");
}
```

code download XslSample01.sln

A transform doesn't get any simpler than this. First, a new `XmlCompiledTransform` object is created. It loads the `books.xsl` transform document and then performs the transform. In this example, a string with the filename is used as the input. The output is `out.html`. This file is then loaded into the web browser control used on the form. Instead of using the filename `books.xml` as the input document, you can use an `IXPathNavigable`-based object. This would be any object that can create an `XPathNavigator`.

After the `XmlCompiledTransform` object is created and the stylesheet is loaded, the transform is performed. The `Transform` method can take just about any combination of `IXPathNavigable objects`, `Streams`, `TextWriters`, `XmlWriters`, and URIs as parameters. This allows a great deal of flexibility on transform flow. You can pass the output of one transform in as the input to the next transform.

`XsltArgumentLists` and `XmlResolver` objects are also included in the parameter options. We look at the `XsltArgumentList` object in the next section. `XmlResolver`-based objects are used to resolve items that are external to the current document. This could be things such as schemas, credentials, or, of course, stylesheets.

The `books.xsl` document is a fairly straightforward stylesheet. The document looks like this:

```
<xsl:stylesheet version="1.0"
 xmlns:xsl="http://www.w3.org/1999/XSL/Transform">
<xsl:template match="/">
   <html>
      <head>
         <title>Price List</title>
         </head>
         <body>
            <table>
               <xsl:apply-templates/>
            </table>
         </body>
      </html>
       </xsl:template>
      <xsl:template match="bookstore">
         <xsl:apply-templates select="book"/>
      </xsl:template>
      <xsl:template match="book">
         <tr><td>
            <xsl:value-of select="title"/>
         </td><td>
            <xsl:value-of select="price"/>
         </td></tr>
      </xsl:template>
   </xsl:stylesheet>
```

Using XsltArgumentList

`XsltArgumentList` is a way that you can bind an object with methods to a namespace. Once this is done, you can invoke the methods during the transform. Here is an example:

```
private void button3_Click(object sender, EventArgs e)
{
  //new XPathDocument
  XPathDocument doc = new XPathDocument("books.xml");
  //new XslTransform
  XslCompiledTransform trans = new XslCompiledTransform();
  trans.Load("booksarg.xsl");
  //new XmlTextWriter since we are creating a new xml document
  XmlWriter xw = new XmlTextWriter("argSample.xml", null);
  //create the XslArgumentList and new BookUtils object
  XsltArgumentList argBook = new XsltArgumentList();
  BookUtils bu = new BookUtils();
  //this tells the argumentlist about BookUtils
  argBook.AddExtensionObject("urn:XslSample", bu);
  //new XPathNavigator
  XPathNavigator nav = doc.CreateNavigator();
  //do the transform
  trans.Transform(nav, argBook, xw);
  xw.Close();
  webBrowser1.Navigate(AppDomain.CurrentDomain.BaseDirectory + "argSample.xml");
}
```

code download XslSample01.sln

The following is the code for the `BooksUtil` class. This is the class that will be called from the transform:

```
class BookUtils
{
  public BookUtils() { }

  public string ShowText()
  {
    return "This came from the ShowText method!";
  }
}
```

code snippet BookUtils.cs

The following is what the output of the transform looks like; the output has been formatted for easier viewing (`argSample.xml`):

```
<books>
   <discbook>
      <booktitle>The Autobiography of Benjamin Franklin</booktitle>
      <showtext>This came from the ShowText method!</showtext>
   </discbook>
   <discbook>
      <booktitle>The Confidence Man</booktitle>
      <showtext>This came from the ShowText method!</showtext>
   </discbook>
   <discbook>
      <booktitle>The Gorgias</booktitle>
      <showtext>This came from the ShowText method!</showtext>
   </discbook>
   <discbook>
      <booktitle>The Great Cookie Caper</booktitle>
      <showtext>This came from the ShowText method!</showtext>
   </discbook>
   <discbook>
      <booktitle>A Really Great Book</booktitle>
      <showtext>This came from the ShowText method!</showtext>
   </discbook>
</books>
```

In this example, you define a new class, `BookUtils`. In this class, you have one rather useless method that returns the string `This came from the ShowText method!` In the `button3_Click()` event, you create the `XPathDocument` and `XslTransform` objects. In a previous example, you loaded the XML document and the transform document directly into the `XslCompiledTransform` object. This time, you will use the `XPathNavigator` to load the documents.

Next, you need to write the following:

```
XsltArgumentList argBook=new XsltArgumentList();
BookUtils bu=new BookUtils();
argBook.AddExtensionObject("urn:XslSample",bu);
```

This is where you create the `XsltArgumentList` object. You create an instance of the `BookUtils` object, and when you call the `AddExtensionObject()` method, you pass in a namespace for your extension and the object that you want to be able to call methods from. When you make the `Transform()` call, you pass in the `XsltArgumentList` (`argBook`), along with the `XPathNavigator` and the `XmlWriter` object you made.

The following is the `booksarg.xsl` document (based on `books.xsl`):

```
<xsl:stylesheet version="1.0" xmlns:xsl="http://www.w3.org/1999/XSL/Transform"
   xmlns:bookUtil="urn:XslSample">
   <xsl:output method="xml" indent="yes"/>

   <xsl:template match="/">
      <xsl:element name="books">
         <xsl:apply-templates/>
      </xsl:element>
   </xsl:template>
   <xsl:template match="bookstore">
      <xsl:apply-templates select="book"/>
   </xsl:template>
   <xsl:template match="book">
      <xsl:element name="discbook">
         <xsl:element name="booktitle">
            <xsl:value-of select="title"/>
         </xsl:element>
         <xsl:element name="showtext">
```

```
            <xsl:value-of select="bookUtil:ShowText()"/>
         </xsl:element>
      </xsl:element>
   </xsl:template>
</xsl:stylesheet>
```

The two important new lines are highlighted. First, you add the namespace that you created when you added the object to `XsltArgumentList`. Then, when you want to make the method call, you use standard XSLT namespace-prefixing syntax and make the method call.

Another way you could have accomplished this is with XSLT scripting. You can include C#, Visual Basic, and JavaScript code in the stylesheet. The great thing about this is that unlike current non-.NET implementations, the script is compiled at the `XslTransform.Load()` call; this way, you are executing already compiled scripts.

Go ahead and modify the previous XSLT file in this way. First, you add the script to the stylesheet. You can see the following changes in `booksscript.xsl`:

```
<xsl:stylesheet version="1.0" xmlns:xsl="http://www.w3.org/1999/XSL/Transform"
                              xmlns:msxsl="urn:schemas-microsoft-com:xslt"
                              xmlns:user="http://wrox.com">

   <msxsl:script language="C#" implements-prefix="user">

      string ShowText()
         {
            return "This came from the ShowText method!";

         }
   </msxsl:script>
   <xsl:output method="xml" indent="yes"/>
      <xsl:template match="/">
   <xsl:element name="books">
      <xsl:apply-templates/>
   </xsl:element>
      </xsl:template>
   <xsl:template match="bookstore">
      <xsl:apply-templates select="book"/>
   </xsl:template>
      <xsl:template match="book">
      <xsl:element name="discbook">
      <xsl:element name="booktitle">
         <xsl:value-of select="title"/>
      </xsl:element>
      <xsl:element name="showtext">
        <xsl:value-of select="user:ShowText()"/>
      </xsl:element>
    </xsl:element>
   </xsl:template>
</xsl:stylesheet>
```

Once again, the changes are highlighted. You set the scripting namespace, add the code (which was copied and pasted in from the Visual Studio .NET IDE), and make the call in the stylesheet. The output looks the same as that of the previous example.

Debugging XSLT

Visual Studio 2010 has the capability to debug transforms. You can actually step through a transform line by line, inspect variables, access the call stack, and set breakpoints just like you were debugging C# source code. You can debug a transform in two ways: by just using the stylesheet and input XML file or by running the application that the transform belongs to.

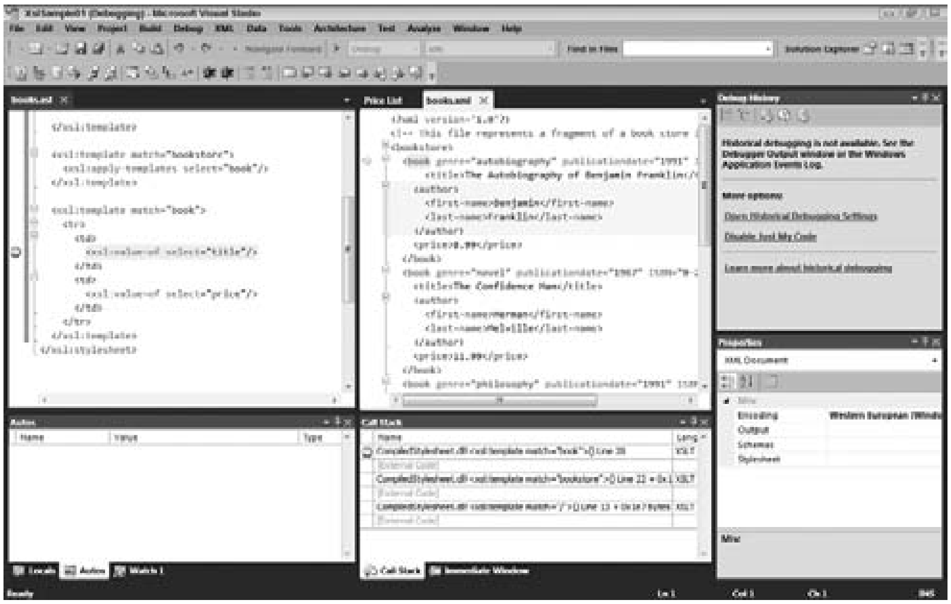
Debugging without the Application

When you first start creating the transforms, sometimes you don't really want to run through the entire application. You just want to get a stylesheet working. Visual Studio 2010 allows you to do this using the XSLT editor.

Load the `books.xsl` stylesheet into the Visual Studio 2010 XSLT editor. Set a breakpoint on the following line:

```
<xsl:value-of select="title"/>
```

Now, select the XML menu and then Debug XSLT. You will be asked for the input XML document. This is the XML that you will want transformed. Now under the default configuration the next thing you will see is in Figure 33-4.



```
  </xsl:template>

  <xsl:template match="bookstore">
    <xsl:apply-templates select="book"/>
  </xsl:template>

  <xsl:template match="book">
    <tr>
      <td>
        <xsl:value-of select="title"/>
      </td>
      <td>
        <xsl:value-of select="price"/>
      </td>
    </tr>
  </xsl:template>
</xsl:stylesheet>
```

```
<?xml version="1.0"?>
<!-- This file represents a fragment of a book store
<bookstore>
  <book genre="autobiography" publicationdate="1991"
    <title>The Autobiography of Benjamin Franklin</t

FIGURE 33-4

Now that the transform has been paused, you can explore almost all of the same debug information you can when debugging source code. Notice that the debugger is showing you the XSLT, the input document with the current element highlighted, and the output of the transform. Now you can step through the transform line by line. If your XSLT had any scripting, you could also set breakpoints in the scripts and have the same debugging experience.

Debugging with the Application

If you want to debug a transform and the application at the same time, then you will have to make one small change when you create the `XslCompiledTransform` object. The constructor has an overload that takes a Boolean as a parameter. This parameter is `enableDebug`. The default is false, which means that even if you have a breakpoint set in the transform, if you run the application code that calls the transform, it will not break. If you set the parameter to true, the debug information for the XSLT is generated and the breakpoint will be hit. Therefore, in the previous example, the line of code that created the `XslCompiledTransform` would change to this:

```
XslCompiledTransform trans = new XslCompiledTransform(true);
```

Now when the application is run in debug mode, even the XSLT will have debug information and you will again have the full Visual Studio debugging experience in your stylesheets.

To summarize, the key thing to keep in mind when performing transforms is to remember to use the proper XML data store. Use `XPathDocument` if you do not need editing capabilities, `XmlDataDocument` if you are getting your data from ADO.NET, and `XmlDocument` if you need to be able to edit the data. In each case, you are dealing with the same process.

XML AND ADO.NET

XML is the glue that binds ADO.NET to the rest of the world. ADO.NET was designed from the ground up to work within the XML environment. XML is used to transfer the data to and from the data store and the application or web page. Because ADO.NET uses XML as the transport in remoting scenarios, data can be exchanged with applications and systems that are not even aware of ADO.NET. Because of the importance of XML in ADO.NET, some powerful features in ADO.NET allow the reading and writing of XML documents. The `System.Xml` namespace also contains classes that can consume or utilize ADO.NET relational data.

The database that is used for the examples is from the AdventureWorksLT sample application. The sample database can be downloaded from `codeplex.com/SqlServerSamples`. Note that there are several versions of the AdventureWorks database. Most will work, but the LT version is the simplified version and is more than adequate for the purposes of this chapter.

Converting ADO.NET Data to XML

The first example uses ADO.NET, streams, and XML to pull some data from the database into a `DataSet`, load an `XmlDocument` object with the XML from the `DataSet`, and load the XML into a text box. To run the next few examples, you need to add the following `using` statements:

```
using System.Data;
using System.Xml;
using System.Data.SqlClient;
using System.IO;
```

The connection string is defined as a module-level variable:

```
string _connectString = "Server=.\\SQLExpress;
                            Database=adventureworkslt;Trusted_Connection=Yes";
```

The ADO.NET samples have a `DataGrid` object added to the forms. This will allow you to see the data in the ADO.NET `DataSet` because it is bound to the grid, as well as the data from the generated XML documents that you load in the text box. Here is the code for the first example. The first step in the examples is to create the standard ADO.NET objects to produce a `DataSet` object. After the data set has been created, it is bound to the grid.

```
private void button1_Click(object sender, EventArgs e)
{
  XmlDocument doc = new XmlDocument();
  DataSet ds = new DataSet("XMLProducts");
  SqlConnection conn = new SqlConnection(_connectString);
  SqlDataAdapter da = new SqlDataAdapter
                  ("SELECT Name, StandardCost FROM SalesLT.Product", conn);
  //fill the dataset
  da.Fill(ds, "Products");
  //load data into grid
  dataGridView1.DataSource = ds.Tables["Products"];
```

code snippet frmADOXML.cs

After you create the ADO.NET objects and bind to the grid, you instantiate a `MemoryStream` object, a `StreamReader` object, and a `StreamWriter` object. The `StreamReader` and `StreamWriter` objects will use the `MemoryStream` to move the XML around:

```
MemoryStream memStrm=new MemoryStream();
StreamReader strmRead=new StreamReader(memStrm);
StreamWriter strmWrite=new StreamWriter(memStrm);
```

You use a `MemoryStream` so that you don't have to write anything to disk; however, you could have used any object that was based on the `Stream` class, such as `FileStream`.

This next step is where the XML is generated. You call the `WriteXml()` method from the `DataSet` class. This method generates an XML document. `WriteXml()` has two overloads: one takes a string with the file path and name, and the other adds a mode parameter. This mode is an `XmlWriteMode` enumeration, with the following possible values:

- `IgnoreSchema`
- `WriteSchema`
- `DiffGram`

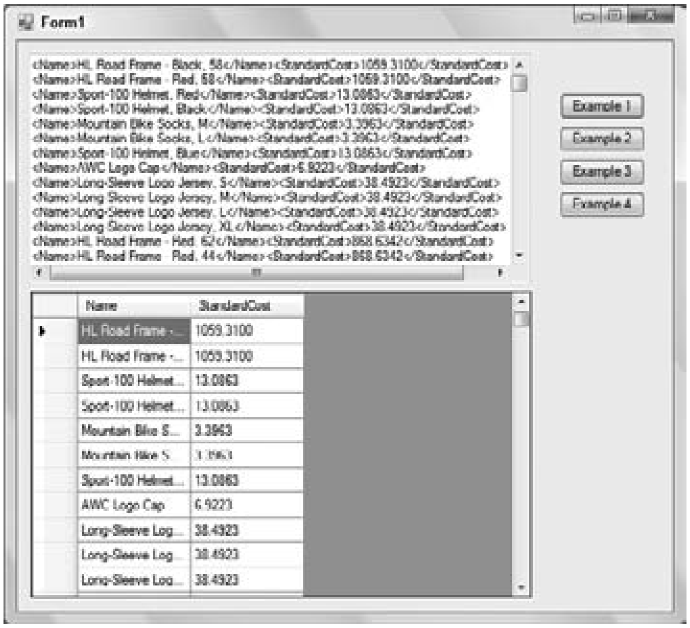
`IgnoreSchema` is used if you do not want `WriteXml()` to write an inline schema at the start of your XML file; use the `WriteSchema` parameter if you do want one. A DiffGram shows the data before and after an edit in a `DataSet`.

```
//write the xml from the dataset to the memory stream
ds.WriteXml(strmWrite, XmlWriteMode.IgnoreSchema);
memStrm.Seek(0, SeekOrigin.Begin);
//read from the memory stream to a XmlDocument object
doc.Load(strmRead);
//get all of the products elements
XmlNodeList nodeLst = doc.SelectNodes("//XMLProducts/Products");
textBox1.Text = "";

foreach (XmlNode node in nodeLst)
{
  textBox1.Text += node.InnerXml + "\r\n";
}
```

code snippet frmADOXML.cs

Figure 33-5 shows the data in the list as well as the bound data grid.



```
<Name>HL Road Frame - Black, 58</Name><StandardCost>1059.3100</StandardCost>
<Name>HL Road Frame - Red, 58</Name><StandardCost>1059.3100</StandardCost>

FIGURE 33-5

If you had wanted only the schema, you could have called `WriteXmlSchema()` instead of `WriteXml()`. This method has four overloads. One takes a string, which is the path and filename of the location where to write the XML document. The second overload uses an object that is based on the `XmlWriter` class. The third overload uses an object based on the `TextWriter` class. The fourth overload is derived from the `Stream` class.

In addition, if you wanted to persist the XML document to disk, you would have used something like this:

```
string file = "c:\\test\\product.xml";
ds.WriteXml(file);
```

This would give you a well-formed XML document on disk that could be read in by another stream or by a `DataSet` or used by another application or web site. Because no `XmlMode` parameter is specified, this `XmlDocument` would have the schema included. In this example, you use the stream as a parameter to the `XmlDocument.Load()` method.

You now have two views of the data, but more importantly, you can manipulate the data using two different models. You can use the `System.Data` namespace to use the data, or you can use the `System.Xml` namespace on the data. This can lead to some very flexible designs in your applications, because now you are not tied to just one object model to program with. This is the real power of the ADO.NET and `System.Xml` combination. You have multiple views of the same data and multiple ways to access the data.

The following example simplifies the process by eliminating the three streams and by using some of the ADO capabilities built into the `System.Xml` namespace. You will need to change the module-level line of code:

```
private XmlDocument doc = new XmlDocument();
```

to:

```
private XmlDataDocument doc;
```

You need this because you are now using the `XmlDataDocument`. Here is the code:

```
private void button3_Click(object sender, EventArgs e)
{
  XmlDataDocument doc;
  //create a dataset
  DataSet ds = new DataSet("XMLProducts");
  //connect to the northwind database and
  //select all of the rows from products table
  SqlConnection conn = new SqlConnection(_connectString);
  SqlDataAdapter da = new SqlDataAdapter
                  ("SELECT Name, StandardCost FROM SalesLT.Product", conn);
  //fill the dataset
  da.Fill(ds, "Products");
  ds.WriteXml("sample.xml", XmlWriteMode.WriteSchema);
  //load data into grid
  dataGridView1.DataSource = ds.Tables[0];
  doc = new XmlDataDocument(ds);
  //get all of the products elements
  XmlNodeList nodeLst = doc.GetElementsByTagName("Products");
  textBox1.Text = "";
  foreach (XmlNode node in nodeLst)
  {
    textBox1.Text += node.InnerXml + "\r\n";
  }
}
```

code snippet frmADOXML.cs

As you can see, the code to load the `DataSet` object into the XML document has been simplified. Instead of using the `XmlDocument` class, you are using the `XmlDataDocument` class. This class was built specifically for using data with a `DataSet` object.

The `XmlDataDocument` is based on the `XmlDocument` class, so it has all of the functionality that the `XmlDocument` class has. One of the main differences is the overloaded constructor that the `XmlDataDocument` has. Note the line of code that instantiates `XmlDataDocument` (`doc`):

```
doc = new XmlDataDocument(ds);
```

It passes in the `DataSet` object that you created, `ds`, as a parameter. This creates the XML document from the `DataSet`, and you do not have to use the `Load()` method. In fact, if you instantiate a new `XmlDataDocument` object without passing in a `DataSet` as the parameter, it will contain a `DataSet` with the name `NewDataSet` that has no `DataTables` in the `tables` collection. There is also a `DataSet` property, which you can set after an `XmlDataDocument`-based object is created.

Suppose that you add the following line of code after the `DataSet.Fill()` call:

```
ds.WriteXml("c:\\test\\sample.xml", XmlWriteMode.WriteSchema);
```

In this case, the following XML file, `sample.xml`, is produced in the folder `c:\test`:

```
<?xml version="1.0" standalone="yes"?>
<XMLProducts>
  <xs:schema id="XMLProducts" xmlns="" xmlns:xs="http://www.w3.org/2001/XMLSchema"
   xmlns:msdata="urn:schemas-microsoft-com:xml-msdata">
    <xs:element name="XMLProducts" msdata:IsDataSet="true"
     msdata:UseCurrentLocale="true">
      <xs:complexType>
        <xs:choice minOccurs="0" maxOccurs="unbounded">
          <xs:element name="Products">
            <xs:complexType>
              <xs:sequence>
                <xs:element name="Name" type="xs:string" minOccurs="0" />
                <xs:element name="StandardCost" type="xs:decimal" minOccurs="0" />
              </xs:sequence>
            </xs:complexType>
          </xs:element>
        </xs:choice>
      </xs:complexType>
    </xs:element>
  </xs:schema>
  <Products>
    <Name>HL Road Frame-Black, 58</Name>
    <StandardCost>1059.3100</StandardCost>
  </Products>
  <Products>
    <Name>HL Road Frame-Red, 58</Name>
    <StandardCost>1059.3100</StandardCost>
  </Products>
  <Products>
    <Name>Sport-100 Helmet, Red</Name>
    <StandardCost>13.0863</StandardCost>
  </Products>
</XMLProducts>
```

Only the first couple of `Products` elements are shown. The actual XML file would contain all of the products in the Products table of Northwind database.

Converting Relational Data

This looks simple enough for a single table, but what about relational data, such as multiple `DataTables` and `Relations` in the `DataSet`? It all still works the same way. Here is an example using two related tables:

```
private void button5_Click(object sender, EventArgs e)
{
  XmlDocument doc = new XmlDocument();
  DataSet ds = new DataSet("XMLProducts");
  SqlConnection conn = new SqlConnection(_connectString);
```

```
      SqlDataAdapter daProduct = new SqlDataAdapter
      ("SELECT Name, StandardCost, ProductCategoryID FROM SalesLT.Product", conn);
      SqlDataAdapter daCategory = new SqlDataAdapter
            ("SELECT ProductCategoryID, Name from SalesLT.ProductCategory", conn);
      //Fill DataSet from both SqlAdapters
      daProduct.Fill(ds, "Products");
      daCategory.Fill(ds, "Categories");
      //Add the relation
      ds.Relations.Add(ds.Tables["Categories"].Columns["ProductCategoryID"],
      ds.Tables["Products"].Columns["ProductCategoryID"]);
      //Write the Xml to a file so we can look at it later
      ds.WriteXml("Products.xml", XmlWriteMode.WriteSchema);
      //load data into grid
      dataGridView1.DataSource = ds.Tables[0];
      //create the XmlDataDocument
      doc = new XmlDataDocument(ds);
      //Select the productname elements and load them in the grid
      XmlNodeList nodeLst = doc.SelectNodes("//XMLProducts/Products");
      textBox1.Text = "";
      foreach (XmlNode node in nodeLst)
      {
        textBox1.Text += node.InnerXml + "\r\n";
      }
    }
```

code snippet frmADOXML.cs

In the sample you are creating, there are two `DataTables` in the `XMLProducts DataSet`: `Products` and `Categories`. You create a new relation on the `ProductCategoryID` column in both tables.

By using the same `WriteXml()` method call that you did in the previous example, you will get the following XML file (`SuppProd.xml`):

```
<?xml version="1.0" standalone="yes"?>
<XMLProducts>
  <xs:schema id="XMLProducts" xmlns="" xmlns:xs="http://www.w3.org/2001/XMLSchema"
   xmlns:msdata="urn:schemas-microsoft-com:xml-msdata">
    <xs:element name="XMLProducts" msdata:IsDataSet="true"
     msdata:UseCurrentLocale="true">
      <xs:complexType>
        <xs:choice minOccurs="0" maxOccurs="unbounded">
          <xs:element name="Products">
            <xs:complexType>
              <xs:sequence>
                <xs:element name="Name" type="xs:string" minOccurs="0" />
                <xs:element name="StandardCost" type="xs:decimal" minOccurs="0" />
                <xs:element name="ProductCategoryID" type="xs:int" minOccurs="0" />
              </xs:sequence>
            </xs:complexType>
          </xs:element>
          <xs:element name="Categories">
            <xs:complexType>
              <xs:sequence>
                <xs:element name="ProductCategoryID" type="xs:int" minOccurs="0" />
                <xs:element name="Name" type="xs:string" minOccurs="0" />
              </xs:sequence>
            </xs:complexType>
          </xs:element>
        </xs:choice>
      </xs:complexType>
      <xs:unique name="Constraint1">
        <xs:selector xpath=".//Categories" />
        <xs:field xpath="ProductCategoryID" />
      </xs:unique>
      <xs:keyref name="Relation1" refer="Constraint1">
        <xs:selector xpath=".//Products" />
        <xs:field xpath="ProductCategoryID" />
      </xs:keyref>
    </xs:element>
  </xs:schema>
  <Products>
    <Name>HL Road Frame-Black, 58</Name>
    <StandardCost>1059.3100</StandardCost>
    <ProductCategoryID>18</ProductCategoryID>
  </Products>
  <Products>
    <Name>HL Road Frame-Red, 58</Name>
    <StandardCost>1059.3100</StandardCost>
    <ProductCategoryID>18</ProductCategoryID>
  </Products>
</XMLProducts>
```

The schema includes both `DataTable`s that were in the `DataSet`. In addition, the data includes all of the data from both tables. For the sake of brevity, only the first `Products` and `ProductCategory` records are shown here. As before, you could have saved just the schema or just the data by passing in the correct `XmlWriteMode` parameter.

Converting XML to ADO.NET Data

Suppose that you have an XML document that you would like to get into an ADO.NET `DataSet`. You would want to do this so that you could load the XML into a database, or perhaps bind the data to a .NET data control such as a `DataGrid`. This way, you could actually use the XML document as your data store and eliminate the overhead of the database altogether. If your data is reasonably small, this is an attractive possibility. Here is some code to get you started:

```
private void button7_Click(object sender, EventArgs e)
{
   //create the DataSet
   DataSet ds = new DataSet("XMLProducts");

   //read in the xml document
   ds.ReadXml("Products.xml");

   //load data into grid
   dataGridView1.DataSource = ds.Tables[0];

   textBox1.Text = "";

   foreach (DataTable dt in ds.Tables)
   {
      textBox1.Text += dt.TableName + "\r\n";
      foreach (DataColumn col in dt.Columns)
      {
         textBox1.Text += "\t" + col.ColumnName + "-" + col.DataType.FullName + "\r\n";
      }
   }
}
```

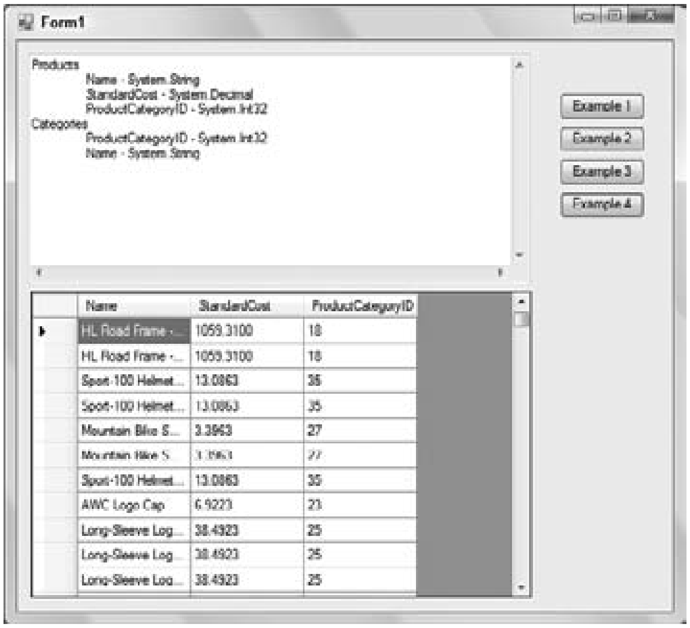
code snippet frmADOXML.cs

It's that easy. In this example, you instantiate a new `DataSet` object. From there, you then call the `ReadXml()` method and you have XML in a `DataTable` in your `DataSet`. As with the `WriteXml()` methods, `ReadXml()` has an `XmlReadMode` parameter. `ReadXml()` has a few more options in the `XmlReadMode`, as shown in the following table.

VALUE	DESCRIPTION
`Auto`	Sets the `XmlReadMode` to the most appropriate setting. If the data is in `DiffGram` format, `DiffGram` is selected. If a schema has already been read, or an inline schema is detected, then `ReadSchema` is selected. If no schema has been assigned to the `DataSet`, and none is detected inline, then `IgnoreSchema` is selected.
`DiffGram`	Reads in the `DiffGram` and applies the changes to the `DataSet`.
`Fragment`	Reads documents that contain XDR schema fragments, such as the type created by SQL Server.
`IgnoreSchema`	Ignores any inline schema that may be found. Reads data into the current `DataSet` schema. If data does not match `DataSet` schema, it is discarded.
`InferSchema`	Ignores any inline schema. Creates the schema based on data in the XML document. If a schema exists in the `DataSet`, that schema is used, and extended with additional columns and tables if needed. An exception is thrown if a column exists but is of a different data type.
`ReadSchema`	Reads the inline schema and loads the data. Will not overwrite a schema in the `DataSet` but will throw an exception if a table in the inline schema already exists in the `DataSet`.

There is also the `ReadXmlSchema()` method. This reads in a standalone schema and creates the tables, columns, and relations. You use this if your schema is not inline with your data. `ReadXmlSchema()` has the same four overloads: a string with filename and pathname, a `Stream`-based object, a `TextReader`-based object, and an `XmlReader`-based object.

To show that the data tables are being created properly, we iterate through the tables and columns and display the names in the text box. You can compare this to the database and see that all is well. The last `foreach` loops perform this task. Figure 33-6 shows the output.



```
Products

FIGURE 33-6

Looking at the list box, you can check that in the data tables that were created all the columns have the correct names and data types.

Something else you might want to note is that, because the previous two examples did not transfer any data to or from a database, no `SqlDataAdapter` or `SqlConnection` was defined. This shows the real flexibility of both the `System.Xml` namespace and ADO.NET: you can look at the same data in multiple formats. If you need to do a transform and show the data in HTML format, or if you need to bind the data to a grid, you can take the same data and, with just a method call, have it in the required format.

SERIALIZING OBJECTS IN XML

Serializing is the process of persisting an object to disk. Another part of your application, or even a separate application, can deserialize the object, and it will be in the same state it was in prior to serialization. The .NET Framework includes a couple of ways to do this.

This section looks at the `System.Xml.Serialization` namespace, which contains classes used to serialize objects into XML documents or streams. This means that an object's public properties and public fields are converted into XML elements, attributes, or both.

The most important class in the `System.Xml.Serialization` namespace is `XmlSerializer`. To serialize an object, you first need to instantiate an `XmlSerializer` object, specifying the type of the object to serialize. Then you need to instantiate a stream/writer object to write the file to a stream/document. The final step is to call the `Serialize()` method on the `XMLSerializer`, passing it the stream/writer object and the object to serialize.

Data that can be serialized can be primitive types, fields, arrays, and embedded XML in the form of `XmlElement` and `XmlAttribute` objects.

To deserialize an object from an XML document, you reverse the process in the previous example. You create a stream/reader and an `XmlSerializer` object and then pass the stream/reader to the `Deserialize()` method. This method returns the deserialized object, although it needs to be cast to the correct type.

The XML serializer cannot convert private data, only public data, and it cannot serialize object graphs. However, these should not be serious limitations; by carefully designing your classes, you should be able to easily avoid these issues. If you do need to be able to serialize public and private data as well as an object graph containing many nested objects, you will want to use the `System.Runtime.Serialization.Formatters.Binary` *namespace.*

Some of the other tasks that you can accomplish with `System.Xml.Serialization` classes are:

- ➤ Determine if the data should be an attribute or element
- ➤ Specify the namespace
- ➤ Change the attribute or element name

The links between your object and the XML document are the custom C# attributes that annotate your classes. These attributes are what are used to inform the serializer how to write out the data. The `xsd.exe` tool, which is included with the .NET Framework, can help create these attributes for you. `xsd.exe` can do the following:

- ➤ Generate an XML schema from an XDR schema file
- ➤ Generate an XML schema from an XML file

- Generate DataSet classes from an XSD schema file
- Generate runtime classes that have the custom attributes for XmlSerialization
- Generate an XSD file from classes that you have already developed
- Limit which elements are created in code
- Determine which programming language the generated code should be in (C#, Visual Basic .NET, or JScript .NET)
- Create schemas from types in compiled assemblies

You should refer to the Framework documentation for details of command-line options for xsd.exe.

Despite these capabilities, you don't *have* to use xsd.exe to create the classes for serialization. The process is quite simple. The following is a simple application that serializes a class. At the beginning of the example, you have very simple code that creates a new Product object, pd, and fills it with some data:

```
private void button1_Click(object sender, EventArgs e)
{
  //new products object
  Product pd = new Product();
  //set some properties
  pd.ProductID = 200;
  pd.CategoryID = 100;
  pd.Discontinued = false;
  pd.ProductName = "Serialize Objects";
  pd.QuantityPerUnit = "6";
  pd.ReorderLevel = 1;
  pd.SupplierID = 1;
  pd.UnitPrice = 1000;
  pd.UnitsInStock = 10;
  pd.UnitsOnOrder = 0;

}
```

code snippet frmSerial.cs

The Serialize() method of the XmlSerializer class actually performs the serialization, and it has nine overloads. One of the parameters required is a stream to write the data to. It can be a Stream, TextWriter, or an XmlWriter parameter. In the example, you create a TextWriter-based object, tr. The next thing to do is to create the XmlSerializer-based object, sr. The XmlSerializer needs to know type information for the object that it is serializing, so you use the typeof keyword with the type that is to be serialized. After the sr object is created, you call the Serialize() method, passing in the tr (Stream-based object) and the object that you want serialized, in this case pd. Be sure to close the stream when you are finished with it:

```
  //new TextWriter and XmlSerializer
  TextWriter tr = new StreamWriter("serialprod.xml");
  XmlSerializer sr = new XmlSerializer(typeof(Product));
  //serialize object
  sr.Serialize(tr, pd);
  tr.Close();
  webBrowser1.Navigate(AppDomain.CurrentDomain.BaseDirectory + "serialprod.xml");
```

code snippet frmSerial.cs

Next is the Product class, the class to be serialized. The only differences between this and any other class that you may write are the C# attributes that have been added. The XmlRootAttribute and XmlElementAttribute classes in the attributes inherit from the System.Attribute class. Don't confuse these attributes with the attributes in an XML document. A C# attribute is simply some declarative information that can be retrieved at runtime by the CLR (see Chapter 8, "Delegates, Lambdas, and Events," for more details). In this case, the attributes describe how the object should be serialized:

```
//class that will be serialized.
//attributes determine how object is serialized
[System.Xml.Serialization.XmlRootAttribute()]
  public class Product {
    private int prodId;
    private string prodName;
    private int suppId;
    private int catId;
    private string qtyPerUnit;
    private Decimal unitPrice;
    private short unitsInStock;
    private short unitsOnOrder;
    private short reorderLvl;
    private bool discont;
    private int disc;
    //added the Discount attribute
    [XmlAttributeAttribute(AttributeName="Discount")]
    public int Discount {
      get {return disc;}
      set {disc=value;}
    }
    [XmlElementAttribute()]
    public int  ProductID {
      get {return prodId;}
      set {prodId=value;}
    }
    [XmlElementAttribute()]
    public string ProductName {
      get {return prodName;}
      set {prodName=value;}
    }
    [XmlElementAttribute()]
    public int SupplierID {
      get {return suppId;}
      set {suppId=value;}
    }
    [XmlElementAttribute()]
    public int CategoryID {
      get {return catId;}
      set {catId=value;}
    }
    [XmlElementAttribute()]
    public string QuantityPerUnit {
      get {return qtyPerUnit;}
      set {qtyPerUnit=value;}
    }
    [XmlElementAttribute()]
    public Decimal UnitPrice {
      get {return unitPrice;}
      set {unitPrice=value;}
    }
    [XmlElementAttribute()]
    public short UnitsInStock {
      get {return unitsInStock;}
      set {unitsInStock=value;}
    }
    [XmlElementAttribute()]
    public short UnitsOnOrder {
      get {return unitsOnOrder;}
```

```
        set {unitsOnOrder=value;}
      }
      [XmlElementAttribute()]
      public short ReorderLevel {
        get {return reorderLvl;}
        set {reorderLvl=value;}
      }
      [XmlElementAttribute()]
      public bool Discontinued {
        get {return discont;}
        set {discont=value;}
      }
      public override string ToString()
      {
        StringBuilder outText = new StringBuilder();
        outText.Append(prodId);
        outText.Append(" ");
        outText.Append(prodName);
        outText.Append(" ");
        outText.Append(unitPrice);
        return outText.ToString();
      }
    }
```

code snippet frmSerial.cs

The `XmlRootAttribute()` invocation in the attribute above the `Products` class definition identifies this class as a root element (in the XML file produced upon serialization). The attribute containing `XmlElementAttribute()` identifies that the member below the attribute represents an XML element.

You will also notice that the `ToString()` method has been overridden. This provides the string that the message box will show when you run the deserialize example.

If you look at the XML document created during serialization, you will see that it looks like any other XML document that you might have created, which is the point of the exercise:

```
<?xml version="1.0" encoding="utf-8"?>
<Products xmlns:xsi=http://www.w3.org/2001/XMLSchema-instance
  xmlns:xsd="http://www.w3.org/2001/XMLSchema"
  Discount="0">
  <ProductID>200</ProductID>
  <ProductName>Serialize Objects</ProductName>
  <SupplierID>1</SupplierID>
  <CategoryID>100</CategoryID>
  <QuantityPerUnit>6</QuantityPerUnit>
  <UnitPrice>1000</UnitPrice>
  <UnitsInStock>10</UnitsInStock>
  <UnitsOnOrder>0</UnitsOnOrder>
  <ReorderLevel>1</ReorderLevel>
  <Discontinued>false</Discontinued>
</Products>
```

There is nothing out of the ordinary here. You could use this any way that you would use an XML document. You could transform it and display it as HTML, load it into a `DataSet` using ADO.NET, load an `XmlDocument` with it, or, as you can see in the example, deserialize it and create an object in the same state that `pd` was in prior to serializing it (which is exactly what you're doing with the second button).

Next, you add another button event handler to deserialize a new `Products`-based object, `newPd`. This time you use a `FileStream` object to read in the XML:

```
private void button2_Click(object sender, EventArgs e)
    {
      //create a reference to product type
```

```
        Product newPd;
        //new filestream to open serialized object
        FileStream f = new FileStream("serialprod.xml", FileMode.Open);
```

Once again, you create a new `XmlSerializer`, passing in the type information of `Product`. You can then make the call to the `Deserialize()` method. Note that you still need to do an explicit cast when you create the `newPd` object. At this point, `newPd` is in exactly the same state that `pd` was:

```
        //new serializer
        XmlSerializer newSr = new XmlSerializer(typeof(Product));
        //deserialize the object
        newPd = (Product)newSr.Deserialize(f);
        f.Close();
        MessageBox.Show(newPd.ToString());
      }
```

code snippet frmSerial.cs

The message box should show you the product ID, product name, and the unit price of the object you just deserialized. This comes from the `ToString()` override that you implemented in the `Product` class.

What about situations where you have derived classes and possibly properties that return an array? `XmlSerializer` has that covered as well. Here's a slightly more complex example that deals with these issues.

First, you define three new classes, `Product`, `BookProduct` (derived from `Product`), and `Inventory` (which contains both of the other classes). Notice that once again you have overridden the `ToString()` method. This time you're just going to list the items in the `Inventory` class:

```
public class BookProduct: Product
{
   private string isbnNum;
   public BookProduct() {}
   public string ISBN
   {
      get {return isbnNum;}
      set {isbnNum=value;}
   }
}

public class Inventory
{
   private Product[] stuff;
   public Inventory() {}
   //need to have an attribute entry for each data type
   [XmlArrayItem("Prod",typeof(Product)),
   XmlArrayItem("Book",typeof(BookProduct))]
   public Product[] InventoryItems
   {
      get {return stuff;}
      set {stuff=value;}
   }
   public override string ToString()
   {
     StringBuilder outText = new StringBuilder();
     foreach (Product prod in stuff)
     {
       outText.Append(prod.ProductName);
       outText.Append("\r\n");
     }
     return outText.ToString();
   }
}
```

code snippet frmSerial.cs

The Inventory class is the one of interest here. If you are to serialize this class, you need to insert an attribute containing XmlArrayItem constructors for each type that can be added to the array. You should note that XmlArrayItem is the name of the .NET attribute represented by the XmlArrayItemAttribute class.

The first parameter supplied to these constructors is what you would like the element name to be in the XML document that is created during serialization. If you leave off the ElementName parameter, the elements will be given the same name as the object type (Product and BookProduct in this case). The second parameter that must be specified is the type of the object.

There is also an XmlArrayAttribute class that you would use if the property were returning an array of objects or primitive types. Because you are returning different types in the array, you use XmlArrayItemAttribute, which allows the higher level of control.

In the button4_Click() event handler, you create a new Product object and a new BookProduct object (newProd and newBook). You add data to the various properties of each object, and add the objects to a Product array. You next create a new Inventory object and pass in the array as a parameter. You can then serialize the Inventory object to recreate it later:

```
private void button4_Click(object sender, EventArgs e)
{
  //create the XmlAttributes object
  XmlAttributes attrs = new XmlAttributes();
  //add the types of the objects that will be serialized
  attrs.XmlElements.Add(new XmlElementAttribute("Book", typeof(BookProduct)));
  attrs.XmlElements.Add(new XmlElementAttribute("Product", typeof(Product)));
  XmlAttributeOverrides attrOver = new XmlAttributeOverrides();
  //add to the attributes collection
  attrOver.Add(typeof(Inventory), "InventoryItems", attrs);
  //create the Product and Book objects
  Product newProd = new Product();
  BookProduct newBook = new BookProduct();
  newProd.ProductID = 100;
  newProd.ProductName = "Product Thing";
  newProd.SupplierID = 10;
  newBook.ProductID = 101;
  newBook.ProductName = "How to Use Your New Product Thing";
  newBook.SupplierID = 10;
  newBook.ISBN = "123456789";
  Product[] addProd ={ newProd, newBook };
  Inventory inv = new Inventory();
  inv.InventoryItems = addProd;
  TextWriter tr = new StreamWriter("inventory.xml");
  XmlSerializer sr = new XmlSerializer(typeof(Inventory), attrOver);
  sr.Serialize(tr, inv);
  tr.Close();
  webBrowser1.Navigate(AppDomain.CurrentDomain.BaseDirectory + "inventory.xml");
}
```

code snippet frmSerial.cs

The XML document looks like this:

```
<?xml version="1.0" encoding="utf-8"?>
<Inventory xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xmlns:xsd="http://www.w3.org/2001/XMLSchema">
  <Product Discount="0">
    <ProductID>100</ProductID>
    <ProductName>Product Thing</ProductName>
    <SupplierID>10</SupplierID>
    <CategoryID>0</CategoryID>
    <UnitPrice>0</UnitPrice>
```

```
      <UnitsInStock>0</UnitsInStock>
      <UnitsOnOrder>0</UnitsOnOrder>
      <ReorderLevel>0</ReorderLevel>
      <Discontinued>false</Discontinued>
    </Product>
    <Book Discount="0">
      <ProductID>101</ProductID>
      <ProductName>How to Use Your New Product Thing</ProductName>
      <SupplierID>10</SupplierID>
      <CategoryID>0</CategoryID>
      <UnitPrice>0</UnitPrice>
      <UnitsInStock>0</UnitsInStock>
      <UnitsOnOrder>0</UnitsOnOrder>
      <ReorderLevel>0</ReorderLevel>
      <Discontinued>false</Discontinued>
      <ISBN>123456789</ISBN>
    </Book>
  </Inventory>
```

The `button2_Click()` event handler implements deserialization of the `Inventory` object. Note that you iterate through the array in the newly created `newInv` object to show that it is the same data:

```
private void button2_Click(object sender, System.EventArgs e)
{
   Inventory newInv;
   FileStream f=new FileStream("order.xml",FileMode.Open);
   XmlSerializer newSr=new XmlSerializer(typeof(Inventory));
   newInv=(Inventory)newSr.Deserialize(f);
   foreach(Product prod in newInv.InventoryItems)
      listBox1.Items.Add(prod.ProductName);
   f.Close();
}
```

Serialization without Source Code Access

Well, this all works great, but what if you don't have access to the source code for the types that are being serialized? You can't add the attribute if you don't have the source. There is another way. You can use the `XmlAttributes` class and the `XmlAttributeOverrides` class. Together these classes enable you to accomplish exactly what you have just done, but without adding the attributes. This section looks at an example of how this works.

For this example, imagine that the `Inventory`, `Product`, and derived `BookProduct` classes are in a separate DLL and that you do not have the source. The `Product` and `BookProduct` classes are the same as in the previous example, but you should note that there are now no attributes added to the `Inventory` class:

```
public class Inventory
{
   private Product[] stuff;
   public Inventory() {}
   public Product[] InventoryItems
   {
      get {return stuff;}
      set {stuff=value;}
   }
}
```

code snippet frmSerial.cs

Next, you deal with the serialization in the `button1_Click()` event handler:

```
private void button1_Click(object sender, System.EventArgs e)
{
```

The first step in the serialization process is to create an `XmlAttributes` object and an `XmlElementAttribute` object for each data type that you will be overriding:

```
    XmlAttributes attrs=new XmlAttributes();
    attrs.XmlElements.Add(new XmlElementAttribute("Book",typeof(BookProduct)));
    attrs.XmlElements.Add(new XmlElementAttribute("Product",typeof(Product)));
```

Here you can see that you are adding new `XmlElementAttribute` objects to the `XmlElements` collection of the `XmlAttributes` class. The `XmlAttributes` class has properties that correspond to the attributes that can be applied; `XmlArray` and `XmlArrayItems`, which you looked at in the previous example, are just a couple of these. You now have an `XmlAttributes` object with two `XmlElementAttribute`-based objects added to the `XmlElements` collection.

The next thing you have to do is create an `XmlAttributeOverrides` object:

```
    XmlAttributeOverrides attrOver=new XmlAttributeOverrides();
    attrOver.Add(typeof(Inventory),"InventoryItems",attrs);
```

The `Add()` method of this class has two overloads. The first one takes the type information of the object to override and the `XmlAttributes` object that you created earlier. The other overload, which is the one you are using, also takes a string value that is the member in the overridden object. In this case, you want to override the `InventoryItems` member in the `Inventory` class.

When you create the `XmlSerializer` object, you add the `XmlAttributeOverrides` object as a parameter. Now the `XmlSerializer` knows which types you want to override and what you need to return for those types:

```
    //create the Product and Book objects
    Product newProd=new Product();
    BookProduct newBook=new BookProduct();
    newProd.ProductID=100;
    newProd.ProductName="Product Thing";
    newProd.SupplierID=10;
    newBook.ProductID=101;
    newBook.ProductName="How to Use Your New Product Thing";
    newBook.SupplierID=10;
    newBook.ISBN="123456789";
    Product[] addProd={newProd,newBook};

    Inventory inv=new Inventory();
    inv.InventoryItems=addProd;
    TextWriter tr=new StreamWriter("inventory.xml");
    XmlSerializer sr=new XmlSerializer(typeof(Inventory),attrOver);
    sr.Serialize(tr,inv);
    tr.Close();
}
```

code snippet frmSerial.cs

If you execute the `Serialize()` method, you get this XML output:

```
<?xml version="1.0" encoding="utf-8"?>
<Inventory xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xmlns:xsd="http://www.w3.org/2001/XMLSchema">
  <Product Discount="0">
    <ProductID>100</ProductID>
    <ProductName>Product Thing</ProductName>
    <SupplierID>10</SupplierID>
    <CategoryID>0</CategoryID>
    <UnitPrice>0</UnitPrice>
    <UnitsInStock>0</UnitsInStock>
    <UnitsOnOrder>0</UnitsOnOrder>
    <ReorderLevel>0</ReorderLevel>
    <Discontinued>false</Discontinued>
  </Product>
```

```
    <Book Discount="0">
      <ProductID>101</ProductID>
      <ProductName>How to Use Your New Product Thing</ProductName>
      <SupplierID>10</SupplierID>
      <CategoryID>0</CategoryID>
      <UnitPrice>0</UnitPrice>
      <UnitsInStock>0</UnitsInStock>
      <UnitsOnOrder>0</UnitsOnOrder>
      <ReorderLevel>0</ReorderLevel>
      <Discontinued>false</Discontinued>
      <ISBN>123456789</ISBN>
    </Book>
  </Inventory>
```

As you can see, you get the same XML as you did with the earlier example. To deserialize this object and recreate the `Inventory`-based object that you started out with, you need to create all of the same `XmlAttributes`, `XmlElementAttribute`, and `XmlAttributeOverrides` objects that you created when you serialized the object. After you do that, you can read in the XML and recreate the `Inventory` object just as you did before. Here is the code to deserialize the `Inventory` object:

```
private void button2_Click(object sender, System.EventArgs e)
{
   //create the new XmlAttributes collection
   XmlAttributes attrs=new XmlAttributes();
   //add the type information to the elements collection
   attrs.XmlElements.Add(new XmlElementAttribute("Book",typeof(BookProduct)));
   attrs.XmlElements.Add(new XmlElementAttribute("Product",typeof(Product)));

   XmlAttributeOverrides attrOver=new XmlAttributeOverrides();
   //add to the Attributes collection
   attrOver.Add(typeof(Inventory),"InventoryItems",attrs);

   //need a new Inventory object to deserialize to
   Inventory newInv;

   //deserialize and load data into the listbox from deserialized object
   FileStream f=new FileStream(".\\.\\.\\inventory.xml",FileMode.Open);
   XmlSerializer newSr=new XmlSerializer(typeof(Inventory),attrOver);

   newInv=(Inventory)newSr.Deserialize(f);
   if(newInv!=null)
   {
      foreach(Product prod in newInv.InventoryItems)
      {
         listBox1.Items.Add(prod.ProductName);
      }
   }
   f.Close();
}
```

Note that the first few lines of code are identical to the code you used to serialize the object.

The `System.Xml.XmlSerialization` namespace provides a very powerful tool set for serializing objects to XML. By serializing and deserializing objects to XML instead of to binary format, you are given the option of doing something else with this XML, greatly adding to the flexibility of your designs.

LINQ TO XML AND .NET

With the introduction of LINQ to the .NET Framework, the focus was on easy access to the data that you want to use in your applications. One of the main data stores in the application space is XML and, therefore, it really was a natural evolution to create the LINQ to XML implementation.

Prior to the LINQ to XML release, working with XML using `System.Xml` was not an easy task. With the inclusion of `System.Xml.Linq`, you now find a series of capabilities that make the process of working with XML in your code much easier.

Many developers previously turned to the `XmlDocument` object to create XML within their application code. This object allows you to create XML documents that enable you to append elements, attributes, and other items in a hierarchical fashion. With LINQ to XML and the inclusion of the new `System.Xml.Linq` namespace, you will now find some new objects that make the creation of XML documents a much simpler process.

WORKING WITH DIFFERENT XML OBJECTS

In addition to the LINQ querying ability included in .NET 4, the .NET Framework includes XML objects that work so well they can stand on their own outside of LINQ. You can use these objects in place of working directly with the DOM in this release. Within the `System.Xml.Linq` namespace, you will find a series of LINQ to XML helper objects that make working with an XML document in memory much easier.

The following sections work through the objects that are available to you within this namespace.

XDocument

The `XDocument` is a replacement of the `XmlDocument` object from the pre-.NET 3.5 world; it is easier to work with in dealing with XML documents. The `XDocument` object works with the other new objects in this space, such as the `XNamespace`, `XComment`, `XElement`, and `XAttribute` objects.

One of the more important members of the `XDocument` object is the `Load()` method:

```
XDocument xdoc = XDocument.Load(@"C:\Hamlet.xml");
```

This operation will load the `Hamlet.xml` contents as an in-memory `XDocument` object. You can also pass a `TextReader` or `XmlReader` object into the `Load()` method. From here, you are able to programmatically work with the XML:

```
XDocument xdoc = XDocument.Load(@"C:\Hamlet.xml");
Console.WriteLine(xdoc.Root.Name.ToString());
Console.WriteLine(xdoc.Root.HasAttributes.ToString());
```

code download ConsoleApplication1.sln

This produces the following results:

```
PLAY
False
```

Another important member to be aware of is the `Save()` method, which, like the `Load()` method, allows you to save to a physical disk location or to a `TextWriter` or `XmlWriter` object:

```
XDocument xdoc = XDocument.Load(@"C:\Hamlet.xml");

xdoc.Save(@"C:\CopyOfHamlet.xml");
```

XElement

One object that you will work with frequently is the `XElement` object. With `XElement` objects, you can easily create single-element objects that are XML documents themselves, as well as fragments of XML. For instance, here is an example of writing an XML element with a corresponding value:

```
XElement xe = new XElement("Company", "Lipper");
Console.WriteLine(xe.ToString());
```

In the creation of a `XElement` object, you can define the name of the element as well as the value used in the element. In this case, the name of the element will be `<Company>`, and the value of the `<Company>` element will be `Lipper`. Running this in a console application with a `System.Xml.Linq` reference produces the following result:

```
<Company>Lipper</Company>
```

You can create an even more complete XML document using multiple `XElement` objects, as illustrated in the following example:

```
using System;
using System.Linq;
using System.Xml.Linq;

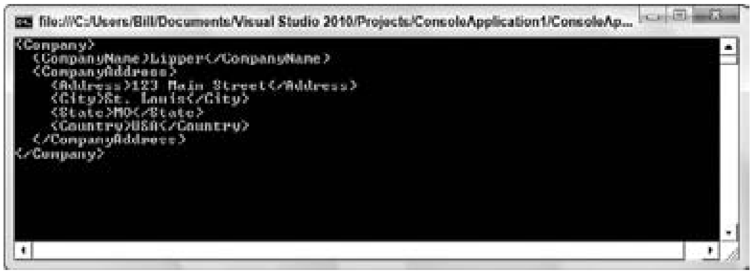
namespace ConsoleApplication1
{
    class Class1
    {
        static void Main()
        {
            XElement xe = new XElement("Company",
                new XElement("CompanyName", "Lipper"),
                new XElement("CompanyAddress",
                    new XElement("Address", "123 Main Street"),
                    new XElement("City", "St. Louis"),
                    new XElement("State", "MO"),
                    new XElement("Country", "USA")));

            Console.WriteLine(xe.ToString());

            Console.ReadLine();
        }
    }
}
```

code download ConsoleApplication1.sln

Running this application produces the results illustrated in Figure 33-7.



file:///C:/Users/Bill/Documents/Visual Studio 2010/Projects/ConsoleApplication1/ConsoleAp...

```
<Company>
  <CompanyName>Lipper</CompanyName>
  <CompanyAddress>
    <Address>123 Main Street</Address>
    <City>St. Louis</City>
    <State>MO</State>
    <Country>USA</Country>
  </CompanyAddress>
</Company>
```

FIGURE 33-7

XNamespace

The `XNamespace` is an object that represents an XML namespace and is easily applied to elements within your document. For instance, you can take the previous example and easily apply a namespace to the root element:

```
using System;
using System.Linq;
using System.Xml.Linq;

namespace ConsoleApplication1
{
    class Class1
    {
        static void Main()
        {
            XNamespace ns = "http://www.lipperweb.com/ns/1";

            XElement xe = new XElement(ns + "Company",
                new XElement("CompanyName", "Lipper"),
                new XElement("CompanyAddress",
                    new XElement("Address", "123 Main Street"),
                    new XElement("City", "St. Louis"),
                    new XElement("State", "MO"),
                    new XElement("Country", "USA")));

            Console.WriteLine(xe.ToString());

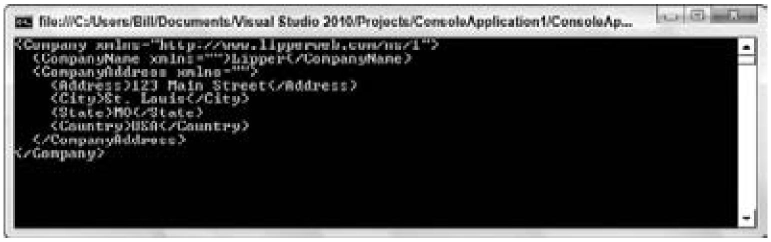
            Console.ReadLine();
        }
    }
}
```

code download ConsoleApplication1.sln

In this case, an `XNamespace` object is created by assigning it a value of `http://www.lipperweb.com/ns/1`. From there, it is actually used in the root element `<Company>` with the instantiation of the `XElement` object:

```
XElement xe = new XElement(ns + "Company", // .
```

This produces the results illustrated in Figure 33-8.



file:///C:/Users/Bill/Documents/Visual Studio 2010/Projects/ConsoleApplication1/ConsoleAp...

```
<Company xmlns="http://www.lipperweb.com/ns/1">
  <CompanyName xmlns="">Lipper</CompanyName>
  <CompanyAddress xmlns="">
    <Address>123 Main Street</Address>
    <City>St. Louis</City>
    <State>MO</State>
    <Country>USA</Country>
  </CompanyAddress>
</Company>
```

FIGURE 33-8

In addition to dealing with only the root element, you can also apply namespaces to all your elements, as shown in the following example:

```
using System;
using System.Linq;
using System.Xml.Linq;

namespace ConsoleApplication1
```

```
{
    class Class1
    {
        static void Main()
        {
            XNamespace ns1 = "http://www.lipperweb.com/ns/root";
            XNamespace ns2 = "http://www.lipperweb.com/ns/sub";

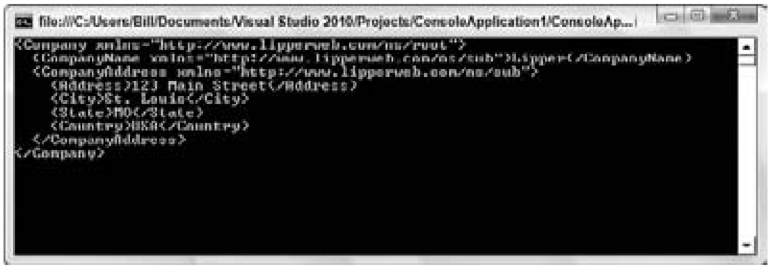
            XElement xe = new XElement(ns1 + "Company",
                new XElement(ns2 + "CompanyName", "Lipper"),
                new XElement(ns2 + "CompanyAddress",
                    new XElement(ns2 + "Address", "123 Main Street"),
                    new XElement(ns2 + "City", "St. Louis"),
                    new XElement(ns2 + "State", "MO"),
                    new XElement(ns2 + "Country", "USA")));

            Console.WriteLine(xe.ToString());

            Console.ReadLine();
        }
    }
}
```

code download ConsoleApplication1.sln

This produces the results shown in Figure 33-9.



```
file:///C:/Users/Bill/Documents/Visual Studio 2010/Projects/ConsoleApplication1/ConsoleAp...
<Company xmlns="http://www.lipperweb.com/ns/root">
  <CompanyName xmlns="http://www.lipperweb.com/ns/sub">Lipper</CompanyName>
  <CompanyAddress xmlns="http://www.lipperweb.com/ns/sub">
    <Address>123 Main Street</Address>
    <City>St. Louis</City>
    <State>MO</State>
    <Country>USA</Country>
  </CompanyAddress>
</Company>
```

FIGURE 33-9

In this case, you can see that the subnamespace was applied to everything you specified except for the `<Address>`, `<City>`, `<State>`, and the `<Country>` elements because they inherit from their parent, `<CompanyAddress>`, which has the namespace declaration.

XComment

The `XComment` object allows you to easily add XML comments to your XML documents. The following example shows the addition of a comment to the top of the document:

```
using System;
using System.Linq;
using System.Xml.Linq;

namespace ConsoleApplication1
{
    class Class1
    {
        static void Main(string[] args)
        {
            XDocument xdoc = new XDocument();

            XComment xc = new XComment("Here is a comment.");
```

```
                xdoc.Add(xc);

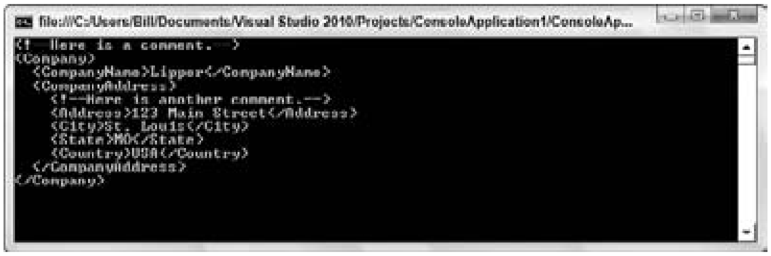
                XElement xe = new XElement("Company",
                    new XElement("CompanyName", "Lipper"),
                    new XElement("CompanyAddress",
                        new XComment("Here is another comment."),
                        new XElement("Address", "123 Main Street"),
                        new XElement("City", "St. Louis"),
                        new XElement("State", "MO"),
                        new XElement("Country", "USA")));
                xdoc.Add(xe);

                Console.WriteLine(xdoc.ToString());

                Console.ReadLine();
            }
        }
    }
```

code download ConsoleApplication1.sln

Here, an XDocument object that contains two XML comments is written to the console, one at the top of the document and another within the <CompanyAddress> element. The output of this is presented in Figure 33-10.



file:///C:/Users/Bill/Documents/Visual Studio 2010/Projects/ConsoleApplication1/ConsoleAp...

```
<!--Here is a comment.-->
<Company>
  <CompanyName>Lipper</CompanyName>
  <CompanyAddress>
    <!--Here is another comment.-->
    <Address>123 Main Street</Address>
    <City>St. Louis</City>
    <State>MO</State>
    <Country>USA</Country>
  </CompanyAddress>
</Company>
```

FIGURE 33-10

XAttribute

In addition to elements, another important factor of XML is attributes. Adding and working with attributes is done through the use of the XAttribute object. The following example shows the addition of an attribute to the root <Company> node:

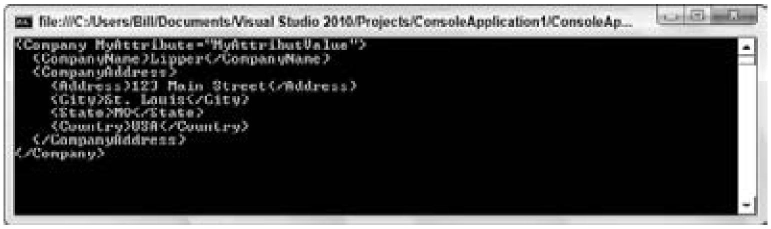
```
using System;
using System.Linq;
using System.Xml.Linq;

namespace ConsoleApplication1
{
    class Class1
    {
        static void Main()
        {
            XElement xe = new XElement("Company",
                new XAttribute("MyAttribute", "MyAttributeValue"),
                new XElement("CompanyName", "Lipper"),
                new XElement("CompanyAddress",
                    new XElement("Address", "123 Main Street"),
                    new XElement("City", "St. Louis"),
                    new XElement("State", "MO"),
                    new XElement("Country", "USA")));

                Console.WriteLine(xe.ToString());

                Console.ReadLine();
            }
        }
    }
```

Here, the attribute `MyAttribute` with a value of `MyAttributeValue` is added to the root element of the XML document, producing the results shown in Figure 33-11.



file:///C:/Users/Bill/Documents/Visual Studio 2010/Projects/ConsoleApplication1/ConsoleAp...

```
<Company MyAttribute="MyAttributValue">
  <CompanyName>Lipper</CompanyName>
  <CompanyAddress>
    <Address>123 Main Street</Address>
    <City>St. Louis</City>
    <State>MO</State>
    <Country>USA</Country>
  </CompanyAddress>
</Company>
```

FIGURE 33-11

USING LINQ TO QUERY XML DOCUMENTS

Now that you can get your XML documents into an `XDocument` object and work with the various parts of this document, you can also use LINQ to XML to query your XML documents and work with the results.

Querying Static XML Documents

You will notice that querying a static XML document using LINQ to XML takes almost no work at all. The following example makes use of the `hamlet.xml` file and queries to get all the players (actors) that appear in the play. Each of these players is defined in the XML document with the `<PERSONA>` element:

```
using System;
using System.Linq;
using System.Xml.Linq;

namespace ConsoleApplication1
{
    class Class1
    {
        static void Main(string[] args)
        {
            XDocument xdoc = XDocument.Load(@"C:\hamlet.xml");

            var query = from people in xdoc.Descendants("PERSONA")
                        select people.Value;

            Console.WriteLine("{0} Players Found", query.Count());
            Console.WriteLine();

            foreach (var item in query)
            {
                Console.WriteLine(item);
            }
```

```
                Console.ReadLine();
            }
        }
    }
```

code download ConsoleApplication1.sln

In this case, an `XDocument` object loads up a physical XML file (`hamlet.xml`) and then performs a LINQ query over the contents of the document:

```
    var query = from people in xdoc.Descendants("PERSONA")
                select people.Value;
```

The `people` object is a representation of all the `<PERSONA>` elements found in the document. Then the `select` statement gets at the values of these elements. From there, a `Console .WriteLine()` method is used to write out a count of all the players found using `query.Count()`. Next, each of the items is written to the screen in a `foreach` loop. The results you should see are presented here:

```
    26 Players Found

    CLAUDIUS, king of Denmark.
    HAMLET, son to the late king, and nephew to the present king.
    POLONIUS, lord chamberlain.
    HORATIO, friend to Hamlet.
    LAERTES, son to Polonius.
    LUCIANUS, nephew to the king.
    VOLTIMAND
    CORNELIUS
    ROSENCRANTZ
    GUILDENSTERN
    OSRIC
    A Gentleman
    A Priest.
    MARCELLUS
    BERNARDO
    FRANCISCO, a soldier.
    REYNALDO, servant to Polonius.
    Players.
    Two Clowns, grave-diggers.
    FORTINBRAS, prince of Norway.
    A Captain.
    English Ambassadors.
    GERTRUDE, queen of Denmark, and mother to Hamlet.
    OPHELIA, daughter to Polonius.
    Lords, Ladies, Officers, Soldiers, Sailors, Messengers, and other Attendants.
    Ghost of Hamlet's Father.
```

Querying Dynamic XML Documents

A lot of dynamic XML documents are available on the Internet these days. You will find blog feeds, podcast feeds, and more that provide an XML document by sending a request to a specific URL endpoint. These feeds can be viewed either in the browser, through an RSS-aggregator, or as pure XML. This example shows you how to work with an RSS feed directly from your code.

```
    using System;
    using System.Linq;
    using System.Xml.Linq;

    namespace ConsoleApplication1
    {
        class Class1
        {
```

```
        static void Main()
        {
            XDocument xdoc =
               XDocument.Load(@"http://geekswithblogs.net/evjen/Rss.aspx");

            var query = from rssFeed in xdoc.Descendants("channel")
                        select new
                        {
                          Title = rssFeed.Element("title").Value,
                          Description = rssFeed.Element("description").Value,
                          Link = rssFeed.Element("link").Value,
                        };

            foreach (var item in query)
            {
               Console.WriteLine("TITLE: " + item.Title);
                Console.WriteLine("DESCRIPTION: " + item.Description);
                Console.WriteLine("LINK: " + item.Link);
            }

            Console.WriteLine();

            var queryPosts = from myPosts in xdoc.Descendants("item")
                             select new
                             {
                                Title = myPosts.Element("title").Value,
                                Published =
                                   DateTime.Parse(
                                     myPosts.Element("pubDate").Value),
                                Description =
                                   myPosts.Element("description").Value,
                                Url = myPosts.Element("link").Value,
                                Comments = myPosts.Element("comments").Value
                             };

            foreach (var item in queryPosts)
            {
                Console.WriteLine(item.Title);
            }

            Console.ReadLine();
        }
    }
}
```

code download ConsoleApplication1.sln

Looking at this code, you can see that the `Load()` method of the `XDocument` object points to a URL where the XML is retrieved. The first query pulls out all the main subelements of the `<channel>` element in the feed and creates new objects called `Title`, `Description`, and `Link` to get at the values of these subelements.

From there, a `foreach` statement is run to iterate through all the items found in this query. The results are as follows:

```
TITLE: Bill Evjen's Blog
DESCRIPTION: Code, Life and Community
LINK: http://geekswithblogs.net/evjen/Default.aspx
```

The second query works through all the `<item>` elements and the various subelements it finds (these are all the blog entries found in the blog). Though a lot of the items found are rolled up into properties, in the foreach loop, only the Title property is used. You will see something similar to the following results from this query:

```
AJAX Control Toolkit Controls Grayed Out-HOW TO FIX
Welcome .NET 4.0!
Visual Studio
IIS 7.0 Rocks the House!
Word Issue-Couldn't Select Text
Microsoft Releases XML Schema Designer CTP1

First Review of Professional XML
Go to MIX07 for free!
Microsoft Surface and the Future of Home Computing?
Alas my friends-I'm *not* TechEd bound
```

MORE QUERY TECHNIQUES FOR XML DOCUMENTS

If you have been working with the XML document hamlet.xml, you will notice that it is quite large. So far, you've seen a couple of ways to query into the XML document in this chapter, but this next section takes a look at reading and writing to the XML document.

Reading from an XML Document

Earlier you saw just how easy it was to query into an XML document using the LINQ query statements, as shown here:

```
var query = from people in xdoc.Descendants("PERSONA")
            select people.Value;
```

This query returned all the players that were found in the document. Using the Element() method of the XDocument object, you can also get at specific values of the XML document that you are working with. For instance, the following XML fragment shows you how the title is represented in the hamlet.xml document:

```
<?xml version="1.0"?>

<PLAY>
   <TITLE>The Tragedy of Hamlet, Prince of Denmark</TITLE>

   <!-XML removed for clarity->

</PLAY>
```

As you can see, the <TITLE> element is a nested element of the <PLAY> element. You can easily get at the title by using the following bit of code in your console application:

```
XDocument xdoc = XDocument.Load(@"C:\hamlet.xml");

Console.WriteLine(xdoc.Element("PLAY").Element("TITLE").Value);
```

This bit of code will write out the title, The Tragedy of Hamlet, Prince of Denmark, to the console screen. In the code, you were able to work down the hierarchy of the XML document by using two Element() method calls — first calling the <PLAY> element and then the <TITLE> element found nested within the <PLAY> element.

Looking more at the hamlet.xml document, you will see a large list of players that are defined with the use of the <PERSONA> element:

```
<?xml version="1.0"?>

<PLAY>
```

```
   <TITLE>The Tragedy of Hamlet, Prince of Denmark</TITLE>

   <!--XML removed for clarity-->

   <PERSONAE>
      <TITLE>Dramatis Personae</TITLE>

      <PERSONA>CLAUDIUS, king of Denmark.</PERSONA>
      <PERSONA>HAMLET, son to the late king,
       and nephew to the present king.</PERSONA>
      <PERSONA>POLONIUS, lord chamberlain.</PERSONA>
      <PERSONA>HORATIO, friend to Hamlet.</PERSONA>
      <PERSONA>LAERTES, son to Polonius.</PERSONA>
      <PERSONA>LUCIANUS, nephew to the king.</PERSONA>

      <!--XML removed for clarity-->

   </PERSONAE>

</PLAY>
```

Now look at this C# query:

```
XDocument xdoc = XDocument.Load(@"C:\hamlet.xml");

Console.WriteLine(
   xdoc.Element("PLAY").Element("PERSONAE").Element("PERSONA").Value);
```

This bit of code starts at `<PLAY>`, works down to the `<PERSONAE>` element, and then makes use of the `<PERSONA>` element. However, using this will produce the following results:

```
CLAUDIUS, king of Denmark
```

The reason for this is that although there is a collection of `<PERSONA>` elements, you are dealing only with the first one that is encountered using the `Element().Value` call.

Writing to an XML Document

In addition to reading from an XML document, you can write to the document just as easily. For instance, if you wanted to change the name of the first player of the Hamlet play file, you could use the following code:

```
using System;
using System.Linq;
using System.Xml.Linq;

namespace ConsoleApplication1
{
    class Class1
    {
        static void Main()
        {
            XDocument xdoc = XDocument.Load(@"C:\hamlet.xml");

            xdoc.Element("PLAY").Element("PERSONAE").
               Element("PERSONA").SetValue("Bill Evjen, king of Denmark");

            Console.WriteLine(xdoc.Element("PLAY").
               Element("PERSONAE").Element("PERSONA").Value);

            Console.ReadLine();
        }
    }
}
```

code download ConsoleApplication1.sln

In this case, the first instance of the `<PERSONA>` element is overwritten with the value of `Bill Evjen, king of Denmark` using the `SetValue()` method of the `Element()` object. After the `SetValue()` is called and the value is applied to the XML document, the value is then retrieved using the same approach as before. When you run this bit of code, you can indeed see that the value of the first `<PERSONA>` element has been changed.

Another way to change the document (by adding items to it in this example) is to create the elements you want as `XElement` objects and then add them to the document:

```
using System;
using System.Linq;
using System.Xml.Linq;

namespace ConsoleApplication1
{
    class Class1
    {
        static void Main()
        {
            XDocument xdoc = XDocument.Load(@"C:\hamlet.xml");

            XElement xe = new XElement("PERSONA",
               "Bill Evjen, king of Denmark");

            xdoc.Element("PLAY").Element("PERSONAE").Add(xe);

            var query = from people in xdoc.Descendants("PERSONA")
                        select people.Value;

            Console.WriteLine("{0} Players Found", query.Count());
            Console.WriteLine();

            foreach (var item in query)
            {
                Console.WriteLine(item);
            }

            Console.ReadLine();
        }
    }
}
```

code download ConsoleApplication1.sln

In this case, an `XElement` document is created called `xe`. The construction of `xe` will give you the following XML output:

```
<PERSONA>Bill Evjen, king of Denmark</PERSONA>
```

Then using the `Element().Add()` method from the `XDocument` object, you are able to add the created element:

```
xdoc.Element("PLAY").Element("PERSONAE").Add(xe);
```

Now when you query all the players, you will find that instead of 26 as before, you now have 27 with the new one at the bottom of the list. In addition to `Add()`, you can also use `AddFirst()`, which will do what it says — add it to the beginning of the list instead of the end (which is the default).

SUMMARY

In this chapter, you explored many aspects of the `System.Xml` namespace of the .NET Framework. You looked at how to read and write XML documents using the very fast `XmlReader`- and `XmlWriter`-based classes. You looked at how the DOM is implemented in .NET and how to use the power of DOM. You saw that XML and ADO.NET are indeed very closely related. A `DataSet` and an XML document are just two different views of the same underlying architecture. In addition, you visited XPath, XSL transforms, and the debugging features added to Visual Studio.

Finally, you serialized objects to XML and were able to bring them back with just a couple of method calls.

XML will be an important part of your application development for years to come. The .NET Framework has made available a very rich and powerful toolset for working with XML.

This chapter also focused on using LINQ to XML and some of the options available to you in reading and writing from XML files and XML sources, whether the source is static or dynamic.

Using LINQ to XML, you are able to have a strongly typed set of operations for performing CRUD operations against your XML files and sources. However, you can still use your `XmlReader` and `XmlWriter` code along with the LINQ to XML capabilities.

This chapter also introduced the LINQ to XML helper objects of `XDocument`, `XElement`, `XNamespace`, `XAttribute`, and `XComment`. You will find these are outstanding objects that make working with XML easier than ever before.

34 .NET Programming with SQL Server

WHAT'S IN THIS CHAPTER?

- Hosting the .NET runtime with SQL Server
- Classes from the namespace `System.Data.SqlServer`
- Creating user-defined types and aggregates
- Stored procedures
- User-defined functions
- Triggers
- Using XML data types

SQL Server 2005 was the first version of this database product to host the .NET runtime. In fact, it was the first new version of Microsoft's SQL Server product in nearly six years. It allows running .NET assemblies in the SQL Server process. Furthermore, it enables you to create stored procedures, functions, and data types with .NET programming languages such as C# and Visual Basic.

.NET RUNTIME HOST

SQL Server is a host of the .NET runtime. In versions prior to CLR 2.0, multiple hosts already existed to run .NET applications; for example, a host for Windows Forms and a host for ASP.NET. Internet Explorer is another runtime host that allows running Windows Forms controls.

SQL Server allows running a .NET assembly inside the SQL Server process, where it is possible to create stored procedures, functions, data types, and triggers with CLR code.

Every database that makes use of CLR code creates its own *application domain*. This guarantees that CLR code from one database doesn't have any influence on any other database.

An important factor in programming for SQL Server is security. SQL Server as a .NET runtime host defines permission levels: safe, external, and unsafe.

Safe — With the safety level *safe*, only computational CLR classes can be used. The assembly is able to perform only local data access. The functionality of these classes is similar to a T-SQL stored procedure. The code access security defines that the only .NET permission is execution of CLR code.

External — With the safety level *external*, it is possible to access the network, file system, registry, or other databases with client-side ADO.NET.

Unsafe — The safety level *unsafe* means that everything can happen, because this safety level allows you to invoke native code. Assemblies with the unsafe permission level can be installed only by a database administrator.

With SQL Server 2008 you need to use a target framework set to version 2.0 because the assemblies from this version are trusted with SQL Server 2008.

To enable custom .NET code to be run within SQL Server, the CLR must be enabled with the `sp_configure` stored procedure:

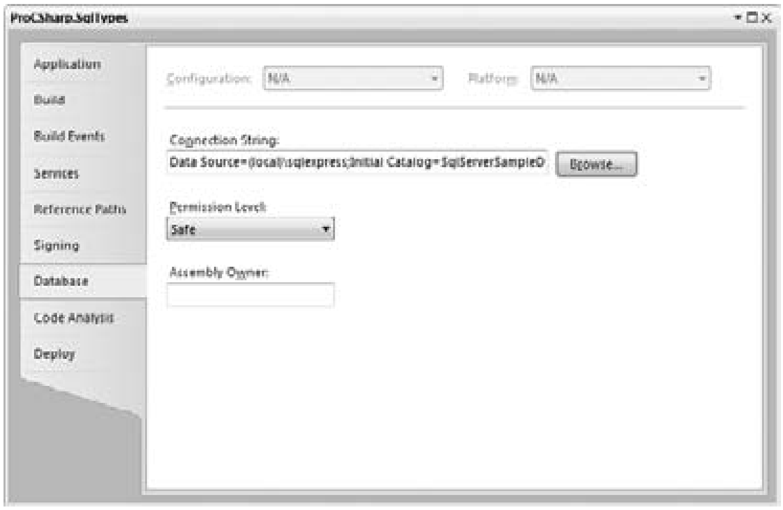
```
sp_configure [clr enabled], 1
reconfigure
```

The attribute class `HostProtectionAttribute` in the namespace `System.Security.Permissions` is suited for protection of the hosting environment. With this attribute, it is possible to define whether a method uses shared state, exposes synchronization, or controls the hosting environment. Because such behavior is usually not needed within SQL Server code (and could influence the performance of the SQL Server), assemblies that have these settings applied are not allowed to be loaded in SQL Server with safe and external safety levels.

For using assemblies with SQL Server, the assembly can be installed with the `CREATE ASSEMBLY` command. With this command, the name of the assembly used in SQL Server, the path to the assembly, and the safety level can be applied:

```
CREATE ASSEMBLY mylibrary FROM c:/ProCSharp/SqlServer/Demo.dll
   WITH PERMISSION SET = SAFE
```

With Visual Studio 2010, the permission level of the generated assembly can be defined with the Database tab of the project properties, as shown in Figure 34-1.



Configuration: N/A
Platform: N/A
Connection String: Data Source=(local)\sqlexpress;Initial Catalog=SqlServerSampleD
Permission Level: Safe
Assembly Owner:

FIGURE 34-1

MICROSOFT.SQLSERVER.SERVER

Chapter 30, "Core ADO.NET," discusses classes from the namespace `System.Data.SqlClient`. This section discusses another namespace, the `Microsoft.SqlServer.Server` namespace. The `Microsoft.SqlServer.Server` namespace includes classes, interfaces, and enumerations specific to the .NET Framework. However, many of the `System.Data.SqlClient` classes are also needed within server-side code as you will see.

The following table lists the major classes from the `Microsoft.SqlServer.Server` namespace and their functionality.

CLASS	DESCRIPTION
`SqlContext`	Like an HTTP context, the SQL context is associated with the request of a client. With static members of the `SqlContext` class, `SqlPipe`, `SqlTriggerContext`, and `WindowsIdentity` can be accessed.
`SqlPipe`	With the `SqlPipe` class, results or information can be sent to the client. This class offers the methods `ExecuteAndSend()`, `Send()`, and `SendResultsRow()`. The `Send()` method has different overloads to either send a `SqlDataReader`, `SqlDataRecord`, or `string`.
`SqlDataRecord`	The `SqlDataRecord` represents a single row of data. This class is used in conjunction with `SqlPipe` to send or receive information from the client.
`SqlTriggerContext`	The `SqlTriggerContext` class is used within triggers. This class provides information about the trigger that was fired.

This namespace also includes several attribute classes: `SqlProcedureAttribute`, `SqlFunctionAttribute`, `SqlUserDefinedAttribute`, and `SqlTriggerAttribute`. These classes are used for deployment of stored procedures, functions, user-defined types, and triggers in SQL Server. When deploying from Visual Studio, it is required that you apply these attributes. When deploying the database objects using SQL statements, these attributes are not needed but they help, because some properties of these attributes influence the characteristics of the database objects.

You see these classes in action later in this chapter when writing stored procedures and user-defined functions is discussed, but first, the following section looks into creating user-defined types with C#.

USER-DEFINED TYPES

User-defined types (UDTs) can be used similarly to normal SQL Server data types to define the type of a column in a table. With older versions of SQL Server, it was already possible to define UDTs. Of course, these UDTs could be based only on SQL types, such as the `ZIP` type shown in the following code. The stored procedure `sp_addtype` allows you to create user-defined types. Here the user-defined type `ZIP` is based on the `CHAR` data type with a length of `5`. `NOT NULL` specifies that `NULL` is not allowed with the `ZIP` data type. By using `ZIP` as a data type, it is no longer necessary to remember that it should be 5 char long and not null:

```
EXEC sp_addtype ZIP 'CHAR(5)', 'NOT NULL'
```

With SQL Server 2005 and later, UDTs can be defined with CLR classes. However, this feature is not meant to add object orientation to the database; for example, to create a `Person` class to have a `Person` data type. SQL Server is a relational data store, and this is still true with UDTs. You cannot create a class hierarchy of UDTs, and it is not possible to reference fields or properties of a UDT type with a `SELECT` statement. If properties of a person (for example, `FirstName` or `LastName`) must be accessed or a list of `Person` objects must be sorted (for example, by `FirstName` or `LastName`), it is still better to define columns for first name or last name inside a `Persons` table or to use the XML data type.

UDTs are meant for very simple data types. Before .NET, it was also possible to create custom data types; for example, the `ZIP` data type. With UDTs it is not possible to create a class hierarchy, and they are not meant to get complex data types to the database. One requirement of a UDT is that it must be convertible to a string, because the string representation is used to display the value.

How the data is stored within SQL Server can be defined: either an automatic mechanism can be used to store the data in a native format, or you can convert the data to a byte stream to define how the data should be stored.

Creating UDTs

In this example, you create a `SqlCoordinate` type representing the world coordinates longitude and latitude for easily defining the location of places, cities, and the like. To create CLR objects with Visual Studio, create a new Visual C# SQL CLR Database Project in the category Database Projects ⇨ SQL Server, and add a UDT by using the User-Defined Type template from the Solution Explorer. The name of the UDT should be `SqlCoordinate`.

With the template, the base functionality of a custom type is already defined:

```
using System;
using System.Data;
using System.Data.SqlClient;
using System.Data.SqlTypes;
using Microsoft.SqlServer.Server;

[Serializable]
[Microsoft.SqlServer.Server.SqlUserDefinedType(Format.Native)]
public struct SqlCoordinate: INullable
{
   public override string ToString()
   {
      // Replace the following code with your code
      return "";
   }

   public bool IsNull
   {
      get
      {
            // Put your code here
            return m_Null;
         }
      }

      public static SqlCoordinate Null
      {
         get
         {
            SqlCoordinate h = new SqlCoordinate();
            h.m_Null = true;
            return h;
         }
      }

      public static SqlCoordinate Parse(SqlString s)
      {
         if (s.IsNull)
            return Null;
         SqlCoordinate u = new SqlCoordinate();
         // Put your code here
         return u;
      }

      // This is a place-holder method
      public string Method1()
      {
         //Insert method code here
         return "Hello";
      }

      // This is a place-holder static method
      public static SqlString Method2()
      {
         // Insert method code here
         return new SqlString("Hello");
      }

      // This is a placeholder field member
      public int var1;
      // Private member
      private bool m_Null;
   }
```

Because this type can also be used directly from client code, it is a good idea to add a namespace, which is not done automatically.

The struct `SqlCoordinate` implements the interface `INullable`. The interface `INullable` is required for UDTs because database types can also be null. The attribute `SqlUserDefinedType` is used for automatic deployment with Visual Studio for UDTs. The argument `Format.Native` defines the serialization format to be used. Two serialization formats are possible: `Format.Native` and `Format.UserDefined`. `Format.Native` is the simple serialization format where the engine performs serialization and deserialization of instances. This serialization allows only value types (predefined and structs of value types). Reference types (which include the `string` type) require the `UserDefined` serialization format. With the `SqlCoordinate` struct, the data types to serialize are of type `int` and `bool`, which are value types.

Using `Format.UserDefined` requires the interface `IBinarySerialize` to be implemented. The `IBinarySerialize` interface provides custom implementation for user-defined types. `Read()` and `Write()` methods must be implemented for serialization of the data to a `BinaryReader` and a `BinaryWriter`.

```
namespace Wrox.ProCSharp.SqlServer

{
   [Serializable]
   [SqlUserDefinedType(Format.Native)]
   public struct SqlCoordinate: INullable
   {
      private int longitude;
      private int latitude;
      private bool isNull;
```

code snippet SqlTypes/SqlCoordinate.cs

The attribute `SqlUserDefinedType` allows setting several properties, which are shown in the following table.

SQLUSERDEFINEDTYPE ATTRIBUTE PROPERTY	DESCRIPTION
`Format`	The property `Format` defines how the data type is stored within SQL Server. Currently supported formats are `Format.Native` and `Format.UserDefined`.
`IsByteOrdered`	If the property `IsByteOrdered` is set to `true`, it is possible to create an index for the data type, and it can be used with `GROUP BY` and `ORDER BY` SQL statements. The disk representation will be used for binary comparisons. Each instance can have only one serialized representation, so binary comparisons can succeed. The default is `false`.
`IsFixedLength`	If the disk representation of all instances is of the same size, `IsFixedLength` can be set to `true`.
`MaxByteSize`	The maximum number of bytes needed to store the data is set with `MaxByteSize`. This property is specified only with a user-defined serialization.
`Name`	With the `Name` property, a different name of the type can be set. By default the name of the class is used.
`ValidationMethodName`	With the `ValidationMethodName` property a method name can be defined to validate instances when the deserialization takes place.

To represent the direction of the coordinate, the enumeration `Orientation` is defined:

```
public enum Orientation
{
   NorthEast,
   NorthWest,
   SouthEast,
   SouthWest
}
```

This enumeration can be used only within methods of the struct `SqlCoordinate`, not as a member field, because enumerations are not supported by the native serialization format although enums are based on number types. Future versions may support enums with the native format in SQL Server.

The struct `SqlCoordinate` specifies some constructors to initialize the `longitude`, `latitude`, and `isNull` variables. The variable `isNull` is set to `true` if no values are assigned to `longitude` and `latitude`, which is the case in the default constructor. A default constructor is needed with UDTs.

With the worldwide coordination system, longitude and latitude are defined with degrees, minutes, and seconds. Vienna, Austria has the coordinates 48° 14´ longitude and 16° 20´ latitude. (The symbols °, ´, and ˝ represent degrees, minutes, and seconds, respectively.)

With the variables `longitude` and `latitude`, the longitude and latitude values are stored using seconds. The constructor with seven integer parameters converts degrees, minutes, and seconds to seconds, and sets the longitude and latitude to negative values if the coordinate is based in the South or West:

```
public SqlCoordinate(int longitude, int latitude)
{
   isNull = false;
   this.longitude = longitude;
   this.latitude = latitude;
}

public SqlCoordinate(int longitudeDegrees, int longitudeMinutes,
      int longitudeSeconds, int latitudeDegrees, int latitudeMinutes,
      int latitudeSeconds, Orientation orientation)
{
   isNull = false;
   this.longitude = longitudeSeconds + 60 * longitudeMinutes + 3600 *
         longitudeDegrees;
   this.latitude = latitudeSeconds + 60 * latitudeMinutes + 3600 *
         latitudeDegrees;
   switch (orientation)
   {
      case Orientation.SouthWest:
         longitude = -longitude;
         latitude = -latitude;
         break;
      case Orientation.SouthEast:
         longitude = -longitude;
         break;
      case Orientation.NorthWest:
         latitude = -latitude;
         break;
   }
}
```

The `INullable` interface defines the property `IsNull`, which must be implemented to support nullability. The static property `Null` is used to create an object that represents a null value. In the `get` accessor a `SqlCoordinate` object is created, and the `isNull` field is set to `true`:

```
public bool IsNull
{
   get
   {
      return isNull;
   }
}

public static SqlCoordinate Null
{
   get
   {
      return new SqlCoordinate { isNull = true };
   }
}
```

A UDT must be converted from and to a string. For conversion to a string, the `ToString()` method of the `Object` class must be overridden. The variables `longitude` and `latitude` are converted in the following code for a string representation to show the degrees, minutes, and seconds notation:

```
public override string ToString()
{
   if (this.isNull)
```

```
            return null;

         char northSouth = longitude > 0 ? 'N': 'S';
         char eastWest = latitude > 0 ? 'E': 'W';

         int longitudeDegrees = Math.Abs(longitude) / 3600;
         int remainingSeconds = Math.Abs(longitude) % 3600;
         int longitudeMinutes = remainingSeconds / 60;
         int longitudeSeconds = remainingSeconds % 60;

         int latitudeDegrees = Math.Abs(latitude) / 3600;
         remainingSeconds = Math.Abs(latitude) % 3600;
         int latitudeMinutes = remainingSeconds / 60;
         int latitudeSeconds = remainingSeconds % 60;

         return String.Format("{0}˚{1}'{2}\"{3},{4}˚{5}'{6}\"{7}",
               longitudeDegrees, longitudeMinutes, longitudeSeconds,
               northSouth, latitudeDegrees, latitudeMinutes,
               latitudeSeconds, eastWest);
      }
```

Conversion from a string happens with the `Parse()` method. The string that is entered from the user is represented in the `SqlString` parameter of the static method `Parse()`. First, the `Parse()` method checks if the string represents a null value, in which case the `Null` property is invoked to return an empty `SqlCoordinate` object. If the `SqlString s` does not represent a null value, the text of the string is converted to pass the longitude and latitude values to the `SqlCoordinate` constructor:

```
      public static SqlCoordinate Parse(SqlString s)
      {
         if (s.IsNull)
            return SqlCoordinate.Null;

         try
         {
            string[] coordinates = s.Value.Split(',');
            char[] separators = { '˚', '\'', '\"' };
            string[] longitudeVals = coordinates[0].Split(separators);
            string[] latitudeVals = coordinates[1].Split(separators);

            if (longitudeVals.Length != 4 && latitudeVals.Length != 4)
               throw new ArgumentException(
                  "Argument has a wrong syntax. " +
                  "This syntax is required: 37˚47\'0\"N,122˚26\'0\"W");

            Orientation orientation;
            if (longitudeVals[3] == "N" && latitudeVals[3] == "E")
               orientation = Orientation.NorthEast;
            else if (longitudeVals[3] == "S" && latitudeVals[3] == "W")
               orientation = Orientation.SouthWest;
            else if (longitudeVals[3] == "S" && latitudeVals[3] == "E")
               orientation = Orientation.SouthEast;
            else
               orientation = Orientation.NorthWest;

            return new SqlCoordinate(
                  int.Parse(longitudeVals[0]), int.Parse(longitudeVals[1]),
                  int.Parse(longitudeVals[2]),
                  int.Parse(latitudeVals[0]), int.Parse(latitudeVals[1]),
                  int.Parse(latitudeVals[2]), orientation);
         }
         catch (FormatException ex)
```

```
            {
               throw new ArgumentException(
                  "Argument has a wrong syntax. " +
                  "This syntax is required: 37°47\'0\"N,122°26\'0\"W",
                     ex.Message);
            }
         }
      }
```

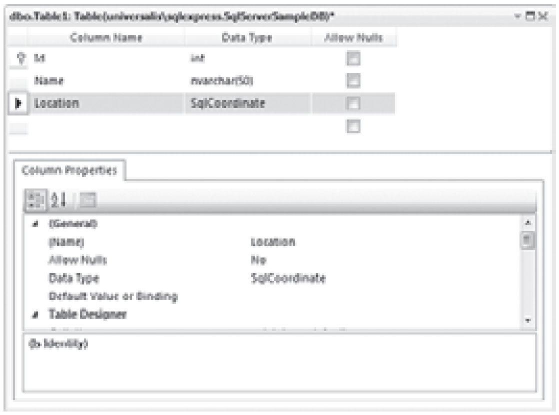
Using UDTs with SQL Server

After building the assembly, it can be deployed with SQL Server. Configuration of the UDT in SQL Server can be done either with Visual Studio 2010 using the Build Deploy Project menu or using these SQL commands:

```
CREATE ASSEMBLY SqlTypes FROM
'c:\ProCSharp\SqlServer\SqlTypes.dll'
CREATE TYPE Coordinate EXTERNAL NAME
[SqlTypes].[Wrox.ProCSharp.SqlServer.SqlCoordinate]
```

With `EXTERNAL NAME`, the name of the assembly as well as the name of the class, including the namespace, must be set.

Now it is possible to create a table called `Cities` that contains the data type `SqlCoordinate`, as shown in Figure 34-2. Fill the table with data as shown in Figure 34-3.



dbo.Table1: Table(universalis\sqlexpress.SqlServerSampleDB)*

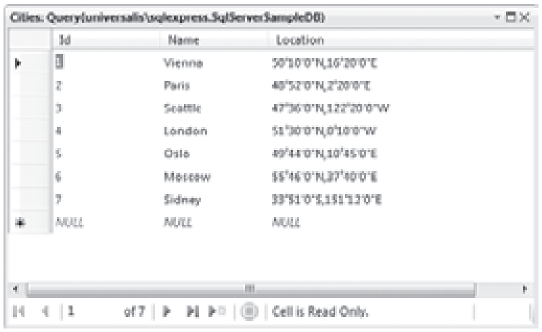
Column Name	Data Type	Allow Nulls
Id	int	☐
Name	nvarchar(50)	☐
Location	SqlCoordinate	☐
		☐

Column Properties

(General)	
(Name)	Location
Allow Nulls	No
Data Type	SqlCoordinate
Default Value or Binding	
Table Designer	

(Is Identity)

FIGURE 34-2



Cities: Query(universalis\sqlexpress.SqlServerSampleDB)

Id	Name	Location
1	Vienna	50°10'0"N,16°20'0"E
2	Paris	48°52'0"N,2°20'0"E
3	Seattle	47°36'0"N,122°20'0"W
4	London	51°30'0"N,0°10'0"W
5	Oslo	49°44'0"N,10°45'0"E
6	Moscow	55°46'0"N,37°40'0"E
7	Sidney	33°51'0"S,151°12'0"E
NULL	NULL	NULL

1 of 7 | Cell is Read Only.

FIGURE 34-3

Using UDTs from Client-Side Code

The assembly of the UDT must be referenced to use the UDT from client-side code. Then it can be used like any other type on the client.

> *Because the assembly containing the UDTs is used both from the client and from the SQL Server, it is a good idea to put UDTs in a separate assembly from the other SQL Server extensions such as stored procedures and functions.*

In the sample code, the `SELECT` statement of the `SqlCommand` object references the columns of the `Cities` table that contains the `Location` column, which is of type `SqlCoordinate`. Calling the method

`ToString()` invokes the `ToString()` method of the `SqlCoordinate` class to display the coordinate value in a string format:

```
// UDTClient
using System;
using System.Data;
using System.Data.SqlClient;
using Wrox.ProCSharp.SqlServer;

class Program
{
   static void Main()
   {
      string connectionString =
         @"server=(local);database=ProCSharp;trusted_connection=true";
      var connection = new SqlConnection(connectionString);
      var command = connection.CreateCommand();
      command.CommandText = "SELECT Id, Name, Location FROM Cities";
      connection.Open();

      SqlDataReader reader =
            command.ExecuteReader(CommandBehavior.CloseConnection);
      while (reader.Read())
      {

         Console.WriteLine("{0,-10} {1}", reader[1].ToString(),
               reader[2].ToString());
      }
      reader.Close();
   }
}
```

code snippet UDTClient/Program.cs

Of course, it is also possible to cast the returned object from the `SqlDataReader` to a `SqlCoordinate` type for using any other implemented methods of the `Coordinate` type:

```
            SqlCoordinate coordinate = (SqlCoordinate)reader[2];
```

Running the application produces the following output:

```
Vienna     50°10'0"N,16°20'0"E
Paris      48°52'0"N,2°20'0"E
Seattle    47°36'0"N,122°20'0"W
London     51°30'0"N,0°10'0"W
Oslo       59°55'0"N,10°45'0"E
Moscow     55°46'0"N,37°40'0"E
Sydney     33°51'0"S,151°12'0"E
```

USER-DEFINED AGGREGATES

An aggregate is a function that returns a single value based on multiple rows. Examples of built-in aggregates are `COUNT`, `AVG`, and `SUM`:

- `COUNT` returns the record count of all selected records
- `AVG` returns the average of values from a column of selected rows
- `SUM` returns the sum of all values of a column

All built-in aggregates work only with built-in value types.

A simple usage of the built-in aggregate `AVG` is shown here to return the average unit price of all products from the AdventureWorks sample database by passing the `ListPrice` column to the `AVG` aggregate in the `SELECT` statement:

```
SELECT AVG(ListPrice) AS 'average list price'
FROM Production.Product
```

The result from the `SELECT` statement gives the average list price of all products:

```
average list price
438,6662
```

The `SELECT` statement returns just a single value that represents the average of all `ListPrice` column values. Aggregates can also work with groups. In the next example, the `AVG` aggregate is combined with the `GROUP BY` clause to return the average list price of every product line:

```
SELECT ProductLine, AVG(ListPrice) AS 'average list price'
FROM Production.Product
GROUP BY ProductLine
```

The average list price is now grouped by the product line:

```
ProductLine     average list price
NULL            16,8429
M               827,0639
R               965,3488
S               50,3988
T               840,7621
```

For custom value types, and if you want to do a specific calculation based on a selection of rows, you can create a user-defined aggregate.

Creating User-Defined Aggregates

To write a user-defined aggregate with CLR code, a simple class with the methods `Init()`, `Accumulate()`, `Merge()`, and `Terminate()` must be implemented. The functionality of these methods is shown in the following table.

METHOD	DESCRIPTION
`Init()`	The `Init()` method is invoked for every group of rows to be processed. In this method, initialization can be done for calculation of every row group.
`Accumulate()`	The `Accumulate()` method is invoked for every value in all groups. The parameter of this method must be of the correct type that is accumulated; this can also be the class of a user-defined type.
`Merge()`	The `Merge()` method is invoked when the result of one aggregation must be combined with another aggregation.
`Terminate()`	After the last row of every group is processed, the `Terminate()` method is invoked. Here, the result of the aggregate must be returned with the correct data type.

The code sample shows how to implement a simple user-defined aggregate to calculate the sum of all rows in every group. For deployment with Visual Studio, the attribute `SqlUserDefinedAggregate` is applied to the class `SampleSum`. As with the UDT, with user-defined aggregates the format for storing the aggregate must be defined with a value from the `Format` enumeration. Again, `Format.Native` is for using automatic serialization with blittable data types.

In the code sample, the variable `sum` is used for accumulation of all values of a group. In the `Init()` method, the variable `sum` is initialized for every new group to accumulate. The method `Accumulate()`, which is invoked for every value, adds the value of the parameter to the `sum` variable. With the `Merge()` method, one aggregated group is added to the current group. Finally, the method `Terminate()` returns the result of a group:

```
[Serializable]
[SqlUserDefinedAggregate(Format.Native)]
public struct SampleSum
{
   private int sum;

   public void Init()
   {
      sum = 0;
   }

   public void Accumulate(SqlInt32 Value)
   {
      sum += Value.Value;
   }

   public void Merge(SampleSum Group)
   {
      sum += Group.sum;
   }

   public SqlInt32 Terminate()
   {
      return new SqlInt32(sum);
   }
}
```

code snippet SqlSamplesUsingAdventureWorks/SampleSum.cs

You can use the Aggregate template from Visual Studio to create the core code for building the user-defined aggregate. The template from Visual Studio creates a struct that uses the `SqlString` *type as a parameter and return type with the* `Accumulate` *and* `Terminate` *methods. You can change the type to a type that represents the requirement of your aggregate. In the example, the* `SqlInt32` *type is used.*

Using User-Defined Aggregates

The user-defined aggregate can be deployed either with Visual Studio or with the `CREATE AGGREGATE` statement. Following the `CREATE AGGREGATE` is the name of the aggregate, the parameter `(@value int)`, and the return type. `EXTERNAL NAME` requires the name of the assembly and the .NET type including the namespace:

```
CREATE AGGREGATE [SampleSum] (@value int) RETURNS [int] EXTERNAL NAME
                 [Demo].[SampleSum]
```

After the user-defined aggregate has been installed, it can be used as shown in the following `SELECT` statement, where the number of ordered products is returned by joining the `Product` and `PurchaseOrderDetail` tables. For the user-defined aggregate, the `OrderQty` column of the `Order PurchaseOrderDetail` table is defined as an argument:

```
SELECT Purchasing.PurchaseOrderDetail.ProductID AS Id,
   Production.Product.Name AS Product,
   dbo.SampleSum(Purchasing.PurchaseOrderDetail.OrderQty) AS Sum
FROM Production.Product INNER JOIN
   Purchasing.PurchaseOrderDetail ON
   Purchasing.PurchaseOrderDetail.ProductID = Production.Product.ProductID
GROUP BY Purchasing.PurchaseOrderDetail.ProductID, Production.Product.Name
ORDER BY Id
```

An extract of the returned result that shows the number of orders for products by using the aggregate function `SampleSum` is presented here:

```
Id       Product               Sum
1        Adjustable Race       154
2        Bearing Ball          150
4        Headset Ball Bearings 153
317      LL Crankarm           44000
318      ML Crankarm           44000
319      HL Crankarm           71500
320      Chainring Bolts       375
321      Chainring Nut         375
322      Chainring             7440
```

STORED PROCEDURES

SQL Server allows the creation of stored procedures with C#. A stored procedure is a subroutine, and they are physically stored in the database. They definitely are not to be considered a replacement for T-SQL. T-SQL still has an advantage when the procedure is mainly data-driven.

Take a look at the T-SQL stored procedure `GetCustomerOrders`, which returns information from customer orders from the AdventureWorks database. This stored procedure returns orders from the customer that is specified with the parameter `CustomerID`:

```
CREATE PROCEDURE GetCustomerOrders
   (
   @CustomerID int
   )
AS
SELECT SalesOrderID, OrderDate, DueDate, ShipDate FROM Sales.SalesOrderHeader
   WHERE (CustomerID = @CustomerID)
   ORDER BY SalesOrderID
```

Creating Stored Procedures

As you can see in the following code listing, implementing the same stored procedure with C# has more complexity. The attribute `SqlProcedure` is used to mark a stored procedure for deployment. With the implementation, a `SqlCommand` object is created. With the constructor of the `SqlConnection` object, the string `"Context Connection=true"` is passed to use the connection that was already opened by the client calling the stored procedure. Very similarly to the code you saw in Chapter 30, the SQL `SELECT` statement is set and one parameter is added. The `ExecuteReader()` method returns a `SqlDataReader` object. This reader object is returned to the client by invoking the `Send()` method of the `SqlPipe`:

```
using System.Data;
using System.Data.SqlClient;
using Microsoft.SqlServer.Server;

public partial class StoredProcedures
{
   [SqlProcedure]
   public static void GetCustomerOrdersCLR(int customerId)
   {
      SqlConnection connection = new SqlConnection("Context Connection=true");
      connection.Open();
```

```
        SqlCommand command = new SqlCommand();
        command.Connection = connection;
        command.CommandText = "SELECT SalesOrderID, OrderDate, DueDate, " +
              "ShipDate " +
              "FROM Sales.SalesOrderHeader " +
              "WHERE (CustomerID = @CustomerID)" +
              "ORDER BY SalesOrderID";

        command.Parameters.Add("@CustomerID", SqlDbType.Int);
        command.Parameters["@CustomerID"].Value = customerId;

        SqlDataReader reader = command.ExecuteReader();
        SqlPipe pipe = SqlContext.Pipe;
        pipe.Send(reader);
        connection.Close();
     }
  };
```

code snippet SqlSamplesUsingAdventureWorks/GetCustomerOrdersCLR.cs

CLR stored procedures are deployed to SQL Server either using Visual Studio or with the `CREATE PROCEDURE` statement. With this SQL statement, the parameters of the stored procedure are defined, as well as the name of the assembly, class, and method:

```
CREATE PROCEDURE GetCustomerOrdersCLR
(
   @CustomerID nchar(5)
)
AS EXTERNAL NAME Demo.StoredProcedures.GetCustomerOrdersCLR
```

Using Stored Procedures

The CLR stored procedure can be invoked just like a T-SQL stored procedure by using classes from the namespace `System.Data.SqlClient`. First, a `SqlConnection` object is created. The `CreateCommand()` method returns a `SqlCommand` object. With the command object, the name of the stored procedure `GetCustomerOrdersCLR` is set to the `CommandText` property. As with all stored procedures, the `CommandType` property must be set to `CommandType.StoredProcedure`. The method `ExecuteReader()` returns a `SqlDataReader` object to read record by record:

```
using System;
using System.Data;
using System.Data.SqlClient;

//...

      string connectionString =
         @"server=(local);database=AdventureWorks;trusted_connection=true";
      var connection = new SqlConnection(connectionString);
      SqlCommand command = connection.CreateCommand();
      command.CommandText = "GetCustomerOrdersCLR";
      command.CommandType = CommandType.StoredProcedure;
      var param = new SqlParameter("@customerId", 3);
      command.Parameters.Add(param);
      connection.Open();
      SqlDataReader reader =
            command.ExecuteReader(CommandBehavior.CloseConnection);
      while (reader.Read())
      {
         Console.WriteLine("{0} {1:d}", reader["SalesOrderID"], reader["OrderDate"]);
      }
      reader.Close();
```

code snippet UsingSP/Program.cs

The classes from the namespace `System.Data.SqlClient` *are discussed in Chapter 30.*

Invoking the stored procedure written with T-SQL or with C# is not different at all. The code for calling stored procedures is completely identical; from the caller code you don't know if the stored procedure is implemented with T-SQL or the CLR. An extract of the result shows the order dates for the customer with ID 3:

```
44124 9/1/2001
44791 12/1/2001
45568 3/1/2002
46377 6/1/2002
47439 9/1/2002
48378 12/1/2002
```

As you have seen, mainly data-driven stored procedures are better done with T-SQL. The code is a lot shorter. Writing stored procedures with the CLR has the advantage if you need some specific data-processing, for example, by using the .NET cryptography classes.

USER-DEFINED FUNCTIONS

User-defined functions are somewhat similar to stored procedures. The big difference is that user-defined functions can be invoked within SQL statements.

Creating User-Defined Functions

A CLR user-defined function can be defined with the attribute `SqlFunction`. The sample function `CalcHash()` converts the string that is passed to a hashed string. The MD5 algorithm that is used for hashing the string is implemented with the class `MD5CryptoServiceProvider` from the namespace `System.Security.Cryptography`. The `ComputeHash()` method computes the hash from the byte array input and returns a computed hash byte array. The hashed byte array is converted back to a `string` by using the `StringBuilder` class:

```
using System.Data.SqlTypes;
using System.Security.Cryptography;
using System.Text;
using Microsoft.SqlServer.Server;

public partial class UserDefinedFunctions
{
   [SqlFunction]
   public static SqlString CalcHash(SqlString value)
   {
      byte[] source = ASCIIEncoding.ASCII.GetBytes(value.ToString());
      byte[] hash = new MD5CryptoServiceProvider().ComputeHash(source);

      var output = new StringBuilder(hash.Length);

      for (int i = 0; i < hash.Length - 1; i++)
      {
         output.Append(hash[i].ToString("X2"));
      }

      return new SqlString(output.ToString());
   }
}
```

code snippet SqlSamplesUsingAdventureWorks/CalcHash.cs

Using User-Defined Functions

A user-defined function can be deployed with SQL Server very similarly to the other .NET extensions: either with Visual Studio 2010 or with the `CREATE FUNCTION` statement:

```
CREATE FUNCTION CalcHash
(
   @value nvarchar
)
RETURNS nvarchar
AS EXTERNAL NAME Demo.UserDefinedFunctions.CalcHash
```

A sample usage of the `CalcHash()` function is shown with this `SELECT` statement, where the credit card number is accessed from the `CreditCard` table in the AdventureWorks database by returning just the hash code from the credit card number:

```
SELECT Sales.CreditCard.CardType AS [Card Type],
   dbo.CalcHash(Sales.CreditCard.CardNumber) AS [Hashed Card]
FROM Sales.CreditCard INNER JOIN Sales.ContactCreditCard ON
   Sales.CreditCard.CreditCardID = Sales.ContactCreditCard.CreditCardID
WHERE Sales.ContactCreditCard.ContactID = 11
```

The result returned shows the hashed credit card number for contact ID 11:

```
Card Type     Hashed Card
ColonialVoice 7482F7B4E613F71144A9B336A3B9F6
```

TRIGGERS

A *trigger* is a special kind of stored procedure invoked when a table is modified (for example, when a row is inserted, updated, or deleted). Triggers are associated with tables and the action that should activate them (for example, on insert/update/delete of rows).

With triggers, changes of rows can be cascaded through related tables or more complex data integrity can be enforced.

Within a trigger you have access to the current data of a row and the original data, so it is possible to reset the change to the earlier state. Triggers are automatically associated with the same transaction as the command that fires the trigger, so you get a correct transactional behavior.

The trigger `uCreditCard` that follows is part of the AdventureWorks sample database. This trigger is fired when a row in the `CreditCard` table is updated. With this trigger, the `ModifiedDate` column of the `CreditCard` table is updated to the current date. For accessing the data that is changed, the temporary table inserted is used:

```
CREATE TRIGGER [Sales].[uCreditCard] ON [Sales].[CreditCard]
AFTER UPDATE NOT FOR REPLICATION AS
BEGIN
    SET NOCOUNT ON;

    UPDATE [Sales].[CreditCard]
    SET [Sales].[CreditCard].[ModifiedDate] = GETDATE()
    FROM inserted
    WHERE inserted.[CreditCardID] = [Sales].[CreditCard].[CreditCardID];
END;
```

Creating Triggers Example

This example demonstrates implementing data integrity with triggers when new records are inserted into the `Users` table. To create a trigger with the CLR, a simple class must be defined that includes static methods that have the attribute `SqlTrigger` applied. The attribute `SqlTrigger` defines the table that is associated with the trigger and the event when the trigger should occur.

In this example, the associated table is `Person.Contact`, which is indicated by the `Target` property. The `Event` property defines when the trigger should occur; here, the event string is set to `FOR INSERT`, which means the trigger is started when a new row is inserted in the `Users` table.

The property `SqlContext.TriggerContext` returns the trigger context in an object of type `SqlTriggerContext`. The `SqlTriggerContext` class offers three properties:

- `ColumnsUpdated` returns a Boolean array to flag every column that was changed
- `EventData` contains the new and the original data of an update in XML format
- `TriggerAction` returns an enumeration of type `TriggerAction` to mark the reason for the trigger

The following code compares whether the `TriggerAction` of the trigger context is set to `TriggerAction.Insert` before continuing.

Triggers can access temporary tables; for example, in the following code listing the `INSERTED` table is accessed. With `INSERT`, `UPDATE`, and `DELETE` SQL statements, temporary tables are created. The `INSERT` statement creates an `INSERTED` table; the `DELETE` statement creates a `DELETED` table. With the `UPDATE` statement both `INSERTED` and `DELETED` tables are used. The temporary tables have the same columns as the table that is associated with the trigger. The SQL statement `SELECT Username, Email FROM INSERTED` is used to access username and e-mail, and to check the e-mail address for correct syntax. `SqlCommand.ExecuteRow()` returns a row represented in a `SqlDataRecord`. Username and e-mail are read from the data record. Using the regular expression class, `RegEx`, the expression used with the `IsMatch()` method checks if the e-mail address conforms to valid e-mail syntax. If it does not conform, an exception is thrown and the record is not inserted, because a rollback occurs with the transaction:

```
using System;
using System.Data.SqlClient;
using System.Text.RegularExpressions;
using Microsoft.SqlServer.Server;

public partial class Triggers
{
   [SqlTrigger(Name ="InsertContact", Target="Person.Contact",
         Event="FOR INSERT")]
   public static void InsertContact()
   {
      SqlTriggerContext triggerContext = SqlContext.TriggerContext;

      if (triggerContext.TriggerAction == TriggerAction.Insert)
      {
         var connection = new SqlConnection("Context Connection=true");
         var command = new SqlCommand();
         command.Connection = connection;
         command.CommandText = "SELECT EmailAddress FROM INSERTED";
         connection.Open();
         string email = (string)command.ExecuteScalar();
         connection.Close();

         if (!Regex.IsMatch(email,
               @"([\w-]+\.)*?[\w-]+@[\w-]+\.([\w-]+\.)*?[\w]+$"))
         {
            throw new FormatException("Invalid email");
         }
      }
   }
}
```

code snippet SqlSamplesUsingAdventureWorks/InsertContact.cs

Using Triggers

Using deployment of Visual Studio 2010, the trigger can be deployed to the database. You can use the `CREATE TRIGGER` command to create the trigger manually:

```
CREATE TRIGGER InsertContact ON Person.Contact
FOR INSERT
AS EXTERNAL NAME Demo.Triggers.InsertContact
```

Trying to insert rows into the `Users` table with an incorrect e-mail throws an exception, and the insert is not done.

XML DATA TYPE

One of the major programming features of SQL Server is the XML data type. With older versions of SQL Server, XML data is stored inside a string or a blob. Now XML is a supported data type that allows you to combine SQL queries with XQuery expressions to search within XML data. An XML data type can be used as a variable, a parameter, a column, or a return value from a UDF.

With Microsoft Office, it is possible to store Word and Excel documents as XML. Word and Excel also support using custom XML schemas, where only the content (and not the presentation) is stored with XML. The output of Office applications can be stored directly in SQL Server, where it is possible to search within this data. Of course, custom XML data can also be stored in SQL Server.

Tables with XML Data

Creating tables with XML data is as simple as selecting the XML data type with a column. The following `CREATE TABLE` SQL command creates the `Exams` table with a column ID that is also the primary key, the column `Number`, and the column `Info`, which is of type XML:

```
CREATE TABLE [dbo].[Exams](
   [Id] [int] IDENTITY(1,1) NOT NULL,
   [Number] [nchar] (10) NOT NULL,
   [Info] [xml] NOT NULL,
   CONSTRAINT [PK_Exams] PRIMARY KEY CLUSTERED
   (
      [Id] ASC
   ) ON [PRIMARY]
) ON [PRIMARY]
```

For a simple test, the table is filled with this data:

```
INSERT INTO Exams values('70-502',
 '<Exam Number="70-502">
    <Title>TS: Microsoft .NET Framework 3.5, Windows Presentation Foundation
        Application Development
    </Title>
    <Certification Name="MCTS Windows Presentation Foundation Application Development"
        Status="Core" />
    <Certification Name="MCTS Web Applications" Status="Core" />
    <Certification Name="MCTS Distributed Applications" Status="Core" />
```

```
      <Course>6460</Course>
      <Topic>Creating a WPF Application</Topic>
      <Topic>Building User Interfaces</Topic>
      <Topic>Adding and Managing Content</Topic>
      <Topic>Binding to Data Sources</Topic>
      <Topic>Customizing Appearance</Topic>
      <Topic>Configuring and Deploying WPF Applications</Topic>
    </Exam>')

  INSERT INTO Exams values('70-562',
   '<Exam Number="70-562">
      <Title>TS: Microsoft .NET Framework 3.5, ASP.NET Application Development</Title>
      <Certification Name="MCTS ASP.NET Applications" Status="Core" />
      <Course>2310</Course>
      <Course>6463</Course>
      <Topic>Configuring and Deploying Web Applications</Topic>
      <Topic>Consuming and Creating Server Controls</Topic>
      <Topic>Working with Data and Services</Topic>
      <Topic>Troubleshooting and Debugging Web Applications</Topic>
      <Topic>Working with ASP.NET AJAX and Client-Side Scripting</Topic>
      <Topic>Targeting Mobile Devices</Topic>
      <Topic>Programming Web Applications</Topic>
    </Exam>')

  INSERT INTO Exams values('70-561',
   '<Exam Number="70-561">
      <Title>TS: Microsoft .NET Framework 3.5, ADO.NET Application Development</Title>
      <Certification Name="MCTS ADO.NET Applications" Status="Core" />
      <Course>2310</Course>
      <Course>6464</Course>

      <Topic>Working with Disconnected Data</Topic>
      <Topic>Object Relational Mapping by Using the Entity Framework</Topic>
    </Exam>')
```

Reading XML Values

You can read the XML data with ADO.NET using a `SqlDataReader` object. The `SqlDataReader` method `GetSqlXml()` returns a `SqlXml` object. The `SqlXml` class has a property `Value` that returns the complete XML representation and a `CreateReader()` method that returns an `XmlReader` object.

The `Read()` method of the `XmlReader` is repeated in a `while` loop to read node by node. With the output there's interest only in information about the value of the attribute `Number`, and the values of the elements `Title` and `Course`. The node to which the reader is positioned is compared with the corresponding XML element names, and the corresponding values are written to the console:

```
using System;
using System.Data;
using System.Data.SqlClient;
using System.Data.SqlTypes;
using System.Text;
using System.Xml;

   class Program
   {
      static void Main()
      {
         string connectionString =
                @"server=(local);database=ProCSharp;trusted_connection=true";
            var connection = new SqlConnection(connectionString);
            var command = connection.CreateCommand();
            command.CommandText = "SELECT Id, Number, Info FROM Exams";
            connection.Open();
            var reader = command.ExecuteReader(CommandBehavior.CloseConnection);
            while (reader.Read())
            {
               SqlXml xml = reader.GetSqlXml(2);

               XmlReader xmlReader = xml.CreateReader();

               StringBuilder courses = new StringBuilder("Course(s): ", 40);
               while (xmlReader.Read())
               {
                  if (xmlReader.Name == "Exam" && xmlReaderIsStartElement())
                  {
                     Console.WriteLine("Exam: {0}", xmlReader.GetAttribute("Number"));
                  }
                  else if (xmlReader.Name == "Title" && xmlReader.IsStartElement())
                  {
                     Console.WriteLine("Title: {0}", xmlReader.ReadString());
                  }
                  else if (xmlReader.Name == "Course" && xmlReader.IsStartElement())
                  {
                     courses.AppendFormat("{0} ", xmlReader.ReadString());
                  }
               }
               xmlReader.Close();
               Console.WriteLine(courses.ToString());
               Console.WriteLine();
            }
            reader.Close();
         }
      }
```

Running the application, you will get the output as shown:

```
Exam: 70-502
Title: TS: Microsoft .NET Framework 3.5, Windows Presentation Foundation Application Development
Course(s): 6460

Exam: 70-562
Title: TS: Microsoft .NET Framework 3.5, ASP.NET Application Development
Course(s): 2310 6463

Exam: 70-561
Title: TS: Microsoft .NET Framework 3.5, ADO.NET Application Development
Course(s): 2310 6464
```

Instead of using the `XmlReader` class, you can read the complete XML content into the `XmlDocument` class and parse the elements by using the DOM model. The method `SelectSingleNode()` requires an XPath expression and returns an `XmlNode` object. The XPath expression `//Exam` looks for the `Exam` XML element inside the complete XML tree. The `XmlNode` object returned can be used to read the children of the represented element. The value of the `Number` attribute is accessed to write the exam number to the console, then the `Title` element is accessed and the content of the `Title` element is written to the console, and the content of all `Course` elements is written to the console as well:

```
           string connectionString =
                 @"server=(local);database=SqlServerSampleDB;trusted_connection=true";
            var connection = new SqlConnection(connectionString);
            var command = connection.CreateCommand();
            command.CommandText = "SELECT Id, Number, Info FROM Exams";
            connection.Open();
            var reader = command.ExecuteReader(CommandBehavior.CloseConnection);
            while (reader.Read())
            {
               SqlXml xml = reader.GetSqlXml(2);
               var doc = new XmlDocument();
               doc.LoadXml(xml.Value);

               XmlNode examNode = doc.SelectSingleNode("//Exam");
               Console.WriteLine("Exam: {0}", examNode.Attributes["Number"].Value);
               XmlNode titleNode = examNode.SelectSingleNode("./Title");
               Console.WriteLine("Title: {0}", titleNode.InnerText);
               Console.Write("Course(s): ");

               foreach (XmlNode courseNode in examNode.SelectNodes("./Course"))
               {
                  Console.Write("{0} ", courseNode.InnerText);
               }
               Console.WriteLine();

            }
            reader.Close();
```

code snippet XmlSamples/Program.cs

The `XmlReader` *and* `XmlDocument` *classes are discussed in Chapter 33, "Manipulating XML."*

With .NET 4 there's another option to access the XML column from the database. You can combine LINQ to SQL and LINQ to XML, which makes the programming code smaller.

You can use the ADO.NET Entity Framework designer by selecting the ADO.NET Entity Data Model template from the Data templates category. Name the file `ExamsModel.edmx` to create a mapping for the database SqlServerSampleDB. Select the Exams table and select the option to singularize object names. After you create the model with the wizard, a design surface, as shown in Figure 34-4, opens.

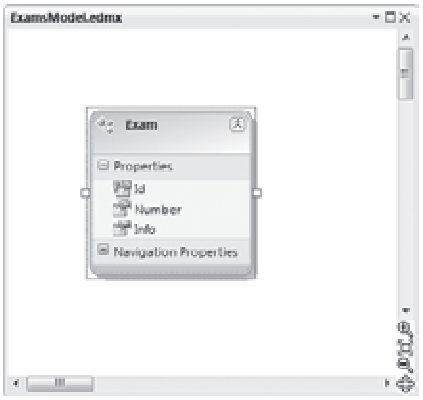

FIGURE 34-4

The data context class that is created by the designer has the name `ExamsEntities` and defines a property `Exams` to return all exam rows. Here a `foreach` statement is used to iterate through all records. Of course you can also define a LINQ query with a `where` expression if not all records are required. The `Exam` class defines the properties `Id`, `Number`, and `Info` according to the columns in the database table. The `Info` property is of type `string`. With the `XElement` class the string can be parsed and accessed by the LINQ to XML classes from the namespace `System.Xml.Linq`. Invoking the method `Element()` passing the name of the XML element `Exam` returns an `XElement` object that is then used to access the values of the attribute `Number` and the elements `Title` and `Course` in a much simpler way, as was done earlier with the `XmlDocument` class:

```
    using System;
    using System.Xml.Linq;

    namespace Wrox.ProCSharp.SqlServer
    {
      class Program
      {
         static void Main()
         {
            using (ExamsEntities data = new ExamsEntities())
            {
               foreach (Exam item in db.Exams)
               {
                  XElement exam = XElement.Parse(item.Info);
                  Console.WriteLine("Exam: {0}", exam.Attribute("Number").Value);
                  Console.WriteLine("Title: {0}", exam.Element("Title").Value);
                  Console.Write("Course(s): ");
                  foreach (var course in exam.Elements("Course"))
                  {
                     Console.Write("{0} ", course.Value);
                  }
                  Console.WriteLine();
               }
            }
         }
      }
    }
```

The ADO.NET Entity Framework and LINQ to XML are explained in Chapter 31, "ADO.NET Entity Framework," and Chapter 33, "Manipulating XML," respectively.

Querying the Data

Up until now, you haven't seen the really great features of the XML data type. SQL `SELECT` statements can be combined with XML XQuery.

A `SELECT` statement combined with an XQuery expression to read into the XML value is shown here:

```
SELECT [Id], [Number], [Info].query('/Exam/Course') AS Course FROM [Exams]
```

The XQuery expression `/Exam/Course` accesses the `Course` elements that are children of the `Exam` element. The result of this query returns the IDs, exam numbers, and courses:

```
1 70-502 <Course>6460</Course>
2 70-562 <Course>2310</Course><Course>6463</Course>
3 70-561 <Course>2310</Course><Course>6464</Course>
```

With an XQuery expression, you can create more complex statements to query data within the XML content of a cell. The next example converts the XML from the exam information to XML that lists information about courses:

```
SELECT [Info].query('
   for $course in /Exam/Course
   return
<Course>
   <Exam>{ data(/Exam[1]/@Number) }</Exam>
   <Number>{ data($course) }</Number>
</Course>')
AS Course
FROM [Exams]
WHERE Id=2
```

Here, just a single row is selected with `SELECT [Info]. FROM Exams WHERE Id = 2`. With the result of this SQL query, the `for` and `return` statements of an XQuery expression are used. `for $course in /Exam/Course` iterates through all `Course` elements. `$course` declares a variable that is set with every iteration (similar to a C# `foreach` statement). Following the `return` statement, the result of the query for every row is defined. The result for every course element is surrounded by the `<Course>` element. Embedded inside the `<Course>` element are `<Exam>` and `<Number>`. The text within the `<Exam>` element is defined with `data(/Exam[1]/@Number)`. `data()` is an XQuery function that returns the value of the node specified with the argument. The node `/Exam[1]` is used to access the first `<Exam>` element; `@Number` specifies the XML attribute `Number`. The text within the element `<Number>` is defined from the variable `$course`.

Contrary to C#, where the first element in a collection is accessed with an index of 0, with XPath the first element in a collection is accessed with an index of 1.

The result of this query is shown here:

```
<Course>
  <Exam>70-562</Exam>
  <Number>2310</Number>
</Course>
<Course>
  <Exam>70-562</Exam>
  <Number>6463</Number>
</Course>
```

You can change the XQuery statement to also include a `where` clause for filtering XML elements. The following example only returns courses from the XML column if the course number has a value higher than 2562:

```
SELECT [Info].query('
   for $course in /Exam/Course
   where ($course > 2562)
   return
<Course>
   <Exam>{ data(/Exam[1]/@Number) }</Exam>
   <Number>{ data($course) }</Number>
</Course>')
AS Course
FROM [Exams]
WHERE Id=2
```

The result is reduced to just one course number:

```
<Course>
  <Exam>70-562</Exam>
  <Number>6463</Number>
</Course>
```

XQuery in SQL Server allows using several other XQuery functions for getting minimum, maximum, or summary values, working with strings, numbers, checking for positions within collections, and so on.

The next example shows the use of the `count()` function to get the number of `/Exam/Course` elements:

```
SELECT [Id], [Number], [Info].query('
   count(/Exam/Course)')
   AS "Course Count"
FROM [Exams]
```

The data returned displays the number of courses for the exams:

```
Id         Number         Course Count
1          70-502         1
2          70-562         2
3          70-561         2
```

XML Data Modification Language (XML DML)

XQuery, as it is defined by the W3C (`http://www.w3c.org`), allowed only querying of data when Microsoft implemented XQuery in SQL Server 2005. Because of this XQuery restriction, Microsoft defined an extension to XQuery that has the name XML Data Modification Language (XML DML).

Today the XQuery Update Facility 1.0 is a candidate recommendation since June 9, 2009. This recommendation was made by IBM, Oracle, and Red Hat, and is different from XML DML.

XML DML makes it possible to modify XML data with the following XQuery extensions: `insert`, `delete`, and `replace value of`.

This section looks at some examples to insert, delete, and modify XML contents within a cell.

You can use the `insert` keyword to insert some XML content within an XML column without replacing the complete XML cell. Here, `<Course>2555</Course>` is inserted as the last child element of the first `Exam` element:

```
UPDATE [Exams]
SET [Info].modify('
   insert <Course>2555</Course> as last into Exam[1]')
WHERE [Id]=3
```

XML content can be deleted with the `delete` keyword. Within the first `Exam` element, the last `Course` element is deleted. The last element is selected by using the `last()` function:

```
UPDATE [Exams]
SET [Info].modify('
   delete /Exam[1]/Course[last()]')
FROM [Exams] WHERE [Id]=3
```

It is also possible to change XML content. Here, the keyword `replace value of` is used. The expression `/Exam/Course[text() = 6463]` accesses only the child elements `Course` where the text content contains the string `6463`. From these elements, only the text content is accessed for replacement with the `text()` function. If only a single element is returned from the query, it is still required that you specify just one element for replacement. This is why explicitly the first text element returned is specified with `[1]`. `2599` specifies that the new course number is `2599`:

```
UPDATE [Exams]
SET [Info].modify('
   replace value of (/Exam/Course[text() = 6463]/text())[1] with 2599')
FROM [Exams]
```

XML Indexes

If some specific elements are often searched within the XML data, you can specify indexes within the XML data type. XML indexes must be distinguished as being a primary or a secondary XML index type. A primary XML index is created for the complete persisted representation of the XML value.

The following SQL command, `CREATE PRIMARY XML INDEX`, creates the index `idx_exams` on the `Info` column:

```
CREATE PRIMARY XML INDEX idx_exams on Exams (Info)
```

Primary indexes don't help if the query contains an XPath expression to directly access XML elements of the XML type. For XPath and XQuery expressions, XML secondary indexes can be used. If an XML secondary index is created, the primary index must already exist. With secondary indexes, these index types must be distinguished:

- `PATH` index
- `VALUE` index
- `PROPERTY` index

A `PATH` index is used if `exists()` or `query()` functions are used and XML elements are accessed with an XPath expression. Using the XPath expression `/Exam/Course`, it might be useful to do a `PATH` index:

```
CREATE XML INDEX idx_examNumbers on [Exams] (Info)
   USING XML INDEX idx_exams FOR PATH
```

The PROPERTY index is used if properties are fetched from elements with the value() function. The FOR PROPERTY statement with the index creation defines a PROPERTY index:

```
CREATE XML INDEX idx_examNumbers on [Exams] (Info)
   USING XML INDEX idx_exams FOR PROPERTY
```

If elements are searched through the tree with an XPath descendant-or-self axis expression, the best performance might be achieved with a VALUE index. The XPath expression //Certification searches all Certification elements with the descendant-or-self axis. The expression [@Name="MCTS ASP.NET Applications"] returns only the elements where the attribute Name has the value MCTS Web Applications:

```
SELECT [Info].query('/Exam/Title/text()') FROM [Exams]
   WHERE [Info].exist('//Certification[@Name="MCTS ASP.NET Applications"]') = 1
```

The result returned lists the titles of the exams that contain the requested certification:

```
TS: Microsoft .NET Framework 3.5, ASP.NET Application Development
```

The VALUE index is created with the FOR VALUE statement:

```
CREATE XML INDEX idx_examNumbers on [Exams] (Info)
   USING XML INDEX idx_exams FOR VALUE
```

Strongly Typed XML

The XML data type in SQL Server can also be strongly typed with XML schemas. With a strongly typed XML column, it is verified if the data conforms to the schema when XML data is inserted.

A XML schema can be created with the CREATE XML SCHEMA COLLECTION statement. The statement shown here creates a simple XML schema, CourseSchema. The schema defines the type CourseElt that contains a sequence of Number and Title, which are both of type string, and an element Any, which can be any type. Number and Title may occur only once. Because Any has the minOccurs attribute set to 0, and the maxOccurs attribute set to unbounded, this element is optional. This allows you to add any additional information to the CourseElt type in future versions, while the schema still remains valid. Finally, the element name Course is of type CourseElt:

```
CREATE XML SCHEMA COLLECTION CourseSchema AS
'<?xml version="1.0" encoding="UTF-8"?>
<xs:schema id="Courses" targetNamespace="http://thinktecture.com/Courses.xsd"
  elementFormDefault="qualified" xmlns="http://thinktecture.com/Courses.xsd"
  xmlns:mstns="http://thinktecture.com/Courses.xsd"
  xmlns:xs="http://www.w3.org/2001/XMLSchema">
    <xs:complexType name="CourseElt">
      <xs:sequence>
        <xs:element name="Number" type="xs:string" maxOccurs="1"
              minOccurs="1" />
        <xs:element name="Title" type="xs:string" maxOccurs="1"
              minOccurs="1" />
        <xs:element name="Any" type="xs:anyType"
            maxOccurs="unbounded" minOccurs="0" />
      </xs:sequence>
    </xs:complexType>
    <xs:element name="Course" type="CourseElt">
    </xs:element>
</xs:schema>'
```

With this schema, a valid XML looks like this:

```
<Course xmlns="http://thinktecture.com/Courses.xsd">
  <Number>2549</Number>
  <Title>Advanced Distributed Application Development with Visual Studio 2008
  </Title>
</Course>
```

With the Visual Studio Database project type, there's no support to add a schema to the database. This feature is not available from the GUI by Visual Studio 2010, but must be created manually. To create an XML schema with Visual Studio 2010, create a new Visual Studio project by using the Empty Project template. Add a new XML schema to the project. Then copy the XML syntax of the schema into the `CREATE XML SCHEMA` statement.

The XML schema can be assigned to a column by setting it with the `XML` data type:

```
CREATE TABLE [Courses]
(
   [Id] [int] IDENTITY(1,1) NOT NULL,
   [Course] [xml]([dbo].[CourseSchema]) NOT NULL
)
```

By creating the table with Visual Studio 2010 or with SQL Server Management Studio, the XML schema can be assigned to a column by setting the property `XML schema namespace`.

Now as you add data to the XML column, the schema is verified. If the XML does not satisfy the schema definition, a `SqlException` is thrown with an XML Validation error.

SUMMARY

This chapter discussed the new features of SQL Server as they relate to CLR functionality. The CLR is hosted by SQL Server, so it is possible to create user-defined types, aggregates, stored procedures, functions, and triggers with C#.

UDTs have some strict requirements in the .NET class for conversion to and from a string. How the data is stored internally in SQL Server depends on the format that is defined in the type. User-defined aggregates make it possible to do a custom accumulation using .NET classes. With stored procedures and functions, it is possible to make use of CLR classes for server-side code.

Using CLR with SQL Server doesn't mean that T-SQL is obsolete. You've seen that T-SQL has advantages because it requires less code if only data-intensive queries are done. CLR classes can have advantages in data-processing if .NET features such as cryptography come into play.

You've also had a glance into the XML data type of SQL Server to combine XQuery expressions with T-SQL statements.

This chapter concludes Part IV, "Data." Part V, "Presentation," gives details about defining the user interface of applications. With the user interface you have the options of working with WPF, Silverlight, Windows Forms, and ASP.NET.

PART V
Presentation

35 Core WPF

WHAT'S IN THIS CHAPTER?

- Shapes and geometry as the base drawing elements
- Scaling, rotating, and skewing with transformations
- Brushes to fill backgrounds
- WPF controls and their features
- Defining a layout with WPF panels
- Styles, templates, and resources
- Triggers and the Visual State Manager
- Animations
- 3-D

Windows Presentation Foundation (WPF) is a library to create the UI for smart client applications. This chapter gives you broad information on the important concepts of WPF. You can read about a large number of different controls and their categories, how to arrange the controls with panels, customize the appearance using styles, resources, and templates, add some dynamic behavior with triggers and animations, and get an introduction to 3-D with WPF.

OVERVIEW

One of the big features of WPF is that work can be easily separated between designers and developers. The outcome from the designer's work can directly be used by the developer. To make this possible, you need to understand *eXtensible Application Markup Language*, or *XAML*. You should read Chapter 27, "Core XAML" to get information on this XAML syntax.

The first topic of this chapter gives you an overview of the class hierarchy and categories of classes that are used with WPF, including additional information to understand the principles of XAML. WPF consists of several assemblies containing thousands of classes. So that you can navigate within this vast number of classes and find what you need, the overview explains the class hierarchy and namespaces in WPF.

Namespaces

Classes from Windows Forms and WPF can easily be confused. The Windows Forms classes are located in the `System.Windows.Forms` namespace, and the WPF classes are located inside the namespace `System.Windows` and subnamespaces thereof, with the exception of `System.Windows.Forms`. The `Button` class for Windows Forms has the full name `System.Windows.Forms.Button`, and the `Button` class for WPF has the full name `System.Windows.Controls.Button`. Windows Forms is covered in Chapter 39.

Namespaces and their functionality with WPF are described in the following table.

NAMESPACE	DESCRIPTION
`System.Windows`	This is the core namespace of WPF. Here you can find core classes from WPF such as the `Application` class; classes for dependency objects, `DependencyObject` and `DependencyProperty`; and the base class for all WPF elements, `FrameworkElement`.
`System.Windows.Annotations`	The classes from this namespace are used for user-created annotations and notes on application data that are stored separately from the document. The namespace `System.Windows.Annotations.Storage` contains classes for storing annotations.
`System.Windows.Automation`	This namespace can be used for automation of WPF applications. Several subnamespaces are available. `System.Windows.Automation.Peers` exposes WPF elements to automation — for example, `ButtonAutomationPeer` and `CheckBoxAutomationPeer`. The namespace `System.Windows.Automation.Provider` is needed if you create a custom automation provider.
`System.Windows.Baml2006`	This namespace is new with .NET 4 and contains the `Baml2006Reader` class, which is used to read binary markup language and produces XAML.
`System.Windows.Controls`	This is the namespace where you can find all the WPF controls, such as `Button`, `Border`, `Canvas`, `ComboBox`, `Expander`, `Slider`, `ToolTip`, `TreeView`, and the like. In the namespace `System.Windows.Controls.Primitives`, you can find classes to be used within complex controls — for example, `Popup`, `ScrollBar`, `StatusBar`, `TabPanel`, and so on.
`System.Windows.Converters`	This namespace contains classes for data conversion. Don't expect to find all converter classes in this namespace; core converter classes are defined in the namespace `System.Windows`.
`System.Windows.Data`	This namespace is used by WPF data binding. An important class in this namespace is the `Binding` class, which is used to define the binding between a WPF target element and a CLR source. Data binding is dealt with in Chapter 36, "Business Applications with WPF."
`System.Windows.Documents`	When working with documents, you can find many helpful classes in this namespace. `FixedDocument` and `FlowDocument` are content elements that can contain other elements from this namespace. With classes from the namespace `System.Windows.Documents.Serialization` you can write documents to disk. The classes from this namespace are explained in Chapter 37, "Creating Documents with WPF."
`System.Windows.Ink`	The Windows Tablet PC and Ultra Mobile PCs are being used more and more. With these PCs, ink can be used for user input. The namespace `System.Windows.Ink` contains classes to deal with ink input.
`System.Windows.Input`	This namespace contains several classes for command handling, keyboard inputs, working with a stylus, and so on.
`System.Windows.Interop`	For integration with Win32 and WPF, you can find classes in this namespace.

NAMESPACE	DESCRIPTION
`System.Windows.Markup`	Helper classes for XAML markup code are located in this namespace.
`System.Windows.Media`	To work with images, audio, and video content, you can use classes in this namespace.
`System.Windows.Navigation`	This namespace contains classes for navigation between windows.
`System.Windows.Resources`	This namespace contains supporting classes for resources.
`System.Windows.Shapes`	The core classes for the UI are located in the `System.Windows.Shapes` namespace: `Line`, `Ellipse`, `Rectangle`, and the like.
`System.Windows.Threading`	WPF elements are bound to a single thread. In the namespace `System.Windows.Threading`, you can find classes to deal with multiple threads — for example, the `Dispatcher` class belongs to this namespace.
`System.Windows.Xps`	XML Paper Specification (XPS) is a new document specification that is also supported by Microsoft Word. In the namespaces `System.Windows.Xps`, `System.Windows.Xps.Packaging` and `System.Windows.Xps.Serialization`, you can find classes to create and stream XPS documents.

Class Hierarchy

WPF consists of thousands of classes with a deep hierarchy. For help in understanding the relationship between the classes, see Figure 35-1. Some classes and their functionalities are described in the following table.

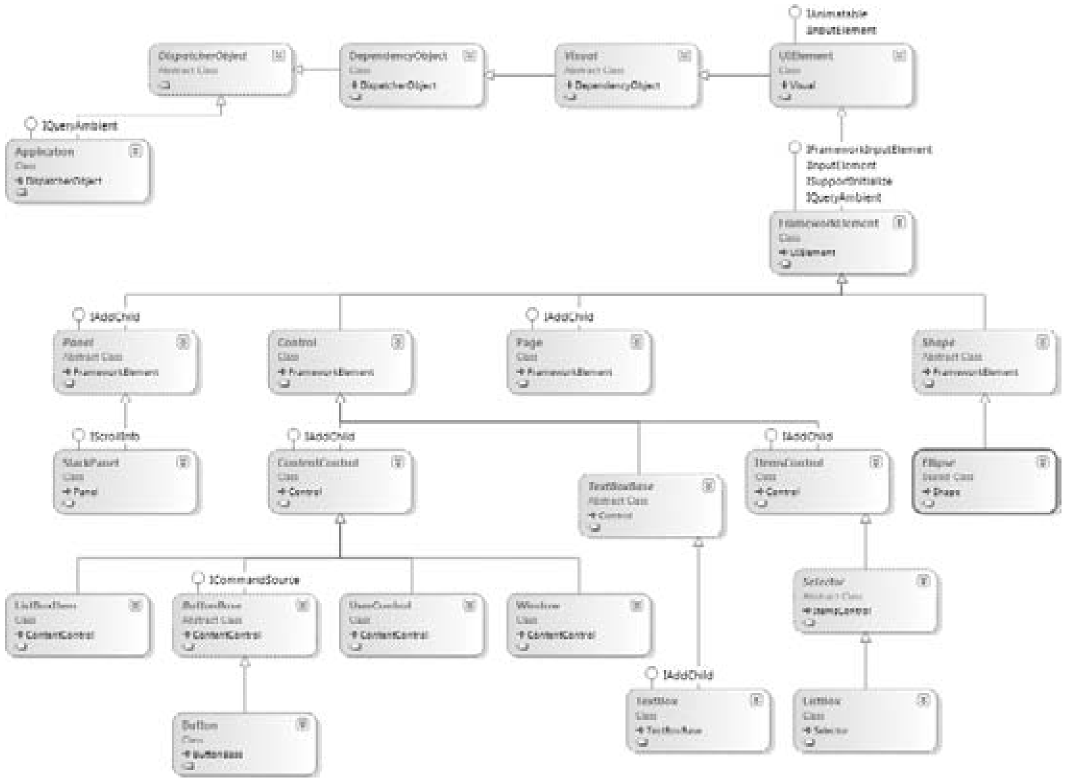

FIGURE 35-1

CLASS	DESCRIPTION
`DispatcherObject`	`DispatcherObject` is an abstract base class for classes that are bound to one thread. WPF controls require that methods and properties be invoked only from the creator thread. Classes that are derived from `DispatcherObject` have an associated `Dispatcher` object that can be used to switch the thread.
`Application`	In a WPF application, one instance of the `Application` class is created. This class implements a Singleton pattern for access to the application windows, resources, and properties.
`DependencyObject`	`DependencyObject` is the base class for all classes that support dependency properties. Dependency properties are discussed in Chapter 27, "Core XAML".
`Visual`	The base class for all visual elements is `Visual`. This class includes features for hit testing and transformation.
`UIElement`	The abstract base class for all WPF elements needing basic presentation features is `UIElement`. This class provides tunneling and bubbling events for mouse moves, drag and drop, and key clicks. It exposes virtual methods for rendering that can be overridden by derived classes, and it provides methods for layout. WPF does not use Window handles. You can consider this class equivalent to Window handles.
`FrameworkElement`	`FrameworkElement` is derived from the base class `UIElement` and implements the default behavior of the methods defined by the base class.
`Shape`	`Shape` is the base class for all shape elements — for example, `Line`, `Ellipse`, `Polygon`, and `Rectangle`.
`Control`	`Control` derives from `FrameworkElement` and is the base class for all user-interactive elements.
`ContentControl`	`ContentControl` is the base class for all controls that have a single content (for example, `Label`, `Button`). The default style of a content control may be limited, but it is possible to change the look by using templates.
`ItemsControl`	`ItemsControl` is the base class for all controls that contain a collection of items content (for example, `ListBox`, `ComboBox`).
`Panel`	The class `Panel` derives from `FrameworkElement` and is the abstract base class for all panels. This class has a `Children` property for all UI elements within the panel and defines methods for arranging the child controls. Classes that are derived from `Panel` define different behavior for how the children are organized — for example, `WrapPanel`, `StackPanel`, `Canvas`, and `Grid`.

As you can see, WPF classes have a really deep hierarchy. In this and the next chapters, you see classes of the core functionality, but it is not possible to cover all the features of WPF in this book.

SHAPES

Shapes are the core elements of WPF. With shapes you can draw 2-dimensional graphics using rectangles, lines, ellipses, paths, polygons, and polylines that are represented by classes derived from the abstract base class `Shape`. Shapes are defined in the namespace `System.Windows.Shapes` namespace.

The following XAML example draws a yellow face consisting of an ellipse for the face, two ellipses for the eyes, two ellipses for the pupils in the eyes, and a path for the mouth:

```
<Window x:Class="ShapesDemo.MainWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        Title="Window1" Height="300" Width="300">
    <Canvas>
        <Ellipse Canvas.Left="10" Canvas.Top="10" Width="100" Height="100" Stroke="Blue"
            StrokeThickness="4" Fill="Yellow" />
        <Ellipse Canvas.Left="30" Canvas.Top="12" Width="60" Height="30">
```

```
                <Ellipse.Fill>
                    <LinearGradientBrush StartPoint="0.5,0" EndPoint="0.5, 1">
                        <GradientStop Offset="0.1" Color="DarkGreen" />
                        <GradientStop Offset="0.7" Color="Transparent" />
                    </LinearGradientBrush>
                </Ellipse.Fill>
            </Ellipse>
            <Ellipse Canvas.Left="30" Canvas.Top="35" Width="25" Height="20" Stroke="Blue"
                StrokeThickness="3" Fill="White" />
            <Ellipse Canvas.Left="40" Canvas.Top="43" Width="6" Height="5" Fill="Black" />

            <Ellipse Canvas.Left="65" Canvas.Top="35" Width="25" Height="20" Stroke="Blue"
                StrokeThickness="3" Fill="White" />
            <Ellipse Canvas.Left="75" Canvas.Top="43" Width="6" Height="5" Fill="Black" />
            <Path Name="mouth" Stroke="Blue" StrokeThickness="4"
                Data="M 40,74 Q 57,95 80,74 " />
        </Canvas>
    </Window>
```

code snippet ShapesDemo/MainWindow.xaml

Figure 35-2 shows the result from the XAML code.

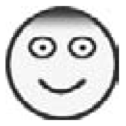

FIGURE 35-2

All these WPF elements can be accessed programmatically, even if they are buttons or shapes such as lines or rectangles. Setting the `Name` or `x:Name` property with the `Path` element to `mouth` allows you to access this element programmatically with the variable name `mouth`:

```
            <Path Name="mouth" Stroke="Blue" StrokeThickness="4"
                Data="M 40,74 Q 57,95 80,74 " />
```

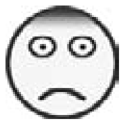

FIGURE 35-3

In the code-behind `Data` property of the `Path` element, `mouth` is set to a new geometry. For setting the path, the `Path` class supports `PathGeometry` with path markup syntax. The letter `M` defines the starting point for the path; the letter `Q` specifies a control point and an endpoint for a quadratic Bézier curve. Running the application, you see the window shown in Figure 35-3.

```
        public MainWindow()
        {
           InitializeComponent();
           mouth.Data = Geometry.Parse("M 40,92 Q 57,75 80,92");
        }
```

code snippet ShapesDemo/MainWindow.xaml.cs

Following are the shapes available in the namespace `System.Windows.Shapes`.

SHAPE CLASS	DESCRIPTION
`Line`	You can draw a line from the coordinates `X1.Y1` to `X2.Y2`.
`Rectangle`	With the `Rectangle` class, you can draw a rectangle by specifying `Width` and `Height`.
`Ellipse`	With the `Ellipse` class, you can draw an ellipse.
`Path`	You can use the `Path` class to draw a series of lines and curves. The `Data` property is a `Geometry` type. You can do the drawing by using classes that derive from the base class `Geometry`, or you can use the path markup syntax to define geometry.
`Polygon`	You can draw a closed shape formed by connected lines with the `Polygon` class. The polygon is defined by a series of `Point` objects assigned to the `Points` property.
`Polyline`	Similar to the `Polygon` class, you can draw connected lines with the `Polyline`. The difference is that the polyline does not need to be a closed shape.

GEOMETRY

One of the shapes, `Path`, uses `Geometry` for its drawing. `Geometry` elements can also be used in other places, for example with a `DrawingBrush`.

Geometry elements are very similar to shapes. Just as there are `Line`, `Ellipse`, and `Rectangle` shapes, there are also geometry elements for these drawings: `LineGeometry`, `EllipseGeometry`, and `RectangleGeometry`. There are big differences between shapes and geometries. A `Shape` is a `FrameworkElement` and can be used with any class that supports `UIElement` as its children. `FrameworkElement` derives from `UIElement`. Shapes participate with the layout system and render themselves. The `Geometry` class can't render itself and has fewer features and less overhead than `Shape`. The `Geometry` class derives from the `Freezable` base class and can be shared from multiple threads.

The `Path` class uses `Geometry` for its drawing. The geometry can be set with the `Data` property of the `Path`. Simple geometry elements that can be set are `EllipseGeometry` for drawing an ellipse, `LineGeometry` for drawing a line, and `RectangleGeometry` for drawing a rectangle. Combining multiple geometries, as is done in the next example, can be done with `CombinedGeometry`.

`CombinedGeometry` has the properties `Geometry1` and `Geometry2` and allows them to combine with `GeometryCombineMode` to form a `Union`, `Intersect`, `Xor`, and `Exclude`. `Union` merges the two geometries. With `Intersect`, only the area that is covered with both geometries is visible. `Xor` contrasts with `Intersect` to show the area that is covered by one of the geometries, but does not show the area covered by both. `Exclude` shows the area of the first geometry minus the area of the second geometry.

The following example combines an `EllipseGeometry` and a `RectangleGeometry` to form a union, as shown in Figure 35-4.

```
<Path Canvas.Top="0" Canvas.Left="250" Fill="Blue" Stroke="Black" >
    <Path.Data>
        <CombinedGeometry GeometryCombineMode="Union">
            <CombinedGeometry.Geometry1>
                <EllipseGeometry Center="80,60" RadiusX="80" RadiusY="40" />
            </CombinedGeometry.Geometry1>
            <CombinedGeometry.Geometry2>
                <RectangleGeometry Rect="30,60 105 50" />
            </CombinedGeometry.Geometry2>
        </CombinedGeometry>
    </Path.Data>
</Path>
```

code snippet GeometryDemo/MainWindow.xaml

Geometries can also be created by using segments. The geometry class `PathGeometry` uses segments for its drawing. The following code segment uses the `BezierSegment` and `LineSegment` elements to build one red and one green figure, as you can see in Figure 35-5. The first `BezierSegment` draws a Bézier curve between the points 70,40, which is the starting point of the figure, and 150,63 with control points 90,37 and 130,46. The following `LineSegment` uses the ending point of the Bézier curve and draws a line to 120,110:

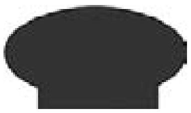

FIGURE 35-4

```
<Path Canvas.Left="0" Canvas.Top="0" Fill="Red" Stroke="Blue"
      StrokeThickness="2.5">
      <Path.Data>
          <GeometryGroup>
              <PathGeometry>
                  <PathGeometry.Figures>
                      <PathFigure StartPoint="70,40" IsClosed="True">
                          <PathFigure.Segments>
                              <BezierSegment Point1="90,37" Point2="130,46"
```

```
                                                    Point3="150,63" />
                                     <LineSegment Point="120,110" />
                                     <BezierSegment Point1="100,95" Point2="70,90"
                                                    Point3="45,91" />
                                     <LineSegment Point="70,40" />
                                 </PathFigure.Segments>
                             </PathFigure>
                         </PathGeometry.Figures>
                     </PathGeometry>
                 </GeometryGroup>
             </Path.Data>
         </Path>

         <Path Canvas.Left="0" Canvas.Top="0" Fill="Green" Stroke="Blue"
               StrokeThickness="2.5">
             <Path.Data>
                 <GeometryGroup>
                     <PathGeometry>
                         <PathGeometry.Figures>
                             <PathFigure StartPoint="160,70">
                                 <PathFigure.Segments>
                                     <BezierSegment Point1="175,85" Point2="200,99"
                                                    Point3="215,100" />
                                     <LineSegment Point="195,148" />
                                     <BezierSegment Point1="174,150" Point2="142,140"
                                                    Point3="129,115" />
                                     <LineSegment Point="160,70" />
                                 </PathFigure.Segments>
                             </PathFigure>
                         </PathGeometry.Figures>
                     </PathGeometry>
                 </GeometryGroup>
             </Path.Data>
         </Path>
```

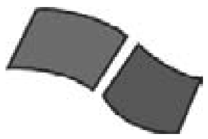

FIGURE 35-5

Other than the BezierSegment and LineSegment elements, you can use ArcSegment to draw an elliptical arc between two points. With PolyLineSegment you can define a set of lines, PolyBezierSegment consists of multiple Bézier curves, QuadraticBezierSegment creates a quadratic Bézier curve, and PolyQuadraticBezierSegment consists of multiple quadratic Bézier curves.

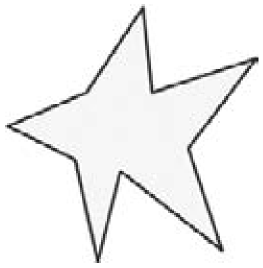

FIGURE 35-6

A high performing drawing can be done with StreamGeometry. Programmatically, the figure can be defined by creating lines, Bézier curves, and arcs with members of the StreamGeometryContext class. With XAML, path markup syntax can be used. Path markup syntax can be used with the Data property of the Path class to define StreamGeometry. Special characters define how the points are connected. With the sample, M marks the start point, L is a line command to the point specified, and Z is the Close command to close the figure. Figure 35-6 shows the result of this drawing. The path markup syntax allows more commands such as horizontal lines (H), vertical lines (V), cubic Bézier curves (C), quadratic Bézier curves (Q), smooth cubic Bézier curves (S), smooth quadratic Bézier curves (T), and elliptical arcs (A):

```
         <Path Canvas.Left="0" Canvas.Top="200" Fill="Yellow" Stroke="Blue"
               StrokeThickness="2.5"
               Data="M 120,5 L 128,80 L 220,50 L 160,130 L 190,220 L 100,150 L 80,230 L
                     60,140 L0,110 L70,80 Z" StrokeLineJoin="Round">
         </Path>
```

TRANSFORMATION

Because WPF is vector-based, you can resize every element. The vector-based graphics are now scaled, rotated, and skewed. Hit testing (for example with mouse moves and mouse clicks) is still working without the need for manual position calculation.

Adding the `ScaleTransform` element to the `LayoutTransform` property of the Canvas element, as shown, resizes the content of the complete canvas by 2 in the X and Y directions:

```
<Canvas.LayoutTransform>
  <ScaleTransform ScaleX="1.5" ScaleY="1.5" />
</Canvas.LayoutTransform>
```

code snippet TransformationDemo/MainWindow.xaml

Rotation can be done in a similar way as scaling. Using the `RotateTransform` element you can define the `Angle` for the rotation:

```
<Canvas.LayoutTransform>
   <RotateTransform Angle="40" />
</Canvas.LayoutTransform>
```

For skewing, you can use the `SkewTransform` element. With skewing you can assign angles for the X and Y directions:

```
<Canvas.LayoutTransform>
   <SkewTransform AngleX="20" AngleY="25" />
</Canvas.LayoutTransform>
```

To rotate and skew together, it is possible to define a `TransformGroup` that contains both `RotateTransform` and `SkewTransform`. It is also possible to define a `MatrixTransform` where the `Matrix` element specifies the properties `M11` and `M22` for stretch and `M12` and `M21` for skew:

```
<Canvas.LayoutTransform>
    <MatrixTransform>
        <MatrixTransform.Matrix>
            <Matrix M11="0.8" M22="1.6" M12="1.3" M21="0.4" />
        </MatrixTransform.Matrix>
    </MatrixTransform>
</Canvas.LayoutTransform>
```

Figure 35-7 shows the results of all the transformations. The figures are placed inside a `StackPanel`. Starting from the left side, the first figure is resized, the second figure rotated, the third figure skewed, and the fourth figure uses a matrix for its transformation. To see the difference more easily, the `Background` property of the `Canvas` elements are set to different colors.

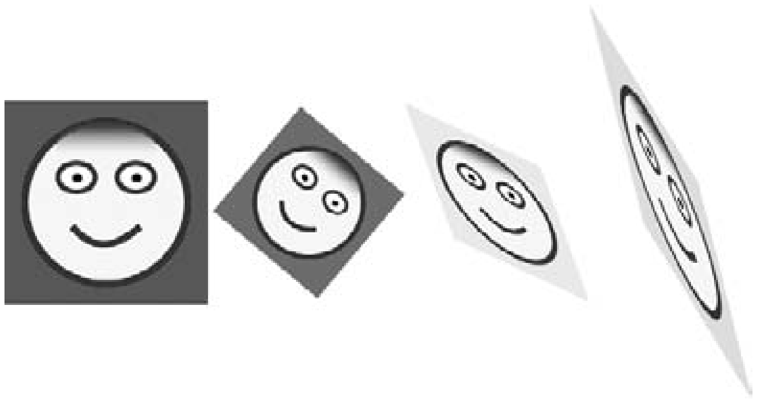

FIGURE 35-7

BRUSHES

This section illustrates how to use the brushes that WPF offers for drawing backgrounds and foregrounds. This section will reference Figure 35-8, which shows the effects of using various brushes within a `Path` and the `Background` of `Button` elements, throughout.

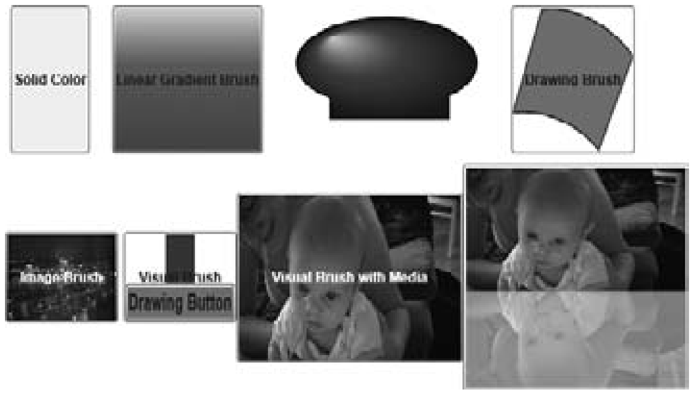

FIGURE 35-8

SolidColorBrush

The first button in Figure 35-8 uses the `SolidColorBrush`, which, by name, uses a solid color. The complete area is drawn with the same color.

You can define a solid color just by setting the `Background` attribute to a string that defines a solid color. The string is converted to a `SolidColorBrush` element with the help of the `BrushValueSerializer`:

```
<Button Height="30" Background="PapayaWhip">Solid Color</Button>
```

Of course, you will get the same effect by setting the `Background` child element and adding a `SolidColorBrush` element as its content. The first button in the application is using `PapayaWhip` as the solid background color:

```
<Button Content="Solid Color" Margin="10">
    <Button.Background>
        <SolidColorBrush Color="PapayaWhip" />
    </Button.Background>
</Button>
```

code snippet BrushesDemo/MainWindow.xaml

LinearGradientBrush

For a smooth color change, you can use the `LinearGradientBrush`, as shown with the second button. This brush defines the `StartPoint` and `EndPoint` properties. With this, you can assign 2-dimensional coordinates for the linear gradient. The default gradient is diagonal linear from `0,0` to `1,1`. By defining different values, the gradient can take different directions. For example, with a `StartPoint` of `0,0` and an `EndPoint` of `0,1`, you get a vertical gradient. The same `StartPoint` and an `EndPoint` value of `1,0` creates a horizontal gradient.

With the content of this brush, you can define the color values at the specified offsets with the `GradientStop` element. Between the stops, the colors are smoothed:

```
<Button Content="Linear Gradient Brush" Margin="10">
    <Button.Background>
        <LinearGradientBrush StartPoint="0,0" EndPoint="0,1">
```

```
                <GradientStop Offset="0" Color="LightGreen" />
                <GradientStop Offset="0.4" Color="Green" />
                <GradientStop Offset="1" Color="DarkGreen" />
            </LinearGradientBrush>
        </Button.Background>
    </Button>
```

RadialGradientBrush

With the `RadialGradientBrush` you can smooth the color in a radiant way. In Figure 35-8, the third element is a `Path` that uses `RadialGradientBrush`. This brush defines the color start with the `GradientOrigin` point:

```
<Canvas Width="200" Height="150">
    <Path Canvas.Top="0" Canvas.Left="20" Stroke="Black" >
        <Path.Fill>
            <RadialGradientBrush GradientOrigin="0.2,0.2">
                <GradientStop Offset="0" Color="LightBlue" />
                <GradientStop Offset="0.6" Color="Blue" />
                <GradientStop Offset="1.0" Color="DarkBlue" />
            </RadialGradientBrush>
        </Path.Fill>
        <Path.Data>
            <CombinedGeometry GeometryCombineMode="Union">
                <CombinedGeometry.Geometry1>
                    <EllipseGeometry Center="80,60" RadiusX="80"
                                     RadiusY="40" />
                </CombinedGeometry.Geometry1>
                <CombinedGeometry.Geometry2>
                    <RectangleGeometry Rect="30,60 105 50" />
                </CombinedGeometry.Geometry2>
            </CombinedGeometry>
        </Path.Data>
    </Path>
</Canvas>
```

DrawingBrush

The `DrawingBrush` allows you to define a drawing that is painted with the brush. The drawing that is shown with the brush is defined within a `GeometryDrawing` element. The `GeometryGroup`, which you can see within the `Geometry` property, consists of the `Geometry` elements that were discussed earlier in this chapter:

```
<Button Content="Drawing Brush" Margin="10" Padding="10">
    <Button.Background>
        <DrawingBrush>
            <DrawingBrush.Drawing>
                <GeometryDrawing Brush="Red">
                    <GeometryDrawing.Pen>
                        <Pen>
                            <Pen.Brush>
                                <SolidColorBrush>Blue</SolidColorBrush>
                            </Pen.Brush>
                        </Pen>
                    </GeometryDrawing.Pen>
                    <GeometryDrawing.Geometry>
                        <PathGeometry>
                            <PathGeometry.Figures>
                                <PathFigure StartPoint="70,40">
                                    <PathFigure.Segments>
```

```
                                        <BezierSegment Point1="90,37"
                                            Point2="130,46" Point3="150,63" />
                                        <LineSegment Point="120,110" />
                                        <BezierSegment Point1="100,95"
                                            Point2="70,90" Point3="45,91" />
                                        <LineSegment Point="70,40" />
                                    </PathFigure.Segments>
                                </PathFigure>
                            </PathGeometry.Figures>
                        </PathGeometry>
                    </GeometryDrawing.Geometry>
                </GeometryDrawing>
            </DrawingBrush.Drawing>
        </DrawingBrush>
    </Button.Background>
</Button>
```

ImageBrush

To load an image into a brush, you can use the `ImageBrush` element. With this element, the image defined by the `ImageSource` property is displayed. The image can be accessed from the file system or from a resource within the assembly. In the example, the image is added as a resource to the assembly and referenced with the assembly and resource names:

```
<Button Content="Image Brush" Width="100" Height="80" Margin="5"
        Foreground="White">
    <Button.Background>
        <ImageBrush ImageSource="/BrushesDemo;component/Budapest.jpg" />
    </Button.Background>
</Button>
```

VisualBrush

The `VisualBrush` allows you to use other WPF elements in a brush. Here, you can add a WPF element to the `Visual` property. The sixth element in Figure 35-8 contains a `Rectangle` and a `Button`:

```
<Button Content="Visual Brush" Width="100" Height="80">
    <Button.Background>
        <VisualBrush>
            <VisualBrush.Visual>
                <StackPanel Background="White">
                    <Rectangle Width="25" Height="25" Fill="Blue" />
                    <Button Content="Drawing Button" Background="Red" />
                </StackPanel>
            </VisualBrush.Visual>
        </VisualBrush>
    </Button.Background>
</Button>
```

You can add any `UIElement` to the `VisualBrush`. One example is that you can play a video by using the `MediaElement`:

```
<Button Content="Visual Brush with Media" Width="200" Height="150"
        Foreground="White">
    <Button.Background>
        <VisualBrush>
            <VisualBrush.Visual>
                <MediaElement Source="./Stephanie.wmv" />
            </VisualBrush.Visual>
        </VisualBrush>
    </Button.Background>
</Button>
```

You can use the VisualBrush to create interesting effects such as reflection. The button shown here contains a StackPanel that itself contains a MediaElement playing a video and a Border. The Border contains a Rectangle that is filled with a VisualBrush. This brush defines an opacity value and a transformation. The Visual property is bound to the Border element. The transformation is done by setting the RelativeTransform property of the VisualBrush. This transformation uses relative coordinates. By setting ScaleY to -1, a reflection in the Y direction is done. TranslateTransform moves the transformation in the Y direction so that the reflection is below the original object. You can see the result in the eighth element in Figure 35-8.

Data binding and the Binding *element that is used here are explained in detail in Chapter 36.*

```
<Button Width="200" Height="200" Foreground="White">
    <StackPanel>
        <MediaElement x:Name="reflected" Source="./Stephanie.wmv" />
        <Border Height="100">
            <Rectangle>
                <Rectangle.Fill>
                    <VisualBrush Opacity="0.35" Stretch="None"
                                 Visual="{Binding ElementName=reflected}">
                        <VisualBrush.RelativeTransform>
                            <TransformGroup>
                                <ScaleTransform ScaleX="1" ScaleY="-1" />
                                <TranslateTransform Y="1" />

                            </TransformGroup>
                        </VisualBrush.RelativeTransform>
                    </VisualBrush>
                </Rectangle.Fill>
            </Rectangle>
        </Border>
    </StackPanel>
</Button>
```

CONTROLS

You can use hundreds of controls with WPF. For a better understanding, the controls are categorized into these groups:

- Simple
- Content
- Headered content
- Items
- Headered items
- Decoration

Simple Controls

Simple controls are controls that don't have a Content property. With the Button class, you have seen that the Button can contain any shape, or any element you like. This is not possible with simple controls. The following table shows simple controls and their functionality.

SIMPLE CONTROL	DESCRIPTION
PasswordBox	This control is used to enter a password and has specific properties for password input, for example, PasswordChar, to define the character that should show up as the user enters the password, or Password to access the password entered. The PasswordChanged event is invoked as soon as the password is changed.
ScrollBar	This control contains a Thumb where the user can select a value. A scrollbar can be used, for example, if a document doesn't fit on the screen. Some controls contain scrollbars that show up if the content is too big.
ProgressBar	With this control, you can indicate the progress of a lengthy operation.
Slider	With this control, the user can select a range of values by moving a Thumb. ScrollBar, ProgressBar, and Slider are derived from the same base class, RangeBase.
TextBox	Used to display simple, unformatted text.
RichTextBox	Supports rich text with the help of the FlowDocument class. RichTextBox and TextBox are derived from the same base class, TextBoxBase.
Calendar	The Calendar control is new with .NET 4 — it displays a month, year, or decade. The user can select a date or range of dates.
DatePicker	The DatePicker is a control that opens a Calendar onscreen for date selection by the user.

Although simple controls do not have a Content *property, you can completely customize the look of the control by defining a template. Templates are discussed later in this chapter.*

Content Controls

A ContentControl has a Content property, with which you can add any content to the control. The Button class derives from the base class ContentControl, so you can add any content to this control. In a previous example, you saw a Canvas control within the Button. Content controls are described in the following table.

CONTENTCONTROL CONTROLS	DESCRIPTION
Button RepeatButton ToggleButton CheckBoxRadioButton	The classes Button, RepeatButton, ToggleButton, and GridViewColumnHeader are derived from the same base class, ButtonBase. All buttons react to the Click event. The RepeatButton raises the Click event repeatedly until the button is released. ToggleButton is the base class for CheckBox and RadioButton. These buttons have an on and off state. The CheckBox can be selected and cleared by the user; the RadioButton can be selected by the user. Clearing the RadioButton must be done programmatically.
Label	The Label class represents the text label for a control. This class also has support for access keys, for example, a menu command.
Frame	The Frame control supports navigation. You can navigate to a page content with the Navigate() method. If the content is a Web page, then the Web browser control is used for display.
ListBoxItem	ListBoxItem is an item inside a ListBox control.
StatusBarItem	StatusBarItem is an item inside a StatusBar control.
ScrollViewer	The ScrollViewer control is a content control that includes scrollbars. You can put any content in this control; the scrollbars will show up as needed.
ToolTip	ToolTip creates a pop-up window to display additional information for a control.

continues

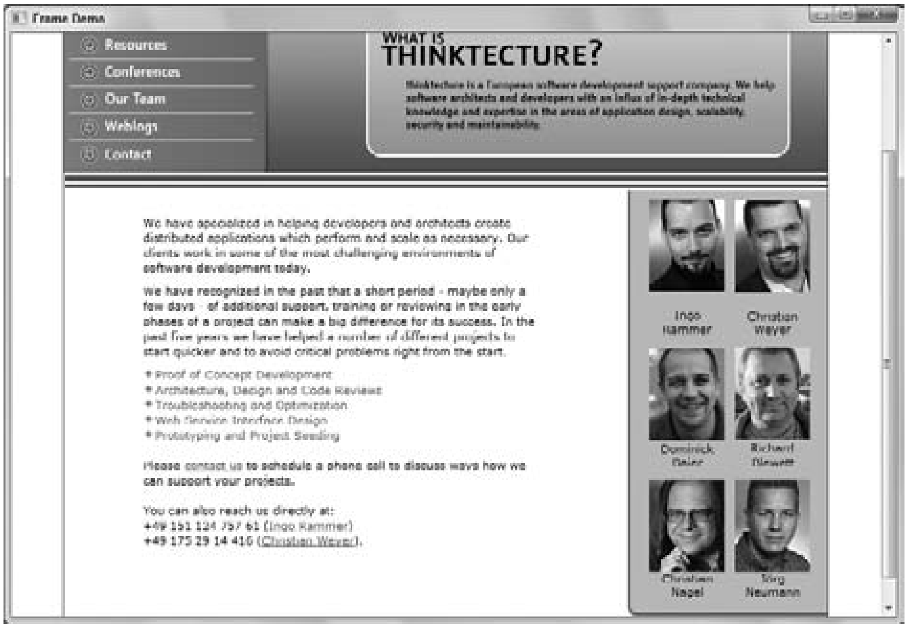
(continued)

CONTENTCONTROL CONTROLS	DESCRIPTION
`UserControl`	Using the class `UserControl` as a base class provides a simple way to create custom controls. However, the `UserControl` base class does not support templates.
`Window`	The `Window` class allows you to create windows and dialog boxes. With the `Window` class, you get a frame with minimize/maximize/close buttons and a system menu. When showing a dialog box, you can use the `ShowDialog()` method; the `Show()` method opens a window.
`NavigationWindow`	The `NavigationWindow` class derives from the `Window` class and supports content navigation.

Only a `Frame` control is contained within the `Window` of the following XAML code. The `Source` property is set to `http://www.thinktecture.com`, so the `Frame` control navigates to this web site, as you can see in Figure 35-9.

```
<Window x:Class="FrameDemo.MainWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        Title="Frame Demo" Height="240" Width="500">
    <Frame Source="http://www.thinktecture.com" />
</Window>
```

code snippet FrameDemo/MainWindow.xaml



WHAT IS THINKTECTURE?

Thinktecture is a European software development support company. We help software architects and developers with an influx of in-depth technical knowledge and expertise in the areas of application design, scalability, security and maintainability.

We have specialized in helping developers and architects create distributed applications which perform and scale as necessary. Our clients work in some of the most challenging environments of software development today.

We have recognized in the past that a short period - maybe only a few days - of additional support, training or reviewing in the early phases of a project can make a big difference for its success. In the past five years we have helped a number of different projects to start quicker and to avoid critical problems right from the start.

* Proof of Concept Development
* Architecture, Design and Code Reviews
* Troubleshooting and Optimization
* Web Service Interface Design
* Prototyping and Project Seeding

Please contact us to schedule a phone call to discuss ways how we can support your projects.

You can also reach us directly at:
+49 151 124 757 61 (Ingo Rammer)
+49 175 29 14 416 (Christian Weyer).

FIGURE 35-9

Headered Content Controls

Content controls with a header are derived from the base class `HeaderedContentControl`, which itself is derived from the base class `ContentControl`. The `HeaderedContentControl` class has a property `Header` to define the content of the header and `HeaderTemplate` for complete customization of the header. The controls that are derived from the base class `HeaderedContentControl` are listed in the following table.

HEADEREDCONTENTCONTROL	DESCRIPTION
`Expander`	With the `Expander` control, you can create an "advanced" mode with a dialog box that, by default, does not show all information but that can be expanded by the user to show more information. In the unexpanded mode, header information is shown. In expanded mode, the content is visible.
`GroupBox`	The `GroupBox` control provides a border and a header to group controls.
`TabItem`	`TabItem` controls are items within the class `TabControl`. The `Header` property of the `TabItem` defines the content of the header shown with the tabs of the `TabControl`.

A simple use of the `Expander` control is shown in the next example. The `Expander` control has the property `Header` set to `Click for more`. This text is displayed for expansion. The content of this control is shown only if the control is expanded. Figure 35-10 shows the application with a collapsed `Expander` control. Figure 35-11 shows the same application with an expanded `Expander` control:

```
<Window x:Class="ExpanderDemo.MainWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        Title="Expander Demo" Height="240" Width="500">
    <StackPanel>
        <TextBlock>Short information</TextBlock>
        <Expander Header="Additional Information">
            <Border Height="200" Width="200" Background="Yellow">
                <TextBlock HorizontalAlignment="Center"
                  VerticalAlignment="Center">
                  More information here!
                </TextBlock>
            </Border>
        </Expander>
    </StackPanel>
</Window>
```

code snippet ExpanderDemo/MainWindow.xaml

To make the header text of the `Expander` *control change when the control is expanded, you can create a trigger. Triggers are explained later in this chapter.*

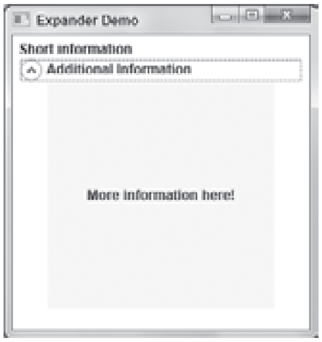

FIGURE 35-11

Items Controls

The `ItemsControl` class contains a list of items that can be accessed with the `Items` property. Classes that are derived from `ItemsControl` are shown in the following table.

ITEMSCONTROL	DESCRIPTION
`Menu` `ContextMenu`	The classes `Menu` and `ContextMenu` are derived from the abstract base class `MenuBase`. You can offer menus to the user by placing `MenuItem` elements in the items list and associating commands.
`StatusBar`	The `StatusBar` control is usually shown at the bottom of an application to give status information to the user. You can put `StatusBarItem` elements inside a `StatusBar` list.
`TreeView`	For a hierarchical display of items, you can use the `TreeView` control.

`ListBox`
`ComboBox`
`TabControl`
	`ListBox`, `ComboBox`, and `TabControl` have the same abstract base class, `Selector`. This base class makes it possible to select items from a list. The `ListBox` displays the items from a list. The `ComboBox` has an additional `Button` control to display the items only if the button is clicked. With `TabControl`, content can be arranged in tabular form.

`DataGrid`	The `DataGrid` control is a customizable grid that displays data. This control is new with .NET 4 and is discussed in detail in the next chapter.

Headered Items Controls

`HeaderedItemsControl` is the base class of controls that include items but also has a header. The class `HeaderedItemsControl` is derived from `ItemsControl`.

Classes that are derived from `HeaderedItemsControl` are listed in the following table.

HEADEREDITEMSCONTROL	DESCRIPTION
`MenuItem`	The menu classes `Menu` and `ContextMenu` include items of the `MenuItem` type. Menu items can be connected to commands, as the `MenuItem` class implements the interface `ICommandSource`.
`TreeViewItem`	The `TreeView` class can include items of type `TreeViewItem`.
`ToolBar`	The `ToolBar` control is a container for a group of controls, usually `Button` and `Separator` elements. You can place the `ToolBar` inside a `ToolBarTray` that handles rearranging of `ToolBar` controls.

Decoration

Adding decorations to a single element is done with the `Decorator` class. `Decorator` is a base class that has derivations such as `Border`, `Viewbox`, and `BulletDecorator`. Theme elements such as `ButtonChrome` and `ListBoxChrome` are also decorators.

The following example demonstrates a `Border`, `Viewbox`, and `BulletDecorator`, as in Figure 35-12.

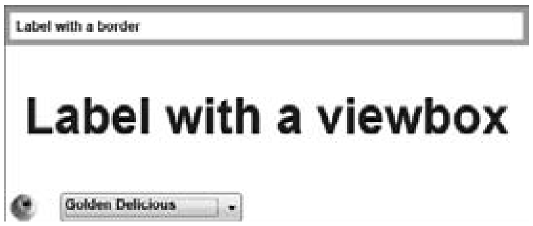

FIGURE 35-12

The `Border` class decorates the `Children` element by adding a border around it. You can define a brush and the thickness of the border, the background, the radius of the corner, and the padding of its children:

```
<Border BorderBrush="Violet" BorderThickness="5.5">
    <Label>Label with a border</Label>
</Border>
```

code snippet DecorationsDemo/MainWindow.xaml

The `Viewbox` stretches and scales its child to the available space. The `StretchDirection` and `Stretch` properties are specific to the functionality of the `Viewbox`. These properties allow setting if the child is stretched in both directions, and if the aspect ratio is preserved:

```
<Viewbox StretchDirection="Both" Stretch="Uniform">
    <Label>Label with a viewbox</Label>
</Viewbox>
```

The `BulletDecorator` class decorates its child with a bullet. The child can be any element (in this example, a `ComboBox`). Similarly, the bullet can also be any element. The example uses an `Image`, but you can use any `UIElement`:

```
<BulletDecorator>
    <BulletDecorator.Bullet>
        <Image Width="25" Height="25" Margin="5" HorizontalAlignment="Center"
               VerticalAlignment="Center"
               Source="/DecorationsDemo;component/images/apple1.jpg" />
    </BulletDecorator.Bullet>
    <BulletDecorator.Child>
        <ComboBox Margin="25,5,5,5" Width="120" HorizontalAlignment="Left">
            <ComboBoxItem>Granny Smith</ComboBoxItem>
            <ComboBoxItem>Gravenstein</ComboBoxItem>
            <ComboBoxItem>Golden Delicious</ComboBoxItem>
            <ComboBoxItem>Braeburn</ComboBoxItem>
        </ComboBox>
    </BulletDecorator.Child>
</BulletDecorator>
```

LAYOUT

To define the layout of the application, you can use a class that derives from the `Panel` base class. Several layout containers are available that are discussed here. A layout container needs to do two main tasks: measure and arrange. With measuring, the container asks its children for the preferred sizes. Because the complete size answered by the controls might not be available, the container next decides and arranges the size and positions of its children.

StackPanel

The `Window` can contain just a single element as content. If you want to have more than one element inside there, then you can use a `StackPanel` as a child of the `Window`, and add elements to the content of the `StackPanel`. The `StackPanel` is a simple container control that just shows one element after the other. The orientation of the `StackPanel` can be horizontal or vertical. The class `ToolBarPanel` is derived from `StackPanel`:

```
<Window x:Class="LayoutDemo.StackPanelWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        Title="StackPanelWindow" Height="300" Width="300">
    <StackPanel Orientation="Vertical">
        <Label>Label</Label>
        <TextBox>TextBox</TextBox>
        <CheckBox>CheckBox</CheckBox>
        <CheckBox>CheckBox</CheckBox>
        <ListBox>
            <ListBoxItem>ListBoxItem One</ListBoxItem>
            <ListBoxItem>ListBoxItem Two</ListBoxItem>
            </ListBox>
            <Button>Button</Button>
        </StackPanel>
    </Window>
```

code snippet LayoutDemo/StackPanelWindow.xaml

You can see the child controls of the `StackPanel` organized vertically in Figure 35-13.

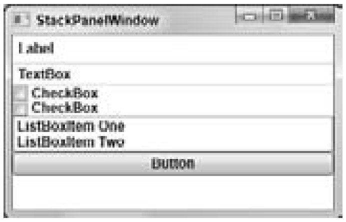

FIGURE 35-13

WrapPanel

The `WrapPanel` positions the children from left to right, one after the other, as long as they fit into the line, and then continues with the next line. The orientation of the panel can be horizontal or vertical:

```
    <Window x:Class="LayoutDemo.WrapPanelWindow"
            xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
            xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
            Title="WrapPanelWindow" Height="300" Width="300">
        <WrapPanel>
            <Button Width="100" Margin="5">Button</Button>
            <Button Width="100" Margin="5">Button</Button>
            <Button Width="100" Margin="5">Button</Button>
            <Button Width="100" Margin="5">Button</Button>
            <Button Width="100" Margin="5">Button</Button>
            <Button Width="100" Margin="5">Button</Button>
            <Button Width="100" Margin="5">Button</Button>
            <Button Width="100" Margin="5">Button</Button>
        </WrapPanel>
    </Window>
```

code snippet LayoutDemo/WrapPanelWindow.xaml

Figure 35-14 shows the output of the panel. If you resize the application, then the buttons will be rearranged so that they fit into a line.

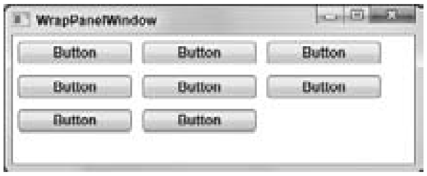

FIGURE 35-14

Canvas

`Canvas` is a panel that allows you to explicitly position controls. `Canvas` defines the attached properties `Left`, `Right`, `Top`, and `Bottom` that can be used by the children for positioning within the panel:

```
    <Window x:Class="LayoutDemo.CanvasWindow"
            xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
            xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
            Title="CanvasWindow" Height="300" Width="300">
        <Canvas Background="LightBlue">
            <Label Canvas.Top="30" Canvas.Left="20">Enter here:</Label>
            <TextBox Canvas.Top="30" Canvas.Left="120" Width="100" />
            <Button Canvas.Top="70" Canvas.Left="130" Content="Click Me!" Padding="5" />
        </Canvas>
    </Window>
```

code snippet LayoutDemo/CanvasWindow.xaml

Figure 35-15 shows the output of the `Canvas` panel with the positioned children `Label`, `TextBox`, and `Button`.

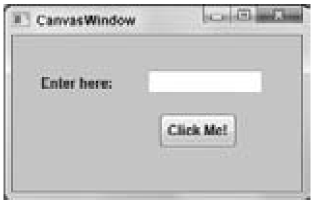

FIGURE 35-15

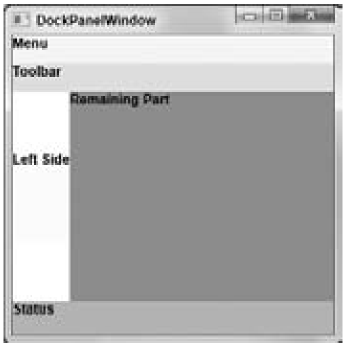

FIGURE 35-16

DockPanel

The `DockPanel` is very similar to the Windows Forms docking functionality. Here, you can specify the area where child controls should be arranged. `DockPanel` defines the attached property `Dock`, which you can set in the children of the controls to the values `Left`, `Right`, `Top`, and `Bottom`. Figure 35-16 shows the outcome of text blocks with borders that are arranged in the dock panel. For easier differentiation, different colors are specified for the various areas:

```
<Window x:Class="LayoutDemo.DockPanelWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        Title="DockPanelWindow" Height="300" Width="300">
    <DockPanel>
        <Border Height="25" Background="AliceBlue" DockPanel.Dock="Top">
            <TextBlock>Menu</TextBlock>
        </Border>
        <Border Height="25" Background="Aqua" DockPanel.Dock="Top">
            <TextBlock>Toolbar</TextBlock>
        </Border>
        <Border Height="30" Background="LightSteelBlue" DockPanel.Dock="Bottom">
            <TextBlock>Status</TextBlock>
        </Border>
        <Border Height="80" Background="Azure" DockPanel.Dock="Left">
            <TextBlock>Left Side</TextBlock>
        </Border>
        <Border Background="HotPink">
            <TextBlock>Remaining Part</TextBlock>
        </Border>
    </DockPanel>
</Window>
```

code snippet LayoutDemo/DockPanelWindow.xaml

Grid

Using the `Grid`, you can arrange your controls with rows and columns. For every column, you can specify a `ColumnDefinition`. For every row, you can specify a `RowDefinition`. The sample code lists two columns and three rows. With each column and row, you can specify the width or height. `ColumnDefinition` has a `Width` dependency property; `RowDefinition` has a `Height` dependency property. You can define the height and width in pixels, centimeters, inches, or points, or by setting it to `Auto` to determine the size depending on the content. The grid also allows star sizing, whereby the space for the rows and columns is calculated according to the available space and relative to other rows and columns. When providing the available space for a column, you can set the `Width` property to `*`. To have the size doubled for another column, you specify `2*`. The sample code, which defines two columns and three rows, doesn't define additional settings with the column and row definitions; the default is the star sizing.

The grid contains several `Label` and `TextBox` controls. Because the parent of these controls is a grid, you can set the attached properties `Column`, `ColumnSpan`, `Row`, and `RowSpan`:

```
<Window x:Class="LayoutDemo.GridWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        Title="GridWindow" Height="300" Width="300">
    <Grid ShowGridLines="True">
        <Grid.ColumnDefinitions>
            <ColumnDefinition />
            <ColumnDefinition />
        </Grid.ColumnDefinitions>
        <Grid.RowDefinitions>
            <RowDefinition />
            <RowDefinition />
            <RowDefinition />
        </Grid.RowDefinitions>
        <Label Grid.Column="0" Grid.ColumnSpan="2" Grid.Row="0"
               VerticalAlignment="Center" HorizontalAlignment="Center" Content="Title" />
        <Label Grid.Column="0" Grid.Row="1" VerticalAlignment="Center"
               Content="Firstname:" Margin="10" />
        <TextBox Grid.Column="1" Grid.Row="1" Width="100" Height="30" />
        <Label Grid.Column="0" Grid.Row="2" VerticalAlignment="Center"
               Content="Lastname:" Margin="10" />
        <TextBox Grid.Column="1" Grid.Row="2" Width="100" Height="30" />
    </Grid>
</Window>
```

code snippet LayoutDemo/GridWindow.xaml

The outcome arranging controls in a grid is shown in Figure 35-17. For easier viewing of the columns and rows, the property `ShowGridLines` is set to `true`.

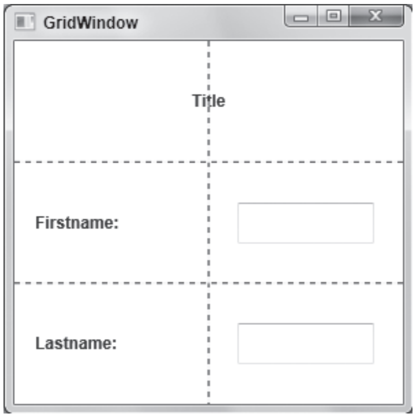

FIGURE 35-17

For a grid where every cell has the same size, you can use the `UniformGrid` *class.*

STYLES AND RESOURCES

You can define the look and feel of the WPF elements by setting properties, such as `FontSize` and `Background`, with the `Button` element as shown:

```
<Button Width="150" FontSize="12" Background="AliceBlue" Content="Click Me!" />
```

code snippet StylesAndResources/MainWindow.xaml

Instead of defining the look and feel with every element, you can define styles that are stored with resources. To completely customize the look for controls, you can use templates and store them into resources.

Styles

The `Style` property of a control can be assigned to a `Style` element that has setters associated with it. A `Setter` element defines the `Property` and `Value` properties and sets a specified property to a value. Here, the `Background`, `FontSize`, and `FontWeight` properties are set. The `Style` is set to the `TargetType` `Button`, so that the properties of the `Button` can be directly accessed. If the `TargetType` of the style is not set, the properties can be accessed via `Button.Background`, `Button.FontSize`. This is especially important if properties of different element types need to be set:

```
<Button Width="150" Content="Click Me!">
    <Button.Style>
        <Style TargetType="Button">
            <Setter Property="Background" Value="Yellow" />
            <Setter Property="FontSize" Value="14" />
            <Setter Property="FontWeight" Value="Bold" />
        </Style>
    </Button.Style>
</Button>
```

code snippet StylesAndResources/MainWindow.xaml

Setting the `Style` directly with the `Button` element doesn't really help a lot in regard to style sharing. Styles can be put into resources. Within the resources you can assign styles to specific elements, assign a style to all elements of a type, or use a key for the style. To assign a style to all elements of a type, use the `TargetType` property of the `Style` and assign it to a `Button` by specifying the `x:Type` markup extension `{x:Type Button}`. For defining a style that needs to be referenced, `x:Key` must be set:

```
<Window.Resources>
    <Style TargetType="{x:Type Button}">
        <Setter Property="Background" Value="LemonChiffon" />
        <Setter Property="FontSize" Value="18" />
    </Style>
    <Style x:Key="ButtonStyle">
        <Setter Property="Button.Background" Value="Red" />
        <Setter Property="Button.Foreground" Value="White" />
        <Setter Property="Button.FontSize" Value="18" />
    </Style>
</Window.Resources>
```

In the following XAML code the first button — which doesn't have a style defined with the element properties — gets the style that is defined for the `Button` type. With the next button, the `Style` property is set with the `StaticResource` markup extension to `{StaticResource ButtonStyle}`, whereas `ButtonStyle` specifies the key value of the style resource defined earlier, so this button has a red background and a white foreground:

```
<Button Width="200" Content="Uses named style"
        Style="{StaticResource ButtonStyle}" Margin="3" />
```

Instead of setting the Background of a button to just a single value, you can also do more. You can set the Background property to a LinearGradientBrush with a gradient color definition as shown:

```
<Style x:Key="FancyButtonStyle">
    <Setter Property="Button.FontSize" Value="22" />
    <Setter Property="Button.Foreground" Value="White" />
    <Setter Property="Button.Background">
        <Setter.Value>
            <LinearGradientBrush StartPoint="0,0" EndPoint="0,1">
                <GradientStop Offset="0.0" Color="LightCyan" />
                <GradientStop Offset="0.14" Color="Cyan" />
                <GradientStop Offset="0.7" Color="DarkCyan" />
            </LinearGradientBrush>
        </Setter.Value>
    </Setter>
</Style>
```

The next button in this example has a fancy style with cyan applied as the linear gradient:

```
<Button Width="200" Content="Fancy button style"
        Style="{StaticResource FancyButtonStyle}" Margin="3" />
```

Styles offer a kind of inheritance. One style can be based on another one. The style AnotherButtonStyle is based on the style FancyButtonStyle. It uses all the settings defined by that style, and referenced by the BasedOn property, except the Foreground property — which is set to LinearGradientBrush:

```
<Style x:Key="AnotherButtonStyle" BasedOn="{StaticResource FancyButtonStyle}"
      TargetType="Button">
    <Setter Property="Foreground">
        <Setter.Value>
            <LinearGradientBrush>
                <GradientStop Offset="0.2" Color="White" />
                <GradientStop Offset="0.5" Color="LightYellow" />
                <GradientStop Offset="0.9" Color="Orange" />
            </LinearGradientBrush>
        </Setter.Value>
    </Setter>
</Style>
```

The last button has the AnotherButtonStyle applied:

```
<Button Width="200" Content="Style inheritance"
        Style="{StaticResource AnotherButtonStyle}" Margin="3" />
```

You can see the results of all these buttons styled in Figure 35-18.

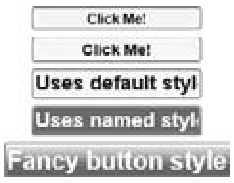

FIGURE 35-18

Resources

As you have seen with the styles sample, usually styles are stored within resources. You can define any freezable element within a resource. For example, the brush created earlier for the background style of the button can itself be defined as a resource, so you can use it everywhere a brush is required.

The following example defines a LinearGradientBrush with the key name MyGradientBrush inside the StackPanel resources. button1 assigns the Background property by using a StaticResource markup extension to the resource MyGradientBrush. Figure 35-19 shows the output from this XAML code:

```
<StackPanel x:Name="myContainer">
    <StackPanel.Resources>
        <LinearGradientBrush x:Key="MyGradientBrush" StartPoint="0,0"
                             EndPoint="0.3,1">
            <GradientStop Offset="0.0" Color="LightCyan" />
            <GradientStop Offset="0.14" Color="Cyan" />
            <GradientStop Offset="0.7" Color="DarkCyan" />
        </LinearGradientBrush>
    </StackPanel.Resources>
```

```
        <Button Width="200" Height="50" Foreground="White" Margin="5"
                Background="{StaticResource MyGradientBrush}" Content="Click Me!" />
    </StackPanel>
```

code snippet StylesAndResources/MainWindow.xaml

FIGURE 35-19

Here, the resources have been defined with the `StackPanel`. In the previous example, the resources were defined with the `Window` element. The base class `FrameworkElement` defines the property `Resources` of type `ResourceDictionary`. That's why resources can be defined with every class that is derived from the `FrameworkElement` — any WPF element.

Resources are searched hierarchically. If you define the resource with the `Window`, it applies to every child element of the `Window`. If the `Window` contains a `Grid`, and the `Grid` contains a `StackPanel`, and if you define the resource with the `StackPanel`, then the resource applies to every control within the `StackPanel`. If the `StackPanel` contains a `Button`, and you define the resource just with the `Button`, then this style is valid just for the button.

In regard to hierarchies, you need to pay attention if you use the `TargetType` *without a* `Key` *for styles. If you define a resource with the* `Canvas` *element and set the* `TargetType` *for the style to apply to* `TextBox` *elements, then the style applies to all* `TextBox` *elements within the* `Canvas`*. The style even applies to* `TextBox` *elements that are contained in a* `ListBox` *when the* `ListBox` *is in the* `Canvas`*.*

If you need the same style for more than one window, then you can define the style with the application. In a Visual Studio WPF project, the file `App.xaml` is created for defining global resources of the application. The application styles are valid for every window of the application. Every element can access resources that are defined with the application. If resources are not found with the parent window, then the search for resources continues with the `Application`:

```
<Application x:Class="StylesAndResources.App"
             xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
             xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
             StartupUri="MainWindow.xaml">
    <Application.Resources>

    </Application.Resources>
</Application>
```

code snippet StylesAndResources/App.xaml

System Resources

There are also some system-wide resources for colors and fonts that are available for all applications. These resources are defined with the classes `SystemColors`, `SystemFonts`, and `SystemParameters`:

- With `SystemColors` you get the color settings for borders, controls, the desktop, and windows, such as `ActiveBorderColor`, `ControlBrush`, `DesktopColor`, `WindowColor`, `WindowBrush`, and so on.
- The class `SystemFonts` returns the settings for the fonts of the menu, status bar, and message box. These include `CaptionFont`, `DialogFont`, `MenuFont`, `MessageBoxFont`, `StatusFont`, and so on.
- The class `SystemParameters` gives you settings for sizes of menu buttons, cursors, icons, borders, captions, timing information, and keyboard settings, such as `BorderWidth`, `CaptionHeight`, `CaptionWidth`, `MenuButtonWidth`, `MenuPopupAnimation`, `MenuShowDelay`, `SmallIconHeight`, `SmallIconWidth`, and so on.

Accessing Resources from Code

To access resources from code-behind, the base class `FrameworkElement` implements the method `FindResource()`, so you can invoke the `FindResource()` method with every WPF object.

To do this, `button1` doesn't have a background specified, but the `Click` event is assigned to the method `button1_Click`:

```
<Button Name="button1" Width="220" Height="50" Margin="5" Click="button1_Click">
    Apply Resource Programmatically
</Button>
```

code snippet StylesAndResources/ResourceDemo.xaml

With the implementation of `button1_Click()`, the `FindResource()` method is used on the `Button` that was clicked. Then a search for the resource `MyGradientBrush` happens hierarchically, and the brush is applied to the `Background` property of the control. The resource `MyGradientBrush` was created previously in the resources of the `StackPanel`:

```
public void button1_Click(object sender, RoutedEventArgs e)
{
   Control ctrl = sender as Control;
   ctrl.Background = ctrl.FindResource("MyGradientBrush") as Brush;
}
```

***code snippet StylesAndResources/ResourceDemo.xaml**.cs*

Dynamic Resources

With the `StaticResource` markup extension, resources are searched at load time. If the resource changes while the program is running, then you should use the `DynamicResource` markup extension instead.

The next example is using the same resource as defined previously. The earlier example used `StaticResource`. This button uses `DynamicResource` with the `DynamicResource` markup extension. The event handler of this button changes the resource programmatically. The handler method `button2_Click` is assigned to the `Click` event handler:

```
<Button Name="button2" Width="200" Height="50" Foreground="White" Margin="5"
        Background="{DynamicResource MyGradientBrush}" Content="Change Resource"
        Click="button2_Click" />
```

code snippet StylesAndResources/ResourceDemo.xaml

The implementation of `button2_Click()` clears the resources of the `StackPanel` and adds a new resource with the same name, `MyGradientBrush`. This new resource is very similar to the resource that is defined in XAML code; it just defines different colors:

```
private void button2_Click(object sender, RoutedEventArgs e)
{
    myContainer.Resources.Clear();
    var brush = new LinearGradientBrush
    {
        StartPoint = new Point(0, 0),
        EndPoint = new Point(0, 1)
    };

    brush.GradientStops = new GradientStopCollection()
```

```
            {
                new GradientStop(Colors.White, 0.0),
                new GradientStop(Colors.Yellow, 0.14),
                new GradientStop(Colors.YellowGreen, 0.7)
            };
            myContainer.Resources.Add("MyGradientBrush", brush);
        }
```

code snippet StylesAndResources/ResourceDemo.xaml.cs

When running the application, the resource changes dynamically by clicking the Change Resource button. Using the button with dynamic resource gets the dynamically created resource; the button with static resource looks the same as before.

Resource Dictionaries

If the same resources are used with different applications, it's useful to put the resource in a resource dictionary. Using resource dictionaries, the files can be shared between multiple applications, or the resource dictionary can be put into an assembly and shared by the applications.

To share a resource dictionary in an assembly, create a library. A resource dictionary file, here `Dictionary1.xaml`, can be added to the assembly. The build action for this file must be set to `Resource` so that it is added as a resource to the assembly.

`Dictionary1.xaml` defines two resources: `LinearGradientBrush` with the `CyanGradientBrush` key, and a style for a `Button` that can be referenced with the `PinkButtonStyle` key:

```
<ResourceDictionary xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
                    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml">
    <LinearGradientBrush x:Key="CyanGradientBrush" StartPoint="0,0" EndPoint="0.3,1">
        <GradientStop Offset="0.0" Color="LightCyan" />
        <GradientStop Offset="0.14" Color="Cyan" />
        <GradientStop Offset="0.7" Color="DarkCyan" />
    </LinearGradientBrush>

    <Style x:Key="PinkButtonStyle" TargetType="Button">
        <Setter Property="FontSize" Value="22" />
        <Setter Property="Foreground" Value="White" />
        <Setter Property="Background">
            <Setter.Value>
                <LinearGradientBrush StartPoint="0,0" EndPoint="0,1">
                    <GradientStop Offset="0.0" Color="Pink" />
                    <GradientStop Offset="0.3" Color="DeepPink" />
                    <GradientStop Offset="0.9" Color="DarkOrchid" />
                </LinearGradientBrush>
            </Setter.Value>
        </Setter>
    </Style>
</ResourceDictionary>
```

code snippet ResourcesLib/Dictionary1.xaml

With the target project, the library needs to be referenced, and the resource dictionary added to the dictionaries. You can use multiple resource dictionary files that can be added with the `MergedDictionaries` property of the `ResourceDictionary`. A list of resource dictionaries can be added to the merged dictionaries. With the `Source` property of `ResourceDictionary`, a dictionary can be referenced. For the reference, the pack URI syntax is used. The pack URI can be assigned as *absolute*, where the URI begins with `pack://`, or as *relative,* as it is used in this example. With relative syntax, the referenced assembly `ResourceLib`, which includes the dictionary, is first after the `/` followed by `;component`. `Component` means that the dictionary is included as a resource in the assembly. After that, the name of the dictionary file `Dictionary1.xaml` is added. If the dictionary is added into a subfolder, the folder name must be declared as well:

```
<Application x:Class="StylesAndResources.App"
             xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
             xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
             StartupUri="MainWindow.xaml">
    <Application.Resources>
        <ResourceDictionary>
            <ResourceDictionary.MergedDictionaries>
                <ResourceDictionary Source="/ResourceLib;component/Dictionary1.xaml" />
            </ResourceDictionary.MergedDictionaries>
        </ResourceDictionary>
    </Application.Resources>
</Application>
```

code snippet StylesAndResources/App.xaml

Now it is possible to use the resources from the referenced assembly in the same way as local resources:

```
<Button Width="300" Height="50" Style="{StaticResource PinkButtonStyle}"
        Content="Referenced Resource" />
```

code snippet StylesAndResources/ResourceDemo.xaml

TRIGGERS

With triggers you can change the look and feel of your controls dynamically because of some events or some property value changes. For example, when the user moves with the mouse over a button, the button can change its look. Usually, you need to do this with the C# code. With WPF, you can also do this with XAML, as long as only the UI is influenced.

There are several triggers with XAML. Property triggers are activated as soon as a property value changes. Multi-triggers are based on multiple property values. Event triggers fire when an event occurs. Data triggers happen when data that is bound is changed. In this section, property triggers, multi-triggers, and data triggers are discussed. Event triggers are explained later with animations.

Property Triggers

The `Style` class has a `Triggers` property where you can assign property triggers. The following example includes a `Button` element inside a `Grid` panel. With the `Window` resources, a default style for `Button` elements is defined. This style specifies that the `Background` is set to `LightBlue` and the `FontSize` to `17`. This is the style of the `Button` elements when the application is started. Using triggers, the style of the controls change. The triggers are defined within the `Style.Triggers` element, using the `Trigger` element. One trigger is assigned to the property `IsMouseOver`; the other trigger is assigned to the property `IsPressed`. Both of these properties are defined with the `Button` class that the style applies to. If `IsMouseOver` has a value of `true`, then the trigger fires and sets the `Foreground` property to `Red` and the `FontSize` property to `22`. If the `Button` is pressed, then the property `IsPressed` is `true`, and the second trigger fires and sets the `Foreground` property of the `TextBox` to `Yellow`.

```
<Window x:Class="TriggerDemo.PropertyTriggerWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        Title="PropertyTriggerWindow" Height="300" Width="300">
    <Window.Resources>
        <Style TargetType="Button">
            <Setter Property="Background" Value="LightBlue" />
            <Setter Property="FontSize" Value="17" />
            <Style.Triggers>
                <Trigger Property="IsMouseOver" Value="True">
                    <Setter Property="Foreground" Value="Red" />
                    <Setter Property="FontSize" Value="22" />
                </Trigger>
                <Trigger Property="IsPressed" Value="True">
                    <Setter Property="Foreground" Value="Yellow" />
                    <Setter Property="FontSize" Value="22" />
                </Trigger>
            </Style.Triggers>
        </Style>
    </Window.Resources>
    <Grid>
        <Button Width="200" Height="30" Content="Click me!" />
    </Grid>
</Window>
```

code snippet TriggerDemo/PropertyTriggerWindow.xaml

You don't need to reset the property values to the original values when the reason for the trigger is not valid anymore. For example, you don't need to define a trigger for `IsMouseOver=true` and `IsMouseOver=false`. As soon as the reason for the trigger is no longer valid, the changes made by the trigger action are reset to the original values automatically.

Figure 35-20 shows the trigger sample application, where on mouse focus the foreground and font size of the button are changed from their original values.

FIGURE 35-20

The `Trigger` class defines the following properties to specify the trigger action.

TRIGGER PROPERTY	DESCRIPTION
`Property` `Value`	With property triggers, the `Property` and `Value` properties are used to specify when the trigger should fire, for example, `Property="IsMouseOver" Value="True"`.
`Setters`	As soon as the trigger fires, you can use `Setters` to define a collection of `Setter` elements to change values for properties. The `Setter` class defines the properties `Property`, `TargetName`, and `Value` for the object properties to change.
`EnterActions` `ExitActions`	Instead of defining setters, you can define `EnterActions` and `ExitActions`. With both of these properties, you can define a collection of `TriggerAction` elements. `EnterActions` fires when the trigger starts (with a property trigger, when the `Property/Value` combination applies); `ExitActions` fires before it ends (just at the moment when the `Property/Value` combination no longer applies).Trigger actions that you can specify with these actions are derived from the base class `TriggerAction`, such as, `SoundPlayerAction` and `BeginStoryboard`. With `SoundPlayerAction`, you can start the playing of sound. `BeginStoryboard` is used with animation, which will be shown later in this chapter.

MultiTrigger

A property trigger fires when a value of a property changes. If you need to set a trigger because two or more properties have a specific value, you can use `MultiTrigger`.

`MultiTrigger` has a `Conditions` property where valid values of properties can be specified. It also has a `Setters` property, where the properties that need to be set can be specified. In the example, a style is defined for `TextBox` elements where the trigger applies if the `IsEnabled` property is `True` and the `Text` property has the `value Test`. If both apply, the `Foreground` property of the `TextBox` is set to `Red`:

```
<Window x:Class="TriggerDemo.MultiTriggerWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        Title="MultiTriggerWindow" Height="300" Width="300">
    <Window.Resources>
        <Style TargetType="TextBox">
            <Style.Triggers>
                <MultiTrigger>
                    <MultiTrigger.Conditions>
                        <Condition Property="IsEnabled" Value="True" />
                        <Condition Property="Text" Value="Test" />
                    </MultiTrigger.Conditions>
                    <MultiTrigger.Setters>
                        <Setter Property="Foreground" Value="Red" />
                    </MultiTrigger.Setters>
                </MultiTrigger>
            </Style.Triggers>
        </Style>
    </Window.Resources>
    <Grid>
        <TextBox />
    </Grid>
</Window>
```

code snippet TriggerDemo/MultiTriggerWindow.xaml

Data Triggers

Data triggers fire if bound data to a control fulfills specific conditions. In the following example, a `Book` class is used that has different displays depending on the publisher of the book.

The `Book` class defines the properties `Title` and `Publisher` and has an overload of the `ToString()` method:

```
    public class Book
    {
        public string Title { get; set; }
        public string Publisher { get; set; }

        public override string ToString()
        {
            return Title;
        }
    }
```

code snippet TriggerDemo/Book.cs

In the XAML code, a style is defined for `ListBoxItem` elements. The style contains `DataTrigger` elements that are bound to the `Publisher` property of the class that is used with the items. If the value of the `Publisher` property is Wrox Press, the `Background` is set to `Red`. With the publishers Dummies and Sybex, the `Background` is set to `Yellow` and `LightBlue` accordingly:

```
<Window x:Class="TriggerDemo.DataTriggerWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        Title="Data Trigger Window" Height="300" Width="300">
    <Window.Resources>
        <Style TargetType="ListBoxItem">
            <Style.Triggers>
                <DataTrigger Binding="{Binding Path=Publisher}" Value="Wrox Press">
                    <Setter Property="Background" Value="Red" />
                </DataTrigger>
                <DataTrigger Binding="{Binding Path=Publisher}" Value="Dummies">
                    <Setter Property="Background" Value="Yellow" />
                </DataTrigger>
                <DataTrigger Binding="{Binding Path=Publisher}" Value="Sybex">
                    <Setter Property="Background" Value="LightBlue" />
                </DataTrigger>
            </Style.Triggers>
        </Style>
    </Window.Resources>
    <Grid>
        <ListBox x:Name="list1" />
    </Grid>
</Window>
```

code snippet TriggerDemo/DataTriggerWindow.xaml

In the code-behind, the list with the name `list1` is initialized to contain several `Book` objects:

```
        public DataTriggerWindow()
        {
            InitializeComponent();
            list1.Items.Add(new Book
                {
                    Title = "Professional C# 4.0",
                    Publisher = "Wrox Press"
                });
            list1.Items.Add(new Book
                {
                    Title = "C# 2008 for Dummies",
                    Publisher = "Dummies"
                });
            list1.Items.Add(new Book
                {
                    Title = "Mastering Integrated HTML and CSS",
                    Publisher = "Sybex"
                });
        }
```

code snippet TriggerDemo/DataTriggerWindow.xaml.cs

Running the application, you can see in Figure 35-21 the `ListBoxItem` elements that are formatted according to the publisher value.

With `DataTrigger`, multiple properties must be set for `MultiDataTrigger` (similar to `Trigger` and `MultiTrigger`).

FIGURE 35-21

TEMPLATES

In this chapter, you have already seen that a `Button` control can have any content. The content can be simple text, but you can also add a `Canvas` element, which can contain shapes. You can add a `Grid`, or a video to the button. However, there is even more than that you can do with a button!

In WPF, the functionality of controls is completely separate from their look and feel. A button has a default look, but you can completely customize that look as you like with templates.

WPF gives you several template types that derive from the base class `FrameworkTemplate`.

TEMPLATE TYPE	DESCRIPTION
`ControlTemplate`	With a `ControlTemplate` you can specify the visual structure of a control and override the look.
`ItemsPanelTemplate`	For an `ItemsControl` you can specify the layout of its items by assigning an `ItemsPanelTemplate`. Each `ItemsControl` has a default `ItemsPanelTemplate`. For the `MenuItem`, it is a `WrapPanel`. The `StatusBar` uses a `DockPanel`, and the `ListBox` uses a `VirtualizingStackPanel`.
`DataTemplate`	`DataTemplate`s are very useful for graphical representations of objects. Styling a `ListBox`, you will see that, by default, the items of the `ListBox` are shown according to the output of the `ToString()` method. By applying a `DataTemplate` you can override this behavior and define a custom presentation of the items.
`HierarchicalDataTemplate`	The `HierarchicalDataTemplate` is used for arranging a tree of objects. This control supports `HeaderedItemsControls`, such as `TreeViewItem` and `MenuItem`.

Control Templates

Previously in this chapter you've seen how the properties of a control can be styled. If setting simple properties of the controls doesn't give you the look you want, you can change the `Template` property. With the `Template` property, the complete look of the control can be customized.

The next example shows customizing buttons, and later, list boxes are customized step by step, so you can see the intermediate results of the changes.

The customization of the `Button` type is done in a separate resource dictionary file, `Styles.xaml`. Here, a style with the key name `RoundedGelButton` is defined.

The style `GelButton` sets the properties `Background`, `Height`, `Foreground`, and `Margin`, and the `Template`. The `Template` is the most interesting aspect with this style. The `Template` specifies a `Grid` with just one row and one column.

Inside this cell, you can find an ellipse with the name `GelBackground`. This ellipse has a linear gradient brush for the stroke. The stroke that surrounds the rectangle is very thin because the `StrokeThickness` is set to 0.5.

The second ellipse, `GelShine`, is a small ellipse where the size is defined by the `Margin` property and so is visible within the first ellipse. The stroke is transparent, so there is no line surrounding the ellipse. This ellipse uses a linear gradient fill brush, which goes from a light, partly transparent color to full transparency. This gives the ellipse a shimmering effect:

```
<ResourceDictionary xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
                    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml">

    <Style x:Key="RoundedGelButton" TargetType="Button">
        <Setter Property="Width" Value="100" />
        <Setter Property="Height" Value="100" />
        <Setter Property="Foreground" Value="White" />
        <Setter Property="Template">
            <Setter.Value>
                <ControlTemplate TargetType="{x:Type Button}">
                    <Grid>
                        <Ellipse Name="GelBackground" StrokeThickness="0.5" Fill="Black">
                            <Ellipse.Stroke>
```

```
                                <LinearGradientBrush StartPoint="0,0" EndPoint="0,1">
                                    <GradientStop Offset="0" Color="#ff7e7e7e" />
                                    <GradientStop Offset="1" Color="Black" />
                                </LinearGradientBrush>
                            </Ellipse.Stroke>
                        </Ellipse>
                        <Ellipse Margin="15,5,15,50">
                            <Ellipse.Fill>
                                <LinearGradientBrush StartPoint="0,0" EndPoint="0,1">
                                    <GradientStop Offset="0" Color="#aaffffff" />
                                    <GradientStop Offset="1" Color="Transparent" />
                                </LinearGradientBrush>
                            </Ellipse.Fill>
                        </Ellipse>
                    </Grid>
                </ControlTemplate>
            </Setter.Value>
        </Setter>
    </Style>
</ResourceDictionary>
```

code snippet TemplateDemo/Styles.xaml

From the `app.xaml` file, the resource dictionary is referenced as shown:

```
<Application x:Class="TemplateDemo.App"
             xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
             xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
             StartupUri="MainWindow.xaml">
    <Application.Resources>
        <ResourceDictionary Source="Styles.xaml" />
    </Application.Resources
</Application>
```

code snippet TemplateDemo/App.xaml

Now a `Button` control can be associated with the style. The new look of the button is shown in Figure 35-22.

```
        <Button Style="{StaticResource RoundedGelButton}" Content="Click Me!" /
```

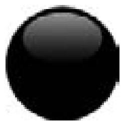

FIGURE 35-22

The button now has a completely different look. However, the content that is defined with the button itself is missing. The template created previously must be extended to get the content of the `Button` into the new look. What needs to be added is a `ContentPresenter`. The `ContentPresenter` is the placeholder for the content of the control and defines the place where the content should be positioned. Here, the content is placed in the first row of the `Grid,` as are the `Ellipse` elements. The `Content` property of the `ContentPresenter` defines what the content should be. The content is set to a `TemplateBinding` markup expression. `TemplateBinding` binds the template parent, which is the `Button` element in this case. `{TempateBinding Content}` specifies that the value of the `Content` property of the `Button` control should be placed inside the placeholder as content. Figure 35-23 shows the result with the content shown:

```
        <Setter Property="Template">
            <Setter.Value>
                <ControlTemplate TargetType="{x:Type Button}">
                    <Grid>
                        <Ellipse Name="GelBackground" StrokeThickness="0.5" Fill="Black">
                            <Ellipse.Stroke>
                                <LinearGradientBrush StartPoint="0,0" EndPoint="0,1">
                                    <GradientStop Offset="0" Color="#ff7e7e7e" />
                                    <GradientStop Offset="1" Color="Black" />
                                </LinearGradientBrush>
                            </Ellipse.Stroke>
                        </Ellipse>
                        <Ellipse Margin="15,5,15,50">
                        <Ellipse.Fill>
                            <LinearGradientBrush StartPoint="0,0" EndPoint="0,1">
                                <GradientStop Offset="0" Color="#aaffffff" />
                                <GradientStop Offset="1" Color="Transparent" />
                            </LinearGradientBrush>
                        </Ellipse.Fill>
                    </Ellipse>
                    <ContentPresenter Name="GelButtonContent"
                                      VerticalAlignment="Center"
                                      HorizontalAlignment="Center"
                                      Content="{TemplateBinding Content}" />
                </Grid>
            </ControlTemplate>
        </Setter.Value>
```

code snippet TemplateDemo/StyledButtonWindow.xaml

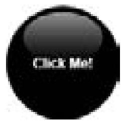

FIGURE 35-23

Such a styled button now looks very fancy on the screen. There's still a problem: there is no action if the mouse is clicked or the mouse moves over the button. This isn't the typical feeling a user has with a button. This can be solved: with a template-styled button, you must have triggers for the button to appear differently in response to mouse moves and mouse clicks.

Using property triggers (discussed previously), this can be solved easily. The triggers just need to be added to the `Triggers` collection of the `ControlTemplate` as shown. Here, two triggers are defined. One property trigger is active when the `IsMouseOver` property of the button is true. Then the `Fill` property of the ellipse with the name `GelBackground` is changed to a `RadialGradientBrush` with values from `Lime` to `DarkGreen`. With the `IsPressed` property, other colors are specified for the `RadialGradientBrush`:

```
<ControlTemplate.Triggers>
    <Trigger Property="IsMouseOver" Value="True">
        <Setter Property="Ellipse.Fill" TargetName="GelBackground">
            <Setter.Value>
                <RadialGradientBrush>
                    <GradientStop Offset="0" Color="Lime" />
                    <GradientStop Offset="1" Color="DarkGreen" />
                </RadialGradientBrush>
            </Setter.Value>
        </Setter>
    </Trigger>
    <Trigger Property="IsPressed" Value="True">
        <Setter Property="Ellipse.Fill" TargetName="GelBackground">
            <Setter.Value>
                <RadialGradientBrush>
                    <GradientStop Offset="0" Color="#ffcc34" />
                    <GradientStop Offset="1" Color="#cc9900" />
                </RadialGradientBrush>
            </Setter.Value>
        </Setter>
    </Trigger>
</ControlTemplate.Triggers>
```

Now you can run the application and see a visual feedback from the button as soon as the mouse hovers over it or the mouse is clicked.

Data Templates

The content of `ContentControl` elements can be any content — not only WPF elements but also .NET objects. For example, an object of the `Country` type can be assigned to the content of a `Button` class. The `Country` class has been created to represent the name and flag with a path to an image. This class defines the `Name` and `ImagePath` properties, and it has an overridden `ToString()` method for a default string representation:

```
public class Country
{
    public string Name { get; set; }
    public string ImagePath { get; set; }

    public override string ToString()
    {
        return Name;
    }
}
```

code snippet TemplateDemo/Country.cs

How does this content look within a `Button` or any other `ContentControl`? By default, the `ToString()` method is invoked, and the string representation of the object is shown. For a custom look you can also create a `DataTemplate` for the `Country` type.

Here, within the resources of the `Window,` a `DataTemplate` is created. This `DataTemplate` doesn't have a key assigned and thus is a default for the `Country`. `src` type — it is also the alias of the XML namespace referencing the .NET assembly and .NET namespace. Within the `DataTemplate` the main elements are a `TextBox` with the `Text` property bound to the `Name` property of the `Country`, and an `Image` with the `Source` property bound to the `ImagePath` property of the `Country`. The `Grid`, `Border`, and `Rectangle` elements define the layout and visual appearance:

```
<Window.Resources>
    <DataTemplate DataType="{x:Type src:Country}">
        <Grid>
            <Grid.ColumnDefinitions>
                <ColumnDefinition Width="Auto" />
                <ColumnDefinition Width="Auto" />
            </Grid.ColumnDefinitions>
            <Grid.RowDefinitions>
                <RowDefinition Height="60" />
            </Grid.RowDefinitions>
            <TextBlock FontSize="16" VerticalAlignment="Center" Margin="5"
                       Text="{Binding Name}" FontWeight="Bold" Grid.Column="0" />
            <Border Margin="4,0" Grid.Column="1" BorderThickness="2"
                    CornerRadius="4">
                <Border.BorderBrush>
                    <LinearGradientBrush StartPoint="0,0" EndPoint="0,1">
                        <GradientStop Offset="0" Color="#aaa" />
                        <GradientStop Offset="1" Color="#222" />
                    </LinearGradientBrush>
                </Border.BorderBrush>
                <Grid>
                    <Rectangle>
                        <Rectangle.Fill>
                            <LinearGradientBrush StartPoint="0,0" EndPoint="0,1">
                                <GradientStop Offset="0" Color="#444" />
                                <GradientStop Offset="1" Color="#fff" />
                            </LinearGradientBrush>
                        </Rectangle.Fill>
                    </Rectangle>
                    <Image Width="48" Margin="2,2,2,1"
                           Source="{Binding ImagePath}" />
                </Grid>
            </Border>
        </Grid>
    </DataTemplate>
</Window.Resources>
```

code snippet TemplateDemo/StyledButtonWindow.xaml

With the XAML code, a simple `Button` element with the name `button1` is defined:

```
<Button Grid.Row="1" x:Name="button1" Margin="10" />
```

Within the code-behind, a new `Country` object is instantiated that is assigned to the `Content` property of `button1`:

```
public StyledButtonWindow()
{
    InitializeComponent();
    button1.Content = new Country
                      {
                          Name = "Austria",
                          ImagePath = "images/Austria.bmp"
                      };
}
```

code snippet TemplateDemo/StyledButtonWindow.xaml.cs

After running the application, you can see that the `DataTemplate` is applied to the `Button` because `Country` data type has a default template, as shown in Figure 35-24.

Of course it is also possible to create a control template and use a data template from within.

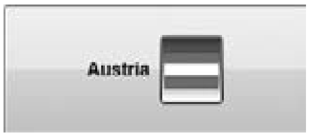

FIGURE 35-24

Styling a ListBox

Changing a style of a button or a label is a simple task. How about changing the style of an element that contains a list of elements? For example, how about changing a `ListBox`? Again, a list box has behavior and a look. It can display a list of elements, and you can select one or more elements from the list. For the behavior, the `ListBox` class defines methods, properties, and events. The look of the `ListBox` is separate from its behavior. The `ListBox` element has a default look, but you can change this look by creating a template.

With a `ListBox` the `ControlTemplate` defines how the complete control looks, an `ItemTemplate` defines how an item looks, and a `DataTemplate` defines the type that might be within an item.

For filling a `ListBox` with some items, the static class `Countries` returns a list of a few countries that will be displayed:

```
public class Countries
{
    public static IEnumerable<Country> GetCountries()
    {
        return new List<Country>
        {
            new Country { Name = "Austria", ImagePath = "Images/Austria.bmp" },
            new Country { Name = "Germany", ImagePath = "Images/Germany.bmp" },
            new Country { Name = "Norway", ImagePath = "Images/Norway.bmp" },
            new Country { Name = "USA", ImagePath = "Images/USA.bmp" }
        };
    }
}
```

code snippet TemplateDemo/Countries.cs

Inside the code-behind file in the constructor of the `StyledListBoxWindow1` class, the `DataContext` property of the `StyledListBoxWindow1` instance is set to the list of countries that is returned from the method `Countries.GetCountries()`. (The `DataContext` property is a data binding feature discussed in the next chapter.)

```
        public partial class StyledListBoxWindow1 : Window
        {
            public StyledListBoxWindow1()
            {
                InitializeComponent();
                this.DataContext = Countries.GetCountries();
            }
        }
```

code snippet TemplateDemo/StyledListBoxWindow1.xaml.cs

Within the XAML code, the `ListBox` named `countryList1` is defined. `countryList1` doesn't have a different style. It uses the default look from the `ListBox` element. The property `ItemsSource` is set to the `Binding` markup extension, which is used by data binding. From the code-behind, you have seen that the binding is done to an array of `Country` objects. Figure 35-25 shows the default look of the `ListBox`. By default, just the names of the countries returned by the `ToString()` method are displayed in a simple list:

```
    <Window x:Class="TemplateDemo.StyledListBoxWindow1"
            xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
            xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
            xmlns:src="clr-namespace:TemplateDemo"
            Title="StyledListBoxWindow1" Height="300" Width="300">
        <Grid>
            <ListBox ItemsSource="{Binding}" Margin="10" />
        </Grid>
    </Window>
```

code snippet TemplateDemo/StyledListBoxWindow1.xaml

ItemTemplate

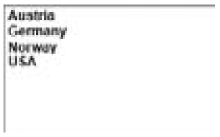

FIGURE 35-25

The `Country` objects do have both the name and the flag in the object. Of course, you can also display both values in the list box. To do this, you need to define a template.

The `ListBox` element contains `ListBoxItem` elements. You can define the content for an item with the `ItemTemplate`. The style `ListBoxStyle1` defines an `ItemTemplate` with a value of a `DataTemplate`. A `DataTemplate` is used to bind data to elements. You can use the `Binding` markup extension with `DataTemplate` elements.

The `DataTemplate` contains a grid with three columns. The first column contains the string `Country:`. The second column contains the name of the country. The third column contains the flag for the country. Because the country names have different lengths, but the view should be the same size for every country name, the `SharedSizeGroup` property is set with the second column definition. This shared size information for the column is used only because the property `Grid.IsSharedSizeScope` is also set.

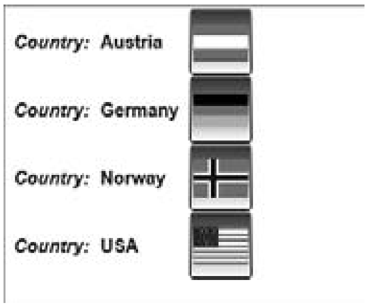

FIGURE 35-26

After the column and row definitions, you can see two `TextBlock` elements. The first `TextBlock` element contains the text `Country:`. The second `TextBlock` element binds to the `Name` property that is defined in the `Country` class.

The content for the third column is a `Border` element containing a `Grid`. The `Grid` contains a `Rectangle` with a linear gradient brush and an `Image` element that is bound to the `ImagePath` property of the `Country` class. Figure 35-26 shows the countries in a `ListBox` with completely different output than before:

```
      <Style x:Key="ListBoxStyle1" TargetType="{x:Type ListBox}" >
            <Setter Property="ItemTemplate">
                <Setter.Value>
                    <DataTemplate>
                    <Grid>
                        <Grid.ColumnDefinitions>
                            <ColumnDefinition Width="Auto" />
                            <ColumnDefinition Width="*" SharedSizeGroup="MiddleColumn" />
                            <ColumnDefinition Width="Auto" />
                        </Grid.ColumnDefinitions>
                        <Grid.RowDefinitions>
                            <RowDefinition Height="60" />
                        </Grid.RowDefinitions>
                        <TextBlock FontSize="16" VerticalAlignment="Center" Margin="5"
                                   FontStyle="Italic" Grid.Column="0" Text="Country:" />
                        <TextBlock FontSize="16" VerticalAlignment="Center" Margin="5"
                                   Text="{Binding Name}" FontWeight="Bold"
                                   Grid.Column="1" />
                        <Border Margin="4,0" Grid.Column="2" BorderThickness="2"
                                CornerRadius="4">
                            <Border.BorderBrush>
                                <LinearGradientBrush StartPoint="0,0" EndPoint="0,1">
                                    <GradientStop Offset="0" Color="#aaa" />
                                    <GradientStop Offset="1" Color="#222" />
                                </LinearGradientBrush>
                            </Border.BorderBrush>
                            <Grid>
                                <Rectangle>
                                    <Rectangle.Fill>
                                        <LinearGradientBrush StartPoint="0,0"
                                                             EndPoint="0,1">
                                            <GradientStop Offset="0" Color="#444" />
                                            <GradientStop Offset="1" Color="#fff" />
                                        </LinearGradientBrush>
                                    </Rectangle.Fill>
                                </Rectangle>
                                <Image Width="48" Margin="2,2,2,1"
                                       Source="{Binding ImagePath}" />
                            </Grid>
                        </Border>
                    </Grid>
                </DataTemplate>
            </Setter.Value>
        </Setter>
        <Setter Property="Grid.IsSharedSizeScope" Value="True" />
    </Style>
```

code snippet TemplateDemo/Styles.xaml

Control Templates for ListBox Elements

It is not necessary that a `ListBox` have items that follow vertically, one after the other. You can give the user a different view with the same functionality. The next style, `ListBoxStyle2`, defines a template in which the items are shown horizontally with a scrollbar.

In the previous example, only an `ItemTemplate` was created to define how the items should look in the default `ListBox`. Now, a template is created to define a different `ListBox`. The template contains a `ControlTemplate` element to define the elements of the `ListBox`. The element is now a `ScrollViewer` — a view with a scrollbar — that contains a `StackPanel`. As the items should now be listed horizontally, the `Orientation` of the `StackPanel` is set to `Horizontal`. The stack panel will contain the items that are defined with the `ItemsTemplate`. As a result, the `IsItemsHost` of the `StackPanel` element is set to `true`. `IsItemsHost` is a property that is available with every `Panel` element that can contain a list of items.

The `ItemTemplate` that defines the look for the items in the stack panel is taken from the style `ListBoxStyle1` where `ListBoxStyle2` is based.

Figure 35-27 shows the `ListBox` styled with `ListBoxStyle2` where the scrollbar appears automatically when the view is too small to display all items in the list:

```
<Style x:Key="ListBoxStyle2" TargetType="{x:Type ListBox}"
       BasedOn="{StaticResource ListBoxStyle1}">
    <Setter Property="Template">
        <Setter.Value>
            <ControlTemplate TargetType="{x:Type ListBox}">
                <ScrollViewer HorizontalScrollBarVisibility="Auto">
                    <StackPanel Name="StackPanel1" IsItemsHost="True"
                  Orientation="Horizontal" />
                </ScrollViewer>
            </ControlTemplate>
        </Setter.Value>
    </Setter>
    <Setter Property="VerticalAlignment" Value="Center" />
</Style>
```

code snippet TemplateDemo/Styles.xaml

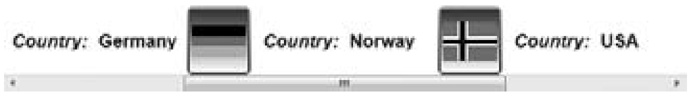

FIGURE 35-27

Certainly you see the advantages of separating the look of the controls from their behavior. You may already have many ideas about how you can display your items in a list that best fits the requirements of your application. Perhaps you just want to display as many items as will fit in the window, position them horizontally, and then continue to the next line vertically. That's where a `WrapPanel` comes in. And, of course, you can have a `WrapPanel` inside a template for a `ListBox`, as shown in `ListBoxStyle3`. Figure 35-28 shows the result of using the `WrapPanel`:

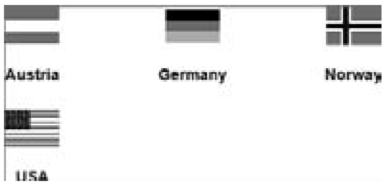

FIGURE 35-28

```
<Style x:Key="ListBoxStyle3" TargetType="{x:Type ListBox}">
    <Setter Property="Template">
        <Setter.Value>
            <ControlTemplate TargetType="{x:Type ListBox}">
                <ScrollViewer VerticalScrollBarVisibility="Auto"
                              HorizontalScrollBarVisibility="Disabled">
                    <WrapPanel IsItemsHost="True" />
                </ScrollViewer>
            </ControlTemplate>
        </Setter.Value>
    </Setter>
    <Setter Property="ItemTemplate">
        <Setter.Value>
            <DataTemplate>
                <Grid>
                    <Grid.ColumnDefinitions>
                        <ColumnDefinition Width="140" />
                    </Grid.ColumnDefinitions>
                    <Grid.RowDefinitions>
```

```
                                <RowDefinition Height="60" />
                                <RowDefinition Height="30" />
                            </Grid.RowDefinitions>
                            <Image Grid.Row="0" Width="48" Margin="2,2,2,1"
                                   Source="{Binding ImagePath}" />
                            <TextBlock Grid.Row="1" FontSize="14"
                                       HorizontalAlignment="Center" Margin="5"
                                       Text="{Binding Name}" />
                        </Grid>
                    </DataTemplate>
                </Setter.Value>
            </Setter>
        </Style>
```

ANIMATIONS

With animations you can make a smooth transition using moving elements, color changes, transforms, and so on. WPF makes it easy to create animations. You can animate the value of any dependency property. Different animation classes exist to animate the values of different properties, depending on their type.

The major elements of animations are as follows:

- **Timeline** — Defines how a value changes over time. Different kinds of timelines are available for changing different types of values. The base class for all timelines is `Timeline`. To animate a `double`, the class `DoubleAnimation` can be used. `Int32Animation` is the animation class for `int` values. `PointAnimation` is used to animate points, and `ColorAnimation` to animate colors.
- **Storyboard** — Used to combine animations. The `Storyboard` class itself is derived from the base class `TimelineGroup`, which derives from `Timeline`. With `DoubleAnimation` you can animate a double value; with `Storyboard` you combine all the animations that belong together.
- **Triggers** — Start and stop animations. You've seen property triggers previously. They fire when a property value changes. You can also create an event trigger. An event trigger fires when an event occurs.

The namespace for animation classes is `System.Windows.Media.Animation`.

Timeline

A `Timeline` defines how a value changes over time. The first example animates the size of an ellipse. Here a `DoubleAnimation` timeline changes to a double value. The `Triggers` property of the `Ellipse` class is set to an `EventTrigger`. The event trigger is fired when the ellipse is loaded as defined with the `RoutedEvent` property of the `EventTrigger`. `BeginStoryboard` is a trigger action that begins the storyboard. With the storyboard, a `DoubleAnimation` element is used to animate the `Width` property of the `Ellipse` class. The animation changes the width of the ellipse from 100 to 300 within three seconds, and reverses the animation after three seconds. The animation `ColorAnimation` animates the color from the `ellipseBrush` which is used to fill the ellipse:

```
<Ellipse Height="50" Width="100">
    <Ellipse.Fill>
        <SolidColorBrush x:Name="ellipseBrush" Color="SteelBlue" />
    </Ellipse.Fill>
    <Ellipse.Triggers>
        <EventTrigger RoutedEvent="Ellipse.Loaded" >
            <EventTrigger.Actions>
                <BeginStoryboard>
                    <Storyboard Duration="00:00:06" RepeatBehavior="Forever">
                        <DoubleAnimation
                            Storyboard.TargetProperty="(Ellipse.Width)"
```

```
                                      Duration="0:0:3" AutoReverse="True"
                                                  FillBehavior="Stop"
                                                  RepeatBehavior="Forever"
                                      AccelerationRatio="0.9" DecelerationRatio="0.1"
                                                  From="100" To="300" />
                                  <ColorAnimation Storyboard.TargetName="ellipseBrush"
                                      Storyboard.TargetProperty="(SolidColorBrush.Color)"
                                      Duration="0:0:3" AutoReverse="True"
                                      FillBehavior="Stop" RepeatBehavior="Forever"
                                                 From="Yellow" To="Red" />
                              </Storyboard>
                          </BeginStoryboard>
                      </EventTrigger.Actions>
                  </EventTrigger>
              </Ellipse.Triggers>
          </Ellipse>
```

code snippet AnimationDemo/EllipseWindow.xaml

Figures 35-29 and 35-30 show two states from the animated ellipse.

FIGURE 35-29

Animations are far more than typical window-dressing animation that appears onscreen constantly and immediately. You can add animation to business applications that make the user interface more responsive.

FIGURE 35-30

The following example demonstrates a decent animation and also shows how the animation can be defined in a style. Within the `Window` resources you can see the style `AnimatedButtonStyle` for buttons. In the template, a rectangle-named outline is defined. This template has a thin stroke with the thickness set to 0.4.

FIGURE 35-31

FIGURE 35-32

The template defines a property trigger for the `IsMouseOver` property. The `EnterActions` property of this trigger applies as soon as the mouse is moved over the button. The action to start is `BeginStoryboard`. `BeginStoryboard` is a trigger action that can contain and thus start `Storyboard` elements. The `Storyboard` element defines a `DoubleAnimation` to animate a double value. The property value that is changed in this animation is the `Rectangle.StrokeThickness` of the `Rectangle` element with the name outline. The value is changed in a smooth way by 1.2, as the `By` property specifies, for a time length of 0.3 seconds as specified by the `Duration` property. At the end of the animation, the stroke thickness is reset to its original value because `AutoReverse="True"`. To summarize: as soon as the mouse moves over the button, the thickness of the outline is incremented by 1.2 for 0.3 seconds. Figure 35-31 shows the button without animation, and Figure 35-32 shows the button 0.3 seconds after the mouse moved over it. (It's just not possible to show the smooth animation and intermediate looks in a print medium.)

```
<Window x:Class="AnimationDemo.ButtonAnimationWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"

code snippet AnimationDemo/ButtonAnimationWindow.xaml

The following table lists things you can do with a timeline.

TIMELINE PROPERTIES	DESCRIPTION
`AutoReverse`	With the `AutoReverse` property, you can specify whether the value that is animated should return to the original value after the animation.
`SpeedRatio`	With `SpeedRatio`, you can transform the speed at which an animation moves. With this property, you can define the relation in regard to the parent. The default value is 1; setting the ratio to a smaller value makes the animation move slower; setting the value greater than 1 makes it move faster.
`BeginTime`	With `BeginTime` you can specify the timespan from the start of the trigger event until the moment the animation starts. You can specify days, hours, minutes, seconds, and fractions of seconds. This might not be real-time, depending on the speed ratio. For example, if the speed ratio is set to 2, and the beginning time is set to six seconds, the animation will start after three seconds.
`AccelerationRatio` `DecelerationRatio`	With an animation the values need not be changed in a linear way. You can specify an `AccelerationRatio` and `DecelerationRatio` to define the impact of acceleration and deceleration. The sum of both values must not be greater than 1.
`Duration`	With the `Duration` property, you specify the length of time for one iteration of the animation.
`RepeatBehavior`	Assigning a `RepeatBehavior` struct to the `RepeatBehavior` property lets you define how many times or how long the animation should be repeated.
`FillBehavior`	The `FillBehavior` property is important if the parent timeline has a different duration. For example, if the parent timeline is shorter than the duration of the actual animation, setting the `FillBehavior` to `Stop` means that the actual animation stops. If the parent timeline is longer than the duration of the actual animation, `HoldEnd` keeps the actual animation active before resetting it to its original value (if `AutoReverse` is set).

Depending on the type of `Timeline` class, more properties may be available. For example, with `DoubleAnimation` you can specify `From` and `To` properties for the start and end of the animation. An alternative is to specify the `By` property where the animation starts with the current value of the `Bound` property and is incremented by the value specified by `By`.

Non-Linear Animations

One way to define non-linear animations is by setting the speed of `AccelerationRatio` and `DecelerationRatio` animation in the beginning and at the end. .NET 4 has more flexible possibilities than that.

Several animation classes have an `EasingFunction` property. This property accepts an object that implements the interface `IEasingFunction`. With this interface an easing function object can define how the value should be animated over time. There are several easing functions available that create a non-linear animation. Examples of these are `ExponentialEase`, which uses an exponential formula for animations; `QuadraticEase`, `CubicEase`, `QuarticEase`, and `QuinticEase` with a power of 2, 3, 4, or 5; and `PowerEase` with a power level that is configurable. Of special interest are `SineEase,` which uses a sinus curve, `BounceEase`, which creates a bouncing effect, and `ElasticEase`, which resembles animation values of a spring oscillating back and forth.

Such an ease can be specified in XAML by adding the ease to the `EasingFunction` property of the animation as shown. Adding different ease functions you will see really interesting effects with the animation:

```
<DoubleAnimation
    Storyboard.TargetProperty="(Ellipse.Width)"
    Duration="0:0:3" AutoReverse="True"
                 FillBehavior="Stop"
                 RepeatBehavior="Forever"
                 From="100" To="300">
    <DoubleAnimation.EasingFunction>
        <BounceEase EasingMode="EaseInOut" />
    </DoubleAnimation.EasingFunction>
</DoubleAnimation>
```

code snippet AnimationDemo/EllipseWindow.xaml

Event Triggers

Instead of having a property trigger, you can define an event trigger to start the animation. The property trigger fires when a property changes its value; the event trigger fires when an event occurs. Examples of such events are the `Load` event from a control, the `Click` event from the `Button`, and the `MouseMove` event.

The next example creates an animation for the face that was created earlier with shapes. It is now animated so the eye moves as soon as a `Click` event from a button is fired.

Inside the `Window` element, a `DockPanel` element is defined to arrange the face and buttons to control the animation. A `StackPanel` that contains three buttons is docked on top. The `Canvas` element that contains the face gets the remaining part of the `DockPanel`.

The first button is used to start the animation of the eye; the second button stops the animation. A third button is used to start another animation to resize the face.

The animation is defined within the `DockPanel.Triggers` section. Instead of a property trigger, an event trigger is used. The first event trigger is fired as soon as the `Click` event occurs with the *`buttonBeginMoveEyes`* button defined by the `RoutedEvent` and `SourceName` properties. The trigger action is defined by the `BeginStoryboard` element that starts the containing `Storyboard`. `BeginStoryboard` has a name defined, because a name is needed to control the storyboard with pause, continue, and stop actions. The `Storyboard` element contains four animations. The first two animate the left eye; the last two animate the right eye. The first and third animation changes the `Canvas.Left` position for the eyes, and the second and fourth animation changes `Canvas.Top`. The animations in x and y direction have different time values that make the eye movement very interesting using the defined repeated behavior.

The second event trigger is fired as soon as the `Click` event of the *`buttonStopMoveEyes`* button occurs. Here, the storyboard is stopped with the `StopStoryboard` element, which references the started storyboard *`beginMoveEye`*.

The third event trigger is fired by clicking the *`buttonResize`* button. With this animation the transformation of the `Canvas` element is changed. Because this animation doesn't run endlessly, there's no stop. This storyboard also makes use of the `EaseFunction` that was explained previously:

```
<Window x:Class="AnimationDemo.EventTriggerWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        Title="EventTriggerWindow" Height="300" Width="300">
    <DockPanel>
        <DockPanel.Triggers>
            <EventTrigger RoutedEvent="Button.Click" SourceName="buttonBeginMoveEyes">
                <BeginStoryboard x:Name="beginMoveEyes">
                    <Storyboard>
                        <DoubleAnimation RepeatBehavior="Forever" DecelerationRatio=".8"
                                         AutoReverse="True" By="6" Duration="0:0:1"
                                         Storyboard.TargetName="eyeLeft"
                                         Storyboard.TargetProperty="(Canvas.Left)" />
                        <DoubleAnimation RepeatBehavior="Forever" AutoReverse="True"
                                         By="6" Duration="0:0:5"
                                         Storyboard.TargetName="eyeLeft"
                                         Storyboard.TargetProperty="(Canvas.Top)" />
                        <DoubleAnimation RepeatBehavior="Forever" DecelerationRatio=".8"
                                         AutoReverse="True" By="-6" Duration="0:0:3"
                                         Storyboard.TargetName="eyeRight"
                                         Storyboard.TargetProperty="(Canvas.Left)" />
                        <DoubleAnimation RepeatBehavior="Forever" AutoReverse="True"
                                         By="6" Duration="0:0:6"
                                         Storyboard.TargetName="eyeRight"
                                         Storyboard.TargetProperty="(Canvas.Top)" />
                    </Storyboard>
                </BeginStoryboard>
            </EventTrigger>
            <EventTrigger RoutedEvent="Button.Click" SourceName="buttonStopMoveEyes">

            <Path Name="mouth" Stroke="Blue" StrokeThickness="4"
                  Data="M 40,74 Q 57,95 80,74 " />
        </Canvas>

    </DockPanel>
</Window>
```

code snippet AnimationDemo/EventTriggerWindow.xaml

Figure 35-33 shows the output after running the application.

Instead of starting and stopping the animation directly from event triggers in XAML, you can easily control the animation from code-behind. You just need to assign a name to the `Storyboard` and invoke the `Begin()`, `Stop()`, `Pause()`, and `Resume()` methods.

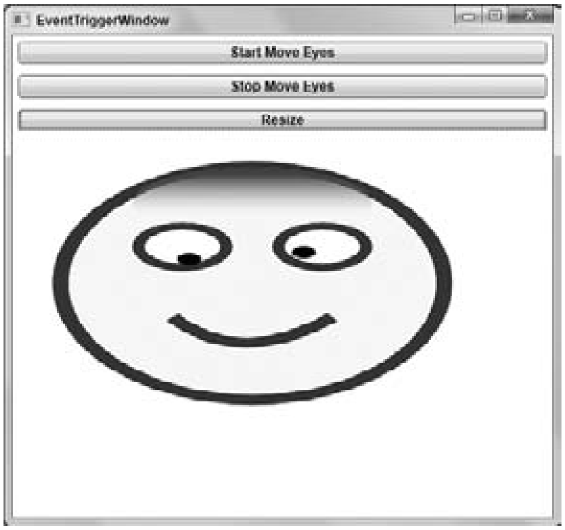

FIGURE 35-33

Keyframe Animations

With acceleration and deceleration ratio as well as the ease functions, you've seen how animations can be built in a non-linear fashion. If you need to specify several values for an animation, you can use keyframe animations. As with normal animations, keyframe animations are different animation types that exist to animate properties of different types.

DoubleAnimationUsingKeyFrames is the keyframe animation for double types. Other keyframe animation types are Int32AnimationUsingKeyFrames, PointAnimationUsingKeyFrames, ColorAnimationUsingKeyFrames, SizeAnimationUsingKeyFrames, and ObjectAnimationUsingKeyFrames.

The example XAML code animates the position of an ellipse by animating the X and Y values of a TranslateTransform element. The animation starts when the ellipse is loaded by defining an EventTrigger to the RoutedEvent Ellipse.Loaded. The event trigger starts a Storyboard with the BeginStoryboard element. The Storyboard contains two keyframe animations of DoubleAnimationUsingKeyFrame type. A keyframe animation consists of frame elements. The first keyframe animation uses a LinearKeyFrame, a DiscreteDoubleKeyFrame, and a SplineDoubleKeyFrame; the second animation is an EasingDoubleKeyFrame. The LinearDoubleKeyFrame makes a linear change of the value. The KeyTime property defines when in the animation the value of the Value property should be reached. Here, the LinearDoubleKeyFrame has three seconds to move the property X to the value 30. DiscreteDoubleKeyFrame makes an immediate change to the new value after four seconds. SplineDoubleKeyFrame uses a Bézier curve where two control points are specified by the KeySpline property. EasingDoubleKeyFrame is a new frame class with .NET 4 that supports setting an easing function such as BounceEase to control the animation value:

```
<Canvas>
    <Ellipse Fill="Red" Canvas.Left="20" Canvas.Top="20" Width="25" Height="25">
        <Ellipse.RenderTransform>
            <TranslateTransform X="50" Y="50" x:Name="ellipseMove" />
        </Ellipse.RenderTransform>
        <Ellipse.Triggers>
            <EventTrigger RoutedEvent="Ellipse.Loaded">
                <BeginStoryboard>
                    <Storyboard>
                        <DoubleAnimationUsingKeyFrames Storyboard.TargetProperty="X"
                            Storyboard.TargetName="ellipseMove">
                            <LinearDoubleKeyFrame KeyTime="0:0:2" Value="30" />
                            <DiscreteDoubleKeyFrame KeyTime="0:0:4" Value="80" />
                            <SplineDoubleKeyFrame KeySpline="0.5,0.0 0.9,0.0"
                                KeyTime="0:0:10" Value="300" />
                            <LinearDoubleKeyFrame KeyTime="0:0:20" Value="150" />
                        </DoubleAnimationUsingKeyFrames>
                        <DoubleAnimationUsingKeyFrames Storyboard.TargetProperty="Y"
                            Storyboard.TargetName="ellipseMove">
                            <SplineDoubleKeyFrame KeySpline="0.5,0.0 0.9,0.0"
                                KeyTime="0:0:2" Value="50" />
                            <EasingDoubleKeyFrame KeyTime="0:0:20" Value="300">
                                <EasingDoubleKeyFrame.EasingFunction>
                                    <BounceEase />
                                </EasingDoubleKeyFrame.EasingFunction>
                            </EasingDoubleKeyFrame>
                        </DoubleAnimationUsingKeyFrames>
                    </Storyboard>
                </BeginStoryboard>
            </EventTrigger>
        </Ellipse.Triggers>
    </Ellipse>
</Canvas>
```

code snippet AnimationDemo/KeyFrameWindow.xaml

VISUAL STATE MANAGER

Since .NET 4, Visual State Manager offers an alternative way to control animations. Controls can have specific states. The *state* defines a look that is applied to controls when the state is reached. A state transition defines what happens when one state changes to another one.

With a data grid you can use `Read`, `Selected`, and `Edit` states to define different looks for a row, depending on user selection. `MouseOver` and `IsPressed` can be states as well that replace the triggers, which have been discussed earlier.

The example code displays different states of a baby and defines the states `Sleeping`, `Playing`, and `Crying`. The states are defined within the element `VisualStateManager.VisualStateGroups`. Here the states are defined within a `Button` element because they are needed only there. With the content, the `Button` defines a `Border` and an `Image` element that are named *`border1`* and *`image1`*. With `VisualStateManager`, a single `VisualStateGroup` named `CommonStates` is defined. This state group contains `VisualState` elements. Within a visual state a `Storyboard` is defined. With all the states the storyboard contains a `ColorAnimation` that changes the color of the border brush, and `ObjectAnimationUsingKeyFrames`. This keyframe animation just makes a one-time change to the `Source` property of the `Image`. The `UriSource` property requires a `BitmapImage` that is created and a filename that is stored within the project.

The `VisualStateGroup` also contains `VisualTransition` elements that define what should happen before a state changes. With `VisualTransition` you can specify both `From` and `To` values. With these you can create different transitions when the state changes from `Sleeping` to `Crying` as opposed to from `Playing` to `Crying`. In the example, only the `To` property is used, so this transition applies no matter what the previous state was. With the transitions, the `Width` property of the `Button` and the `Thickness` of the `Border` element are changed:

```
<Window x:Class="VisualStateDemo.MainWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        Title="MainWindow" Height="240" Width="500">
    <DockPanel>
        <StackPanel Orientation="Vertical" DockPanel.Dock="Left">
            <Button Margin="5" Padding="3" Content="Sleeping" Click="OnSleeping" />
            <Button Margin="5" Padding="3" Content="Playing" Click="OnPlaying" />
            <Button Margin="5" Padding="5" Content="Crying" Click="OnCrying" />
        </StackPanel>
        <Grid>
            <Button Name="button1" Width="300" Height="200">
                <VisualStateManager.VisualStateGroups>
                    <VisualStateGroup Name="CommonStates">
                        <VisualState Name="Sleeping">
                            <Storyboard>
                                <ObjectAnimationUsingKeyFrames Duration="0:0:0"
                                    Storyboard.TargetProperty="(Image.Source)"
                                    Storyboard.TargetName="image1">
                                    <DiscreteObjectKeyFrame KeyTime="0:0:0">
                                        <DiscreteObjectKeyFrame.Value>
                                            <BitmapImage
                                                UriSource="Images/Sleeping.jpg" />
                                        </DiscreteObjectKeyFrame.Value>
                                    </DiscreteObjectKeyFrame>
                                </ObjectAnimationUsingKeyFrames>
                                <ColorAnimation To="LightBlue"
                                    Storyboard.TargetProperty="(SolidColorBrush.Color)"
                                    Storyboard.TargetName="brush1" Duration="0:0:5" />
                            </Storyboard>
                        </VisualState>
                        <VisualState Name="Playing">
                            <Storyboard>
                                <ObjectAnimationUsingKeyFrames Duration="0:0:0"
                                    Storyboard.TargetProperty="(Image.Source)"
                                    Storyboard.TargetName="image1">
                                    <DiscreteObjectKeyFrame KeyTime="0:0:0">
                                        <DiscreteObjectKeyFrame.Value>
                        <BitmapImage
                            UriSource="Images/Playing.jpg" />
                    </DiscreteObjectKeyFrame.Value>
                </DiscreteObjectKeyFrame>
            </ObjectAnimationUsingKeyFrames>
            <ColorAnimation To="Red"

                Storyboard.TargetProperty="(SolidColorBrush.Color)"
                Storyboard.TargetName="brush1" Duration="0:0:5" />
        </Storyboard>
    </VisualState>
    <VisualState Name="Crying">
        <Storyboard>
            <ObjectAnimationUsingKeyFrames Duration="0"
                Storyboard.TargetProperty="(Image.Source)"
                Storyboard.TargetName="image1">
                <DiscreteObjectKeyFrame KeyTime="0">
                    <DiscreteObjectKeyFrame.Value>
                        <BitmapImage UriSource="Images/Crying.jpg" />
                    </DiscreteObjectKeyFrame.Value>
                </DiscreteObjectKeyFrame>
            </ObjectAnimationUsingKeyFrames>
            <ColorAnimation To="LightBlue"
                Storyboard.TargetProperty="(SolidColorBrush.Color)"
                Storyboard.TargetName="brush1" Duration="0:0:5" />
        </Storyboard>
    </VisualState>
    <VisualStateGroup.Transitions>
        <VisualTransition To="Sleeping">
            <Storyboard>
                <DoubleAnimation By="50" AutoReverse="True"
                    Storyboard.TargetProperty="Width"
                    Storyboard.TargetName="button1"
                    Duration="0:0:1.2">
                    <DoubleAnimation.EasingFunction>
                        <BounceEase />
                    </DoubleAnimation.EasingFunction>
                </DoubleAnimation>
            </Storyboard>
        </VisualTransition>
        <VisualTransition To="Crying">
            <Storyboard>
                <ThicknessAnimation Duration="0:0:2" By="100,100"
                    AutoReverse="True"
                    Storyboard.TargetProperty=
                        "(Border.BorderThickness)"
                    Storyboard.TargetName="border1" />
            </Storyboard>
        </VisualTransition>
        <VisualTransition To="Playing">
            <Storyboard>
                <DoubleAnimation By="50" AutoReverse="True"
                    Storyboard.TargetProperty="Width"
                    Storyboard.TargetName="button1"
                    Duration="0:0:1.2">
                    <DoubleAnimation.EasingFunction>
                        <ElasticEase />
                    </DoubleAnimation.EasingFunction>
                </DoubleAnimation>
            </Storyboard>
        </VisualTransition>
```

```
                </VisualStateGroup.Transitions>
            </VisualStateGroup>
        </VisualStateManager.VisualStateGroups>

        <Border x:Name="border1" BorderThickness="12">
            <Border.BorderBrush>
                <SolidColorBrush x:Name="brush1" Color="White" />
            </Border.BorderBrush>
            <Image x:Name="image1" />
        </Border>
    </Button>
</Grid>
</DockPanel>
</Window>
```

code snippet VisualStateDemo/MainWindow.xaml

With the `Click` events, the `Button` elements in the `StackPanel` handlers from code-behind are invoked. Within code-behind the `GoToElementState()` method of the `VisualStateManager` is invoked to change the *`button1`* object to a new state. The third argument of this method defines whether the transition changing to this state should be invoked:

```
private void OnSleeping(object sender, RoutedEventArgs e)
{
    VisualStateManager.GoToElementState(button1, "Sleeping", true);
}

private void OnPlaying(object sender, RoutedEventArgs e)
{
    VisualStateManager.GoToElementState(button1, "Playing", true);
}

private void OnCrying(object sender, RoutedEventArgs e)
{
    VisualStateManager.GoToElementState(button1, "Crying", true);
}
```

code snippet VisualStateDemo/MainWindow.xaml.cs

After running the application you can see the state changes as shown in Figure 35-34.

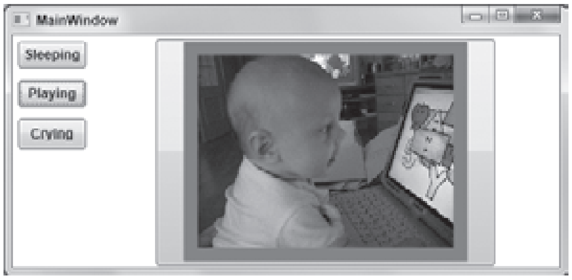

FIGURE 35-34

3-D

The last section in this large chapter gives you an introduction to the 3-D features of WPF. Here you'll find the information to get started.

The namespace for 3-D with WPF is `System.Windows.Media.Media3D`.

To understand 3-D with WPF it is important to know the difference between the coordination systems. Figure 35-35 shows the WPF 3-D coordination system. The origin is placed in the center. The x-axis has positive values to the right and negative values to the left. The y-axis is vertical with positive values up and negative values down. The z-axis defines positive values in direction to the viewer.

The most important concepts that need to be known to understand 3-D with WPF are the model, camera, and lights. The model defines what is shown using triangles. The camera defines the point where and how we look at the model, and without a light the model is dark. The light defines how the complete scene is illuminated. This section gives you information on how to define the model, camera, and light with WPF and what different options you have here. Also, you will get the information on how the scene can be animated.

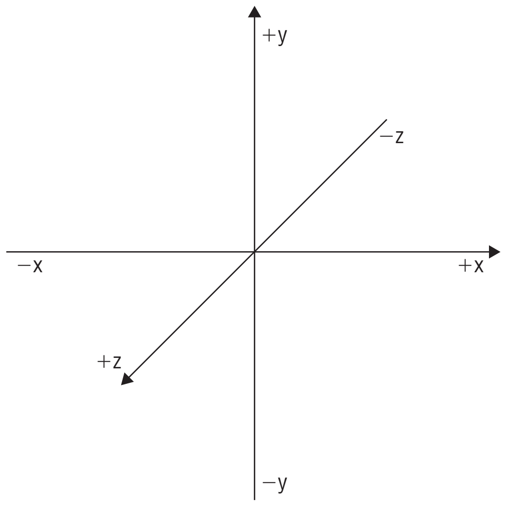

FIGURE 35-35

Model

This section creates a model that has the 3-D look of a book. A 3-D model is made up of triangles, so the simplest model is just one triangle. More complex models are made up from multiple triangles. Rectangles can be made up from two triangles. Balls are made up from a multiplicity of triangles. The more triangles used, the rounder the ball.

With the book model, each side is a rectangle, which could be made up from only two triangles. However, because the front cover has three different materials, six triangles are used.

A triangle is defined by the `Positions` property of the `MeshGeometry3D`. Here is just a part of the front side of the book. The `MeshGeometry3D` defines two triangles. You can count five coordinates for the points because the third point of the first triangle is also the first point of the second triangle. This can be done for optimization to reduce the size of the model. All the points use the same z coordinate, 0, and x/y coordinates 0 0, 10 0, 0 10, 10 10, and 10 0. The property `TriangleIndices` indicates the order of the positions. The first triangle is defined clockwise, the second triangle counterclockwise. With this property you define which side of the triangle is visible. One side of the triangle shows the color defined with the `Material` property of the `GeometryModel3D` class, and the other side shows the `BackMaterial` property.

The rendering surface for 3-D is `ModelVisual3D` that surrounds the models as shown:

```
<ModelVisual3D>
    <ModelVisual3D.Content>
        <Model3DGroup>

            <!-- front -->
            <GeometryModel3D>
                <GeometryModel3D.Geometry>
                    <MeshGeometry3D
                        Positions="0 0 0, 10 0 0, 0 10 0, 10 10 0, 10 0 0"
                        TriangleIndices="0, 1, 2, 2, 4, 3"
                        />
                </GeometryModel3D.Geometry>
```

code snippet 3DDemo/MainWindow.xaml

The `Material` property of the `GeometryModel` defines what material is used by the model. Depending on the viewpoint, the `Material` or `BackMaterial` property is important.

WPF offers different material types: `DiffuseMaterial`, `EmissiveMaterial`, and `SpecularMaterial`. The material will influence the look of the model together with the light that is used to illuminate the scene. `EmmisiveMaterial` and the color that is applied to the brush of the material is part of the calculations to define the light to show the model. SpecularMaterial adds illuminated highlight reflections when specular highlight reflections occur. The example code makes use of DiffuseMaterial and references a brush from the resource named mainCover:

```
                            <GeometryModel3D.Material>
                                <DiffuseMaterial Brush="{StaticResource mainCover}" />
                            </GeometryModel3D.Material>
                        </GeometryModel3D>
```

The brush for the main cover is a VisualBrush. The VisualBrush has a Border with a Grid that consists of two Label elements. One Label element defines the text Professional C# 4 and is written to the cover:

```
            <VisualBrush x:Key="mainCover">
                <VisualBrush.Visual>
                    <Border Background="Red">
                        <Grid>
                            <Grid.RowDefinitions>
                                <RowDefinition Height="30" />
                                <RowDefinition Height="*" />
                            </Grid.RowDefinitions>
                            <Label Grid.Row="0" HorizontalAlignment="Center">
                                Professional C# 4</Label>
                            <Label Grid.Row="1"></Label>
                        </Grid>
                    </Border>
                </VisualBrush.Visual>
            </VisualBrush>
```

Because a brush is defined by a 2-D coordinate system and the model has a 3-D coordinate system, a translation between them needs to be done. This translation is done by the TextureCoordinates property of the MeshGeometry3D. The TextureCoordinates specify every point of the triangle and shows how it maps to 2-D. The first point 0 0 0 maps to 0 1, the second point 10 0 0 maps to 1 1, and so on. Be aware that y has a different direction in the 3-D and 2-D coordinate systems. Figure 35-36 shows the coordinate system for 2-D:

```
                                <MeshGeometry3D
                                    Positions="0 0 0, 10 0 0, 0 10 0, 10 10 0, 10 0 0"
                                    TriangleIndices="0, 1, 2, 2, 4, 3"
                                    TextureCoordinates="0 1, 1 1, 0 0, 1 0, 1 1"
                                    />
```

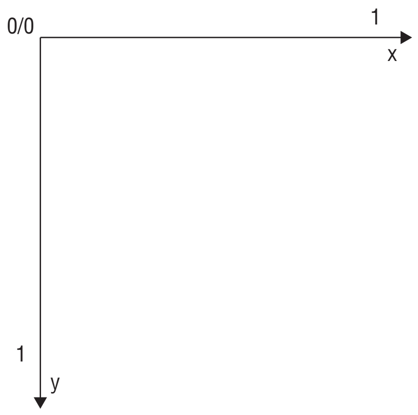

FIGURE 35-36

Cameras

A camera is needed with a 3-D model to see something. The example uses the `PerspectiveCamera` that has a position and a direction to look into. Changing the camera position to the left moves the model to the right and vice versa. Changing the y position of the camera, the model appears larger or smaller. With this camera, the further away the model is, the smaller it becomes:

```
<Viewport3D.Camera>
    <PerspectiveCamera Position="0,0,25" LookDirection="15,6,-50" />
</Viewport3D.Camera>
```

code snippet 3DDemo/MainWindow.xaml

WPF also has an `OrtographicCamera` that doesn't have a horizon on the scene, so the size of the element doesn't change if it is further away. With `MatrixCamera`, the behavior of the camera can be exactly specified.

Lights

Without a light it is dark. A 3-D scene requires a light to make the model visible. There are different lights that can be used. The `AmbientLight` lights the scene uniformly. `DirectionalLight` is a light that shines in one direction, similar to sunlight. `PointLight` has a position in space and lights in all directions. `SpotLight` has a position as well but uses a cone for its lighting.

The example code uses a `SpotLight` with a position, a direction, and cone angles:

```
<ModelVisual3D>
    <ModelVisual3D.Content>
        <SpotLight Color="White" InnerConeAngle="20" OuterConeAngle="60"
                   Direction="15,6,-50" Position="0,0,25" />
     </ModelVisual3D.Content>
</ModelVisual3D>
```

Rotation

To get a 3-D look from the model, it should be able to be rotated. For rotation, the `RotateTransform3D` element is used to define the center of the rotation and the rotation angle:

```
<Model3DGroup.Transform>
    <RotateTransform3D CenterX="0" CenterY="0" CenterZ="0">
        <RotateTransform3D.Rotation>
            <AxisAngleRotation3D x:Name="angle" Axis="-1,-1,-1"
                                 Angle="70" />
        </RotateTransform3D.Rotation>
    </RotateTransform3D>
</Model3DGroup.Transform>
```

To run a rotation from the completed model, an animation is started by an event trigger. The animation changes the `Angle` property of the `AxisAngleRotation3D` element continuously:

```
<Window.Triggers>
    <EventTrigger RoutedEvent=f"Window.Loaded">
        <BeginStoryboard>
            <Storyboard>
                <DoubleAnimation From="0" To="360" Duration="00:00:10"
                                 Storyboard.TargetName="angle"
                                 Storyboard.TargetProperty="Angle"
                                 RepeatBehavior="Forever" />
            </Storyboard>
        </BeginStoryboard>
    </EventTrigger>
</Window.Triggers>
```

After running the application, you will see the output in Figure 35-37.

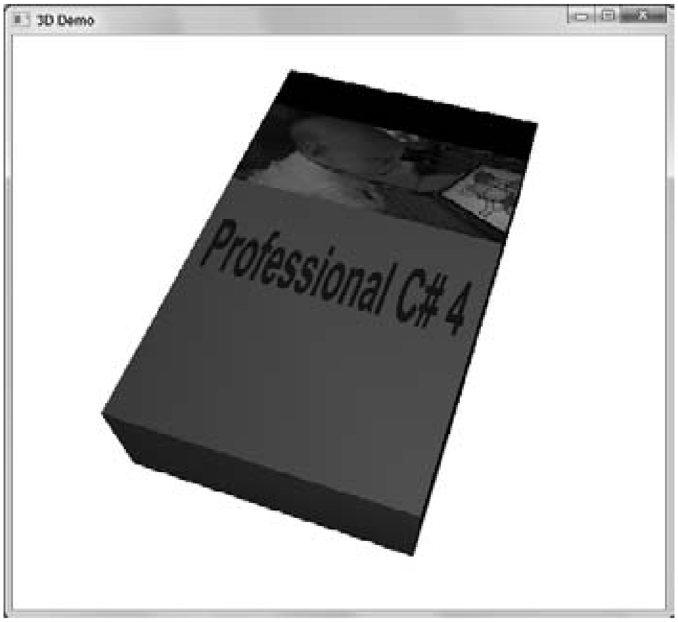

FIGURE 35-37

SUMMARY

In this chapter, you have taken a first tour through the many features of WPF. WPF makes it easy to separate work between developers and designers. All UI features can be created with XAML, and the functionality by using code-behind.

You have seen many controls and containers that are all based on vector-based graphics. Because of vector-based graphics, WPF elements can be scaled, sheared, and rotated. Because of the content flexibility of content controls, the event-handling mechanism is based on bubbling and tunneling events.

Different kinds of brushes are available to paint background and foreground of elements. You can use solid brushes, linear or radial gradient brushes, but also visual brushes to do reflections or show videos.

Styling and templates allow you to customize the look of controls. Triggers allow you to change properties of WPF elements dynamically. Animations can be done easily by animating a property value from a WPF control.

The next chapter continues with WPF showing data binding, commands, navigation, and several more features.

36 Business Applications with WPF

WHAT'S IN THIS CHAPTER?

- Data Binding to Elements, Objects, Lists, and XML
- Value Conversions and Validation
- Commanding
- Using the `TreeView` to display hierarchical data
- Displaying and Grouping data with the `DataGrid`

In the previous chapter you read about some of the core functionality of WPF. In this chapter the journey through WPF continues. Here you read about important aspects for creating complete applications, such as data binding and command handling, and about the new `DataGrid` control. Data binding is an important concept to bring data from .NET classes into the user interface, and allow the user to change data. Commanding allows mapping events from the UI to code. In contrast to the event model, this gives a better separation between XAML and code. The `TreeView` and `DataGrid` controls are UI controls to display bound data.

DATA BINDING

WPF data binding takes another huge step forward compared with previous technologies. Data binding gets data from .NET objects to the UI or the other way around. Simple objects can be bound to UI elements, lists of objects, and also XAML elements itself. With WPF data binding, the target can be any dependency property of a WPF element, and every property of a CLR object can be the source. Because a WPF element is implemented as a .NET class, every WPF element can be the source as well. See Figure 36-1 for the connection between the source and the target. The `Binding` object defines the connection.

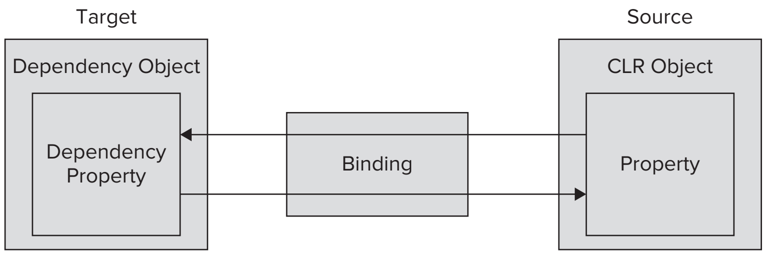

FIGURE 36-1

Binding supports several binding modes between the target and source. Binding can be *one-way*, where the source information goes to the target, but if the user changes information in the user interface, the source does not get updated. For updates to the source, *two-way* binding is required.

The following table shows the binding modes and their requirements.

BINDING MODE	DESCRIPTION
One-time	Binding goes from the source to the target and occurs only once when the application is started or the data context changes. Here, you get a snapshot of the data.
One-way	Binding goes from the source to the target. This is useful for read-only data, because it is not possible to change the data from the user interface. To get updates to the user interface, the source must implement the interface `INotifyPropertyChanged`.
Two-way	With two-way binding, the user can make changes to the data from the UI. Binding occurs in both directions — from the source to the target and from the target to the source. The source needs to implement read/write properties so that changes can be updated from the UI to the source.
One-way-to-source	With one-way-to-source binding, if the target property changes, the source object gets updated.

WPF data binding involves many facets beside the binding modes. This section gives you details on binding to XAML elements, binding to simple .NET objects, and binding to lists. Using change notifications, the UI is updated with changes in the bound objects. You will read about getting the data from object data providers and directly from the code. Multibinding and priority binding demonstrates different binding possibilities other than the default binding. You will also read about dynamically selecting data templates, and validation of binding values.

Let's start with the BooksDemo sample application.

BooksDemo Application

In this section, you create a new WPF application named BooksDemo to use throughout this chapter with data binding and commanding.

Change the XAML file `MainWindow.xaml` and add a `DockPanel`, a `ListBox`, a `Hyperlink`, and a `TabControl`:

```
<Window x:Class="Wrox.ProCSharp.WPF.MainWindow"
Insert IconMargin   [FILENAME]
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        xmlns:local="clr-namespace:Wrox.ProCSharp.WPF"
        Title="Main Window" Height="400" Width="600">
    <DockPanel>
        <ListBox DockPanel.Dock="Left" Margin="5" MinWidth="120">
            <ListBoxItem>
                <Hyperlink Click=OnShowBook">Show Book</Hyperlink>
            </ListBoxItem>
        </ListBox>
        <TabControl Margin="5" x:Name="tabControl1">
        </TabControl>
    </DockPanel>
</Window>
```

code snippet BooksDemo/MainWindow.xaml

Now add a WPF user control named `BookUC`. This user control contains a `DockPanel`, a `Grid` with several rows and columns, a `Label`, and `TextBox` controls:

```
<UserControl x:Class="Wrox.ProCSharp.WPF.BookUC"
             xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
             xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
             xmlns:mc="http://schemas.openxmlformats.org/markup-compatibility/2006"
             xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
             mc:Ignorable="d"
             d:DesignHeight="300" d:DesignWidth="300">
    <DockPanel>
        <Grid>
            <Grid.RowDefinitions>
                <RowDefinition />
                <RowDefinition />
                <RowDefinition />
                <RowDefinition />
            </Grid.RowDefinitions>
            <Grid.ColumnDefinitions>
                <ColumnDefinition Width="Auto" />
                <ColumnDefinition Width="*" />
            </Grid.ColumnDefinitions>
            <Label Content="Title" Grid.Row="0" Grid.Column="0" Margin="10,0,5,0"
                   HorizontalAlignment="Left" VerticalAlignment="Center" />
            <Label Content="Publisher" Grid.Row="1" Grid.Column="0"
                   Margin="10,0,5,0" HorizontalAlignment="Left"
                   VerticalAlignment="Center" />
            <Label Content="Isbn" Grid.Row="2" Grid.Column="0"
                   Margin="10,0,5,0" HorizontalAlignment="Left"
                   VerticalAlignment="Center" />
            <TextBox Grid.Row="0" Grid.Column="1" Margin="5" />
            <TextBox Grid.Row="1" Grid.Column="1" Margin="5" />
            <TextBox Grid.Row="2" Grid.Column="1" Margin="5" />
            <StackPanel Grid.Row="3" Grid.Column="0" Grid.ColumnSpan="2">
                <Button Content="Show Book" Margin="5" Click="OnShowBook" />
            </StackPanel>
        </Grid>
    </DockPanel>
</UserControl>
```

code snippet BooksDemo/BookUC.xaml

Within the `OnShowBook()` handler in the `MainWindow.xaml.cs`, create a new instance of the user control `BookUC` and add a new `TabItem` to the `TabControl`. Then change the `SelectedIndex` property of the `TabControl` to open the new tab:

```
private void OnShowBook(object sender, RoutedEventArgs e)
{
    var bookUI = new BookUC();
    this.tabControl1.SelectedIndex =
        this.tabControl1.Items.Add(
            new TabItem { Header = "Book", Content = bookUI });
}
```

code snippet BooksDemo/MainWindow.xaml.cs

After building the project you can start the application and open the user control within the `TabControl` by clicking the hyperlink.

Binding with XAML

A WPF element can not only be the target for data binding, it can also be the source. You can bind the source property of one WPF element to the target of another WPF element.

In the following code example, data binding is used to resize the controls within the user control with a slider. Add a `StackPanel` control to the user control `BookUC` that contains a `Label` and a `Slider` control. The `Slider` control defines `Minimum` and `Maximum` values that define the scale, and an initial value of 1 is assigned to the `Value` property:

```
<DockPanel>
    <StackPanel DockPanel.Dock="Bottom" Orientation="Horizontal"
                HorizontalAlignment="Right">
        <Label Content="Resize" />
        <Slider x:Name="slider1" Value="1" Minimum="0.4" Maximum="3"
                Width="150" HorizontalAlignment="Right" />
    </StackPanel>
```

code snippet BooksDemo/BookUC.xaml

Set the `LayoutTransform` property of the `Grid` control and add a `ScaleTransform` element. With the `ScaleTransform` element, the `ScaleX` and `ScaleY` properties are data bound. Both properties are set with the `Binding` markup extension. In the `Binding` markup extension, the `ElementName` is set to `slider1` to reference the previously created `Slider` control. The `Path` property is set to the `Value` property to get the value of the slider:

```
<Grid>
    <Grid.LayoutTransform>
        <ScaleTransform x:Name="scale1"
            ScaleX="{Binding Path=Value, ElementName=slider1}"
            ScaleY="{Binding Path=Value, ElementName=slider1}" />
    </Grid.LayoutTransform>
```

When running the application, you can move the slider and thus resize the controls within the `Grid`, as you can see in Figures 36-2 and 36-3.

Instead of defining the binding information with XAML code, as was done in the preceding code with the `Binding` metadata extension, you can do it with code-behind. With code-behind you have to create a new `Binding` object and set the `Path` and `Source` properties. The `Source` property must be set to the source object; here, it is the WPF object `slider1`. The `Path` is set to a `PropertyPath` instance that is initialized with the name of the property of the source object, `Value`. With controls that derive from `FrameworkElement`, you can invoke the method `SetBinding()` to define the binding. However, `ScaleTransform` does not derive from `FrameworkElement` but from the `Freezable` base class instead. Use the helper class `BindingOperations` to bind such controls. The `SetBinding()` method of the `BindingOperations` class requires a `DependencyObject` — which is the `ScaleTransform` instance in the example. The `SetBinding()` method also requires the `dependency` property of the target be bound, and the `Binding` object.

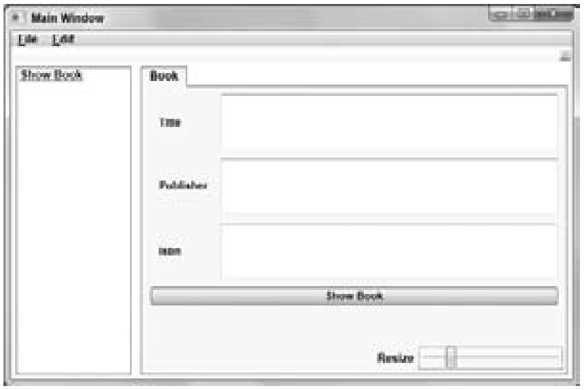

FIGURE 36-2

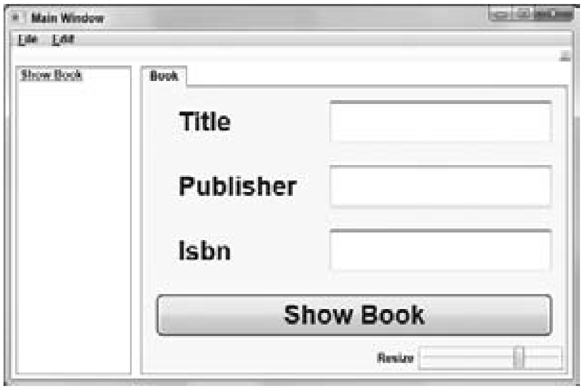

FIGURE 36-3

```
var binding = new Binding
 {
     Path = new PropertyPath("Value"),
     Source = slider1
 };
BindingOperations.SetBinding(scale1,
        ScaleTransform.ScaleXProperty, binding);
BindingOperations.SetBinding(scale1,
        ScaleTransform.ScaleYProperty, binding);
```

Remember that all classes that derive from `DependencyObject` *can have dependency properties. You can learn more about dependency properties in Chapter 27, "Core XAML."*

You can configure a number of binding options with the `Binding` class, as described in the following table.

BINDING CLASS MEMBERS	DESCRIPTION
`Source`	With the `Source` property, you define the source object for data binding.
`RelativeSource`	With `RelativeSource`, you can specify the source in relation to the target object. This is useful to display error messages when the source of the error comes from the same control.
`ElementName`	If the source is a WPF element, you can specify the source with the `ElementName` property.
`Path`	With the `Path` property, you specify the path to the source object. This can be the property of the source object, but indexers and properties of child elements are also supported.
`XPath`	With an XML data source, you can define an XPath query expression to get the data for binding.
`Mode`	The mode defines the direction for the binding. The `Mode` property is of type `BindingMode`. `BindingMode` is an enumeration with the following values: `Default`, `OneTime`, `OneWay`, `TwoWay`, and `OneWayToSource`. The default mode depends on the target: with a `TextBox`, two-way binding is the default; with a `Label` that is read-only, the default is one-way. `OneTime` means that the data is only `init` loaded from the source; `OneWay` updates from the source to the target. With `TwoWay` binding, changes from the WPF elements are written back to the source. `OneWayToSource` means that the data is never read but always written from the target to the source.
`Converter`	With the `Converter` property, you can specify a converter class that converts the data for the UI and back. The converter class must implement the interface `IValueConverter`, which defines the methods `Convert()` and `ConvertBack()`. You can pass parameters to the converter methods with the `ConverterParameter` property. The converter can be culture-sensitive; the culture can be set with the `ConverterCulture` property.
`FallbackValue`	With the `FallbackValue` property, you can define a default value that is used if binding doesn't return a value.
`ValidationRules`	With the `ValidationRules` property, you can define a collection of `ValiationRule` objects that are checked before the source is updated from the WPF target elements. The class `ExceptionValidationRule` is derived from the class `ValidationRule` and checks for exceptions.

Simple Object Binding

For binding to CLR objects, with the .NET classes you just have to define properties, as shown in the `Book` class example and the properties `Title`, `Publisher`, `Isbn`, and `Authors`. This class is in the Data folder of the BooksDemo project.

```
using System.Collections.Generic;

namespace Wrox.ProCSharp.WPF.Data
{
    public class Book
    {
        public Book(string title, string publisher, string isbn,
                    params string[] authors)
        {
            this.Title = title;
            this.Publisher = publisher;
            this.Isbn = isbn;
            this.authors.AddRange(authors);
        }
        public Book()
            : this("unknown", "unknown", "unknown")
        {
        }
        public string Title { get; set; }
        public string Publisher { get; set; }
        public string Isbn { get; set; }

        private readonly List<string> authors = new List<string>();
        public string[] Authors
        {
            get
            {
                return authors.ToArray();
            }
        }

        public override string ToString()
        {
            return Title;
        }
    }
}
```

code snippet BooksDemo/Data/Book.cs

In the XAML code of the user control `BookUC`, several labels and `TextBox` controls are defined to display book information. Using `Binding` markup extensions, the `TextBox` controls are bound to the properties of the `Book` class. With the `Binding` markup extension, nothing more than the `Path` property is defined to bind it to the property of the `Book` class. There's no need to define a source because the source is defined by assigning the `DataContext`, as you can see in the code-behind that follows. The mode is defined by its default with the `TextBox` element, and this is two-way binding:

```
            <TextBox Text="{Binding Path=Title}" Grid.Row="0" Grid.Column="1"
                     Margin="5" />
            <TextBox Text="{Binding Path=Publisher}" Grid.Row="1" Grid.Column="1"
                     Margin="5" />
            <TextBox Text="{Binding Path=Isbn}" Grid.Row="2" Grid.Column="1"
                     Margin="5" />
```

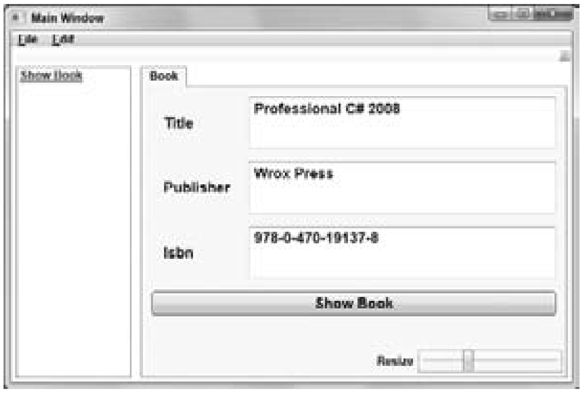
code snippet BooksDemo//BookUC.xaml

With the code-behind, a new `Book` object is created, and the book is assigned to the `DataContext` property of the user control. `DataContext` is a dependency property that is defined with the base class `FrameworkElement`. Assigning the `DataContext` with the user control means that every element in the user control has a default binding to the same data context:

```
private void OnShowBook(object sender, RoutedEventArgs e)
{
    var bookUI = new BookUC();
    bookUI.DataContext = new Book
    {
        Title = "Professional C# 2008",
        Publisher = "Wrox Press",
        Isbn = "978-0-470-19137-8"
    };
    this.tabControl1.SelectedIndex =
        this.tabControl1.Items.Add(
            new TabItem { Header = "Book", Content = bookUI });
}
```

code snippet BooksDemo/MainWindow.xaml.cs

After starting the application, you can see the bound data, as shown in Figure 36-4.



Professional C# 2008

Wrox Press

978-0-470-19137-8

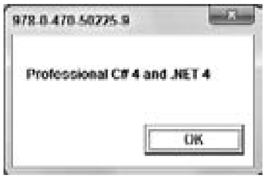
FIGURE 36-4

To see two-way binding in action (changes to the input of the WPF element are reflected inside the CLR object), the `Click` event handler of the button in the user control, the `OnShowBook()` method, is implemented. When implemented, a message box pops up to show the current title and ISBN number of the `book1` object. Figure 36-5 shows the output from the message box after a change to the input was made during runtime:

```
private void OnShowBook(object
sender, RoutedEventArgs e)
{
    Book theBook = this.DataContext as Book;
    if (theBook != null)
        MessageBox.Show(theBook.Title, theBook.Isbn);
}
```

code snippet BooksDemo/BookUC.xaml.cs

Change Notification



978-0-470-50225-9

Professional C# 4 and .NET 4

FIGURE 36-5

With the current two-way binding, the data is read from the object and written back. However, if within the code the data is changed to the user interface, the UI does not receive the change information. You can easily verify this by adding a button to the user control and implementing the `Click` event handler `OnChangeBook()`. The book inside the data context gets changed but the user interface doesn't show the change:

```
<StackPanel Grid.Row="3" Grid.Column="0" Grid.ColumnSpan="2"
            Orientation="Horizontal" HorizontalAlignment="Center">
    <Button Content="Show Book" Margin="5" Click="OnShowBook" />
    <Button Content="Change Book" Margin="5" Click="OnChangeBook" />
</StackPanel>
```

code snippet BooksDemo/BookUC.xaml

```
        private void OnChangeBook(object sender, RoutedEventArgs e)
        {
            Book theBook = this.DataContext as Book;
            if (theBook != null)
            {
                theBook.Title = "Professional C# 4 with .NET 4";
                theBook.Isbn = "978-0-470-50225-9";
            }
        }
```

code snippet BooksDemo/BookUC.xaml.cs

To get change information to the user interface, the entity class must implement the interface `INotifyPropertyChanged`. The `Book` class is modified to implement this interface. This interface defines the `PropertyChanged` event, which also requires changing the implementation of the properties to fire the event:

```
using System.ComponentModel;
using System.Collections.Generic;

namespace Wrox.ProCSharp.WPF.Data
{
    public class Book : INotifyPropertyChanged
    {
        public Book(string title, string publisher, string isbn,
                    params string[] authors)
        {
            this.title = title;
            this.publisher = publisher;
            this.isbn = isbn;
            this.authors.AddRange(authors);
        }
        public Book()
            : this("unknown", "unknown", "unknown")
        {
        }

        public event PropertyChangedEventHandler PropertyChanged;

        private string title;
        public string Title {
            get
            {
                return title;
            }
            set
            {
                title = value;
                if (PropertyChanged != null)
                    PropertyChanged(this, new
                         PropertyChangedEventArgs("Title"));
            }
        }
        private string publisher;
        public string Publisher
        {
            get
            {
                return publisher;
            }
            set
            {
                publisher = value;
                if (PropertyChanged != null)
                    PropertyChanged(this, new PropertyChangedEventArgs(
                                    "Publisher"));
            }
        }
        private string isbn;
        public string Isbn {
            get
            {
                return isbn;
            }
            set
            {
                isbn = value;
                if (PropertyChanged != null)
                    PropertyChanged(this, new PropertyChangedEventArgs("Isbn"));
            }
        }

        private readonly List<string> authors = new List<string>();
        public string[] Authors
        {
            get
            {
                return authors.ToArray();
            }
        }

        public override string ToString()
        {
            return this.title;
        }
    }
}
```

code snippet BooksDemo/Data/Book.cs

With this change, the application can be started again to verify that the user interface gets an update from the change in the event handler.

Object Data Provider

Instead of instantiating the object in code-behind, you can do this with XAML. To reference a class from code-behind within XAML, you have to reference the namespace with the namespace declarations in the XML root element. The XML attribute `xmlns:local="clr-namespace:Wrox.ProCsharp.WPF"` assigns the .NET namespace `Wrox.ProCSharp.WPF` to the XML namespace alias `local`.

One object of the `Book` class is now defined with the `Book` element inside the `DockPanel` resources. By assigning values to the XML attributes `Title`, `Publisher`, and `Isbn`, you set the values of the properties from the `Book` class. `x:Key="theBook"` defines the identifier for the resource so that you can reference the book object:

```
<UserControl x:Class="Wrox.ProCSharp.WPF.BookUC"
             xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
             xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
             xmlns:mc="http://schemas.openxmlformats.org/markup-compatibility/2006"
             xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
             xmlns:local="clr-namespace:Wrox.ProCSharp.WPF.Data"
             mc:Ignorable="d"
```

```
                 d:DesignHeight="300" d:DesignWidth="300">
        <DockPanel>
            <DockPanel.Resources>
                <local:Book x:Key="theBook" Title="Professional C# 2010"
                            Publisher="Wrox Press" Isbn="978-0-470-50225-9" />
            </DockPanel.Resources>
```

code snippet BooksDemo/BookUC.xaml

If the .NET namespace to reference is in a different assembly, you have to add the assembly to the XML declaration:

```
xmlsn:sys="clr-namespace:System;assembly=mscorlib"
```

In the `TextBox` element, the `Source` is defined with the `Binding` markup extension that references the `theBook` resource:

```
<TextBox Text="{Binding Path=Title,
                Source={StaticResource theBook}}"
         Grid.Row="0" Grid.Column="1" Margin="5" />
<TextBox Text="{Binding Path=Publisher,
               Source={StaticResource theBook}}"
         Grid.Row="1" Grid.Column="1" Margin="5" />
<TextBox Text="{Binding Path=Isbn,
               Source={StaticResource theBook}}"
         Grid.Row="2" Grid.Column="1" Margin="5" />
```

Because all these `TextBox` elements are contained within the same control, it is possible to assign the `DataContext` property with a parent control and set the `Path` property with the `TextBox` binding elements. Because the `Path` property is a default, you can also reduce the `Binding` markup extension to the following code:

```
<Grid x:Name="grid1" DataContext="{StaticResource theBook}">
<!-- ... -->
    <TextBox Text="{Binding Title}" Grid.Row="0" Grid.Column="1"
             Margin="5" />
    <TextBox Text="{Binding Publisher}" Grid.Row="1" Grid.Column="1"
             Margin="5" />
    <TextBox Text="{Binding Isbn}" Grid.Row="2" Grid.Column="1"
             Margin="5" />
```

Instead of defining the object instance directly within XAML code, you can define an object data provider that references a class to invoke a method. For use by the `ObjectDataProvider`, it's best to create a factory class that returns the object to display, as shown with the `BookFactory` class:

```
using System.Collections.Generic;

namespace Wrox.ProCSharp.WPF.Data
{
    public class BookFactory
    {
        private List<Book> books = new List<Book>();

        public BookFactory()
              {
            books.Add(new Book
            {
                Title = "Professional C# 2010",
                Publisher = "Wrox Press",
                Isbn = "978-0-470-50225-9"
            });
            }

        public Book GetTheBook()
        {
            return books[0];
        }
    }
}
```

code snippet BooksDemo/Data/BookFactory.cs

The `ObjectDataProvider` element can be defined in the resources section. The XML attribute `ObjectType` defines the name of the class; with `MethodName` you specify the name of the method that is invoked to get the book object:

```
<DockPanel.Resources>
    <ObjectDataProvider x:Key="theBook" ObjectType="local:BookFactory"
                        MethodName="GetTheBook" />
</DockPanel.Resources>
```

code snippet BooksDemo/BookUC.xaml

The properties you can specify with the `ObjectDataProvider` class are listed in the following table.

OBJECTDATAPROVIDER	DESCRIPTION
`ObjectType`	The `ObjectType` property defines the type to create an instance.
`ConstructorParameters`	Using the `ConstructorParameters` collection, you can add parameters to the class to create an instance.
`MethodName`	The `MethodName` property defines the name of the method that is invoked by the object data provider.
`MethodParameters`	With the `MethodParameters` property, you can assign parameters to the method defined with the `MethodName` property.
`ObjectInstance`	With the `ObjectInstance` property, you can get and set the object that is used by the `ObjectDataProvider` class. For example, you can assign an existing object programmatically instead of defining the `ObjectType` so that an object is instantiated by `ObjectDataProvider`.
`Data`	With the `Data` property you can access the underlying object that is used for data binding. If the `MethodName` is defined, with the `Data` property you can access the object that is returned from the method defined.

List Binding

Binding to a list is more frequently done than binding to simple objects. Binding to a list is very similar to binding to a simple object. You can assign the complete list to the `DataContext` from code-behind, or you can use an `ObjectDataProvider` that accesses an object factory that returns a list. With elements that support binding to a list (for example, a `ListBox`), the complete list is bound. With elements that support binding to just one object (for example, a `TextBox`), the current item is bound.

With the `BookFactory` class, now a list of `Book` objects is returned:

```
public class BookFactory
{
    private List<Book> books = new List<Book>();

    public BookFactory()
    {
        books.Add(new Book("Professional C# 4 with .NET 4", "Wrox Press",
                           "978-0-470-50225-9", "Christian Nagel", "Bill Evjen",
                           "Jay Glynn", "Karli Watson", "Morgan Skinner"));
```

```
            books.Add(new Book("Professional C# 2008", "Wrox Press",
                                "978-0-470-19137-8", "Christian Nagel", "Bill Evjen",
                                "Jay Glynn", "Karli Watson", "Morgan Skinner"));
            books.Add(new Book("Beginning Visual C# 2010", "Wrox Press",
                                "978-0-470-50226-6", "Karli Watson", "Christian Nagel",
                                "Jacob Hammer Pedersen", "Jon D. Reid",
                                "Morgan Skinner", "Eric White"));
            books.Add(new Book("Windows 7 Secrets", "Wiley", "978-0-470-50841-1",
                                "Paul Thurrott", "Rafael Rivera"));
            books.Add(new Book("C# 2008 for Dummies", "For Dummies",
                                "978-0-470-19109-5", "Stephen Randy Davis",
                                "Chuck Sphar"));
        }

        public IEnumerable<Book> GetBooks()
        {
            return books;
        }
    }
```

code snippet BooksDemo/Data/BookFactory.cs

To use the list, create a new `BooksUC` user control. The XAML code for this control contains `Label` and `TextBox` controls that display the values of a single book as well as a `ListBox` control that displays a book list. The `ObjectDataProvider` invokes the `GetBooks()` method of the `BookFactory`, and this provider is used to assign the `DataContext` of the `DockPanel`. The `DockPanel` has the bound `ListBox` and `TextBox` as its children.

```
<UserControl x:Class="Wrox.ProCSharp.WPF.BooksUC"
             xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
             xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
             xmlns:mc="http://schemas.openxmlformats.org/markup-compatibility/2006"
             xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
             xmlns:local="clr-namespace:Wrox.ProCSharp.WPF.Data"
             mc:Ignorable="d"
             d:DesignHeight="300" d:DesignWidth="300">
    <UserControl.Resources>
        <ObjectDataProvider x:Key="books" ObjectType="local:BookFactory"
                            MethodName="GetBooks" />
    </UserControl.Resources>
    <DockPanel DataContext="{StaticResource books}">
        <ListBox DockPanel.Dock="Left" ItemsSource="{Binding}" Margin="5"
                 MinWidth="120" />
        <Grid>
            <Grid.RowDefinitions>
                <RowDefinition />
                <RowDefinition />
                <RowDefinition />
                <RowDefinition />
            </Grid.RowDefinitions>
            <Grid.ColumnDefinitions>
                <ColumnDefinition Width="Auto" />
                <ColumnDefinition Width="*" />
            </Grid.ColumnDefinitions>
            <Label Content="Title" Grid.Row="0" Grid.Column="0" Margin="10,0,5,0"
                   HorizontalAlignment="Left" VerticalAlignment="Center" />
            <Label Content="Publisher" Grid.Row="1" Grid.Column="0"
                   Margin="10,0,5,0"
                   HorizontalAlignment="Left" VerticalAlignment="Center" />
            <Label Content="Isbn" Grid.Row="2" Grid.Column="0" Margin="10,0,5,0"
                   HorizontalAlignment="Left" VerticalAlignment="Center" />
            <TextBox Text="{Binding Title}" Grid.Row="0" Grid.Column="1"
```

```
                Margin="5" />
        <TextBox Text="{Binding Publisher}" Grid.Row="1" Grid.Column="1"
                Margin="5" />
        <TextBox Text="{Binding Isbn}" Grid.Row="2" Grid.Column="1"
                Margin="5" />
    </Grid>
  </DockPanel>
</UserControl>
```

code snippet BooksDemo/BooksUC.xaml

The new user control is started by adding a `Hyperlink` to `MainWindow.xaml`. It uses the `Click` event handler `OnShowBooks()` and the implementation of `OnShowBooks()` in the code-behind file `MainWindow.xaml.cs`:

```
<ListBox DockPanel.Dock="Left" Margin="5" MinWidth="120">
    <ListBoxItem>
        <Hyperlink Click="OnShowBook">Show Book</Hyperlink>
    </ListBoxItem>
    <ListBoxItem>
         <Hyperlink Click="OnShowBooks">Show Books</Hyperlink>
    </ListBoxItem>
</ListBox>
```

code snippet BooksDemo/BooksUC.xaml

```
private void OnShowBooks(object sender, RoutedEventArgs e)
{
    var booksUI = new BooksUC();
    this.tabControl1.SelectedIndex =
        this.tabControl1.Items.Add(
            new TabItem { Header="Books", Content=booksUI});

}
```

code snippet BooksDemo/BooksUC.xaml.cs

Because the `DockPanel` has the `Book` array assigned to the `DataContext`, and the `ListBox` is placed within the `DockPanel`, the `ListBox` shows all books with the default template, as illustrated in Figure 36-6.

FIGURE 36-6

For a more flexible layout of the `ListBox`, you have to define a template, as was discussed in the previous chapter for `ListBox` styling. The `ItemTemplate` of the `ListBox` defines a `DataTemplate` with a `Label` element. The content of the label is bound to the `Title`. The item template is repeated for every item in the list. Of course you can also add the item template to a style within resources:

```
<ListBox DockPanel.Dock="Left" ItemsSource="{Binding}" Margin="5"
         MinWidth="120">
    <ListBox.ItemTemplate>
        <DataTemplate>
            <Label Content="{Binding Title}" />
        </DataTemplate>
    </ListBox.ItemTemplate>
</ListBox>
```

code snippet BooksDemo/BooksUC.xaml

Master Details Binding

Instead of just showing all the elements inside a list, you might want or need to show detail information about the selected item. It doesn't require a lot of work to do this. The `Label` and `TextBox` controls are already defined; currently they only show the first element in the list.

There's one important change you have to make to the `ListBox`. By default, the labels are bound to just the first element of the list. By setting the `ListBox` property `IsSynchronizedWithCurrentItem="True"`, the selection of the list box is set to the current item. In Figure 36-7 you can see the result; the selected item is shown in the detail section labels:

FIGURE 36-7

```
<ListBox DockPanel.Dock="Left" ItemsSource="{Binding}" Margin="5"
         MinWidth="120" IsSynchronizedWithCurrentItem="True">
    <ListBox.ItemTemplate>
        <DataTemplate>
            <Label Content="{Binding Title}" />
        </DataTemplate>
    </ListBox.ItemTemplate>
</ListBox>
```

code snippet BooksDemo/BooksUC.xaml

MultiBinding

`Binding` is one of the classes that can be used for data binding. `BindingBase` is the abstract base class of all bindings and has different concrete implementations. Besides `Binding`, there's also `MultiBinding` and `PriorityBinding`. `MultiBinding` allows you to bind one WPF element to multiple sources. For example, with a `Person` class that has `LastName` and `FirstName` properties, it is interesting to bind both properties to a single WPF element:

```
public class Person
{
    public string FirstName { get; set; }
    public string LastName { get; set; }
}
```

code snippet MultiBindingDemo/Person.cs

For `MultiBinding`, a markup extension is not available — thus the binding must be specified with XAML element syntax. The child elements of `MultiBinding` are `Binding` elements that specify the binding to the various properties. Here the `FirstName` and `LastName` properties are used. The data context is set with the `Grid` element to reference the `person1` resource.

To connect the properties together, `MultiBinding` uses a `Converter` to convert multiple values to one. This converter uses a parameter that allows for different conversions based on the parameter:

```
<Window x:Class="Wrox.ProCSharp.WPF.MainWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        xmlns:system="clr-namespace:System;assembly=mscorlib"
        xmlns:local="clr-namespace:Wrox.ProCSharp.WPF"
        Title="MainWindow" Height="240" Width="500">
    <Window.Resources>
        <local:Person x:Key="person1" FirstName="Tom" LastName="Turbo" />
        <local:PersonNameConverter x:Key="personNameConverter" />
    </Window.Resources>
    <Grid DataContext="{StaticResource person1}">
        <TextBox>
            <TextBox.Text>
                <MultiBinding Converter="{StaticResource personNameConverter}" >
                    <MultiBinding.ConverterParameter>
                        <system:String>FirstLast</system:String>
                    </MultiBinding.ConverterParameter>
                    <Binding Path="FirstName" />
                    <Binding Path="LastName" />
                </MultiBinding>
            </TextBox.Text>
        </TextBox>
    </Grid>
</Window>
```

code snippet MultiBindingDemo/MainWindow.xaml

The multi-value converter implements the interface `IMultiValueConverter`. This interface defines two methods, `Convert()` and `ConvertBack()`. `Convert()` receives multiple values with the first argument from the data source and returns one value to the target. With the implementation, depending on whether the parameter has a value of `FirstLast` or `LastFirst`, the result is created differently:

```
using System;
using System.Globalization;
using System.Windows.Data;

namespace Wrox.ProCSharp.WPF
{

    public class PersonNameConverter : IMultiValueConverter
    {
        public object Convert(object[] values, Type targetType, object parameter,
                              CultureInfo culture)
        {
            switch (parameter as string)
            {
                case "FirstLast":
                    return values[0] + " " + values[1];
                case "LastFirst":
                    return values[1] + ", " + values[0];
                default:
                    throw new ArgumentException(
                        String.Format("invalid argument {0}", parameter));
            }
        }

        public object[] ConvertBack(object value, Type[] targetTypes,
                                    object parameter, CultureInfo culture)
        {
            throw new NotSupportedException();
        }
    }
}
```

code snippet MultiBindingDemo/MainWindow.xaml.cs

Priority Binding

`PriorityBinding` makes it easy to bind to data that is not readily available. If you need time to get the result with `PriorityBinding`, you can inform the user about the progress so he knows to wait.

To illustrate priority binding, use the PriorityBindingDemo project to create the Data class. Accessing the ProcessSomeData property needs some time that is simulated by calling the Thread.Sleep() method:

```
public class Data
{
    public string ProcessSomeData
    {
        get
        {
            Thread.Sleep(8000);
            return "the final result is here";
        }
    }
}
```

code snippet PriorityBindingDemo/Data.cs

The Information class gives information to the user. The information from property Info1 is returned immediately while Info2 returns information after five seconds. With a real implementation, this class could be associated with the processing class to get an estimated timeframe for the user:

```
public class Information
{
    public string Info1
    {
        get
        {
            return "please wait...";
        }
    }
    public string Info2
    {
        get
        {
            Thread.Sleep(5000);
            return "please wait a little more";
        }
    }
}
```

code snippet PriorityBindingDemo/Information.cs

In the MainWindow.xaml file, the Data and Information classes are referenced and initiated within the resources of the Window:

```
<Window.Resources>
    <local:Data x:Key="data1" />
    <local:Information x:Key="info" />
</Window.Resources>
```

code snippet PriorityBindingDemo/MainWindow.xaml

PriorityBinding is done in place of normal binding within the Content property of a Label. PriorityBinding consists of multiple Binding elements where all but the last one have the IsAsync property set to True. Because of this, if the first binding expression result is not immediately available, the binding process chooses the next one. The first binding references the ProcessSomeData property of the Data class that needs some time. Because of this, the next binding comes into play and references the Info2 property of the Information class. Info2 does not return a result immediately, and because IsAsync is set, the binding process does not wait but continues to the next binding. The last binding uses the Info1 property and immediately returns a result. If it doesn't return a result immediately, you would wait for the result because IsAsync is set to the default, False:

```
<Label>
    <Label.Content>
        <PriorityBinding>
            <Binding Path="ProcessSomeData" Source="{StaticResource data1}"
                     IsAsync="True" />
            <Binding Path="Info2" Source="{StaticResource info}"
                     IsAsync="True" />
            <Binding Path="Info1" Source="{StaticResource info}"
                     IsAsync="False" />
        </PriorityBinding>
    </Label.Content>
</Label>
```

With the start of the application you can see the message `please wait…` in the user interface. After a few seconds the result from the `Info2` property is returned as `please wait a little more`. It replaces the output from `Info1`. Finally, the result from `ProcessSomeData` replaces the output again.

Value Conversion

Let's get back to the BooksDemo application. The authors of the book are still missing in the user interface. If you bind the `Authors` property to a `Label` element, the `ToString()` method of the `Array` class is invoked, which returns the name of the type. One solution to this is to bind the `Authors` property to a `ListBox`. For the `ListBox`, you can define a template for a specific view. Another solution is to convert the string array returned by the `Authors` property to a string and use the string for binding.

The class `StringArrayConverter` converts a string array to a string. WPF converter classes must implement the interface `IValueConverter` from the namespace `System.Windows.Data`. This interface defines the methods `Convert()` and `ConvertBack()`. With the `StringArrayConverter`, the `Convert()` method converts the string array from the variable `value` to a string by using the `String.Join()` method. The separator parameter of the `Join()` is taken from the variable `parameter` received with the `Convert()` method.

You can read more about the methods of the `String` *classes in Chapter 9, "Strings and Regular Expressions."*

```
using System;
using System.Diagnostics.Contracts;
using System.Globalization;
using System.Windows.Data;

namespace Wrox.ProCSharp.WPF.Utilities
{
    [ValueConversion(typeof(string[]), typeof(string))]
    class StringArrayConverter : IValueConverter
    {
        public object Convert(object value, Type targetType, object parameter,
                              CultureInfo culture)
        {
            Contract.Requires(value is string[]);
            Contract.Requires(parameter is string);

            string[] stringCollection = (string[])value;
            string separator = (string)parameter;

            return String.Join(separator, stringCollection);
        }

        public object ConvertBack(object value, Type targetType, object parameter,
                                        CultureInfo culture)
            {
                throw new NotImplementedException();
            }
        }
    }
```

code snippet BooksDemo/Utilities/Information.cs

In the XAML code, the `StringArrayConverter` class can be declared as a resource for referencing it from the `Binding` markup extension:

```
    <UserControl x:Class="Wrox.ProCSharp.WPF.BooksUC"
                 xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
                 xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
                 xmlns:mc="http://schemas.openxmlformats.org/markup-compatibility/2006"
                 xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
                 xmlns:local="clr-namespace:Wrox.ProCSharp.WPF.Data"
                 xmlns:utils="clr-namespace:Wrox.ProCSharp.WPF.Utilities"
                 mc:Ignorable="d"
                 d:DesignHeight="300" d:DesignWidth="300">
        <UserControl.Resources>
            <utils:StringArrayConverter x:Key="stringArrayConverter" />
            <ObjectDataProvider x:Key="books" ObjectType="local:BookFactory"
                                MethodName="GetBooks" />
        </UserControl.Resources>
        <!--.-->
```

code snippet BooksDemo/BooksUC.xaml

For multiline output, a `TextBlock` element is declared with the `TextWrapping` property set to `Wrap` to make it possible to display multiple authors. In the `Binding` markup extension the `Path` is set to `Authors`, which is defined as a property returning a string array. The string array is converted from the resource `stringArrayConverter` as defined by the `Converter` property. The `Convert` method of the converter implementation receives the `ConverterParameter ', '` as input to separate the authors:

```
                <TextBlock Text="{Binding Authors,
                               Converter={StaticResource stringArrayConverter},
                               ConverterParameter=', '}"
                           Grid.Row="3" Grid.Column="1" Margin="5"
                           VerticalAlignment="Center" TextWrapping="Wrap" />
```

Figure 36-8 shows the book details, including authors.

FIGURE 36-8

Adding List Items Dynamically

What if list items are added dynamically? The WPF element must be notified of elements added to the list.

In the XAML code of the WPF application, a `Button` element is added inside a `StackPanel`. The `Click` event is assigned to the method `OnAddBook()`:

```
<StackPanel Orientation="Horizontal" DockPanel.Dock="Bottom"
            HorizontalAlignment="Center">
    <Button Margin="5" Padding="4" Content="Add Book" Click="OnAddBook" />
</StackPanel>
```

code snippet BooksDemo/BooksUC.xaml

In the method `OnAddBook()`, a new `Book` object is added to the list. If you test the application with the `BookFactory` as it is implemented now, there's no notification to the WPF elements that a new object has been added to the list:

```
private void OnAddBook(object sender, RoutedEventArgs e)
{
    ((this.FindResource("books") as ObjectDataProvider).Data as
        IList<Book>).Add(
            new Book(".NET 3.5 Wrox Box", "Wrox Press",
                     "978-0470-38799-3"));
}
```

code snippet BooksDemo/BooksUC.xaml.cs

The object that is assigned to the `DataContext` must implement the interface `INotifyCollectionChanged`. This interface defines the `CollectionChanged` event that is used by the WPF application. Instead of implementing this interface on your own with a custom collection class, you can use the generic collection class `ObservableCollection<T>` that is defined with the namespace `System.Collections.ObjectModel` in the assembly `WindowsBase`. Now, as a new item is added to the collection, the new item immediately shows up in the `ListBox`:

```
public class BookFactory
{
   private ObservableCollection<Book> books =
         new ObservableCollection<Book>();

   // ...

   public IEnumerable<Book> GetBooks()
   {
      return books;
   }
}
```

code snippet BooksDemo/Utilities/BookFactory.cs

Data Template Selector

In the previous chapter, you saw how controls can be customized with templates. You also saw how to create a data template that defines a display for specific data types. A data template selector can create different data templates dynamically for the same data type. A data template selector is implemented in a class that derives from the base class `DataTemplateSelector`.

Here a data template selector is implemented by selecting a different template based on the publisher. Within the user control resources these templates are defined. One template can be accessed by the key name `wroxTemplate`; the other template has the key name `dummiesTemplate`, and the third one `bookTemplate`:

```
<DataTemplate x:Key="wroxTemplate" DataType="{x:Type local:Book}">
    <Border Background="Red" Margin="10" Padding="10">
        <StackPanel>
            <Label Content="{Binding Title}" />
            <Label Content="{Binding Publisher}" />
        </StackPanel>
    </Border>
</DataTemplate>

<DataTemplate x:Key="dummiesTemplate" DataType="{x:Type local:Book}">
    <Border Background="Yellow" Margin="10" Padding="10">
        <StackPanel>
            <Label Content="{Binding Title}" />
            <Label Content="{Binding Publisher}" />
        </StackPanel>
    </Border>
</DataTemplate>

<DataTemplate x:Key="bookTemplate" DataType="{x:Type local:Book}">
    <Border Background="LightBlue" Margin="10" Padding="10">
        <StackPanel>
            <Label Content="{Binding Title}" />
            <Label Content="{Binding Publisher}" />
        </StackPanel>
    </Border>
</DataTemplate>
```

code snippet BooksDemo/BooksUC.xaml

For selecting the template, the class `BookDataTemplateSelector` overrides the method `SelectTemplate` from the base class `DataTemplateSelector`. The implementation selects the template based on the `Publisher` property from the `Book` class:

```
using System.Windows;
using System.Windows.Controls;
using Wrox.ProCSharp.WPF.Data;

namespace Wrox.ProCSharp.WPF.Utilities
{
    public class BookTemplateSelector : DataTemplateSelector
    {
        public override DataTemplate SelectTemplate(object item,
                                                    DependencyObject container)
        {
            if (item != null && item is Book)
            {
                var book = item as Book;
                switch (book.Publisher)
                {
                    case "Wrox Press":
                        return
                            (container as FrameworkElement).FindResource(
                                "wroxTemplate") as DataTemplate;
                    case "For Dummies":
                        return
                            (container as FrameworkElement).FindResource(
                                "dummiesTemplate") as DataTemplate;
                    default:
                        return
                            (container as FrameworkElement).FindResource(
                                "bookTemplate") as DataTemplate;
                }
            }
```

```
                return null;
            }
        }
    }
```

code snippet BooksDemo/Utilities/BookTemplateSelector.cs

For accessing the class `BookDataTemplateSelector` from XAML code, the class is defined within the `Window` resources:

```
          <src:BookDataTemplateSelector x:Key="bookTemplateSelector" />
```

code snippet BooksDemo/BooksUC.xaml

Now the selector class can be assigned to the `ItemTemplateSelector` property of the `ListBox`:

```
            <ListBox DockPanel.Dock="Left" ItemsSource="{Binding}" Margin="5"
                     MinWidth="120" IsSynchronizedWithCurrentItem="True"
                     ItemTemplateSelector="{StaticResource bookTemplateSelector}">
```

When running the application, you can see different data templates based on the publisher, as shown in Figure 36-9.

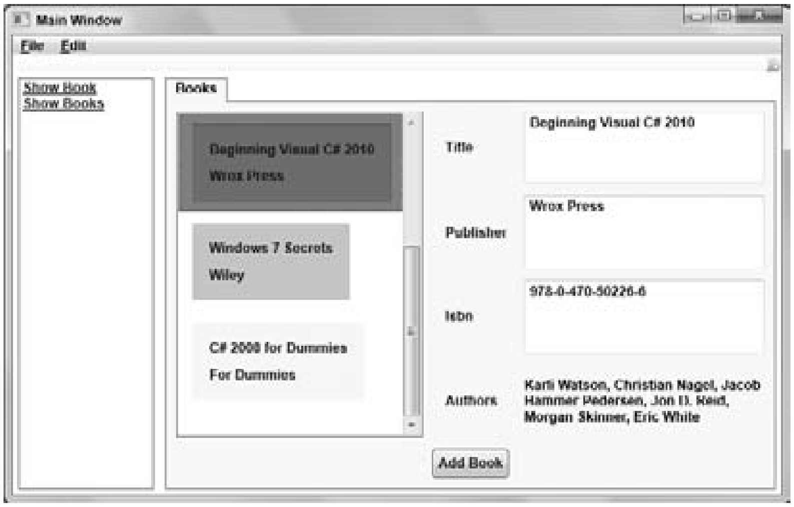

FIGURE 36-9

Binding to XML

WPF data binding has special support for binding to XML data. You can use `XmlDataProvider` as a data source and bind the elements by using XPath expressions. For a hierarchical display, you can use the `TreeView` control and create the view for the items by using the `HierarchicalDataTemplate`.

The following XML file containing `Book` elements is used as a source in the next examples:

```
    <?xml version="1.0" encoding="utf-8" ?>
    <Books>
      <Book isbn="978-0-470-12472-7">
        <Title>Professional C# 2008</Title>
        <Publisher>Wrox Press</Publisher>
        <Author>Christian Nagel</Author>
        <Author>Bill Evjen</Author>
        <Author>Jay Glynn</Author>
        <Author>Karli Watson</Author>
      <Author>Morgan Skinner</Author>
    </Book>
    <Book isbn="978-0-7645-4382-1">
      <Title>Beginning Visual C# 2008</Title>
      <Publisher>Wrox Press</Publisher>
      <Author>Karli Watson</Author>
      <Author>David Espinosa</Author>
      <Author>Zach Greenvoss</Author>
      <Author>Jacob Hammer Pedersen</Author>
      <Author>Christian Nagel</Author>
      <Author>John D. Reid</Author>
      <Author>Matthew Reynolds</Author>
      <Author>Morgan Skinner</Author>
      <Author>Eric White</Author>
    </Book>
  </Books>
```

code snippet XmlBindingDemo/Books.xml

Similarly to defining an object data provider, you can define an XML data provider. Both `ObjectDataProvider` and `XmlDataProvider` are derived from the same base class, `DataSourceProvider`. With the `XmlDataProvider` in the example, the `Source` property is set to reference the XML file `books.xml`. The `XPath` property defines an XPath expression to reference the XML root element `Books`. The `Grid` element references the XML data source with the `DataContext` property. With the data context for the grid, all `Book` elements are required for a list binding, so the XPath expression is set to `Book`. Inside the grid, you can find the `ListBox` element that binds to the default data context and uses the `DataTemplate` to include the title in `TextBlock` elements as items of the `ListBox`. Inside the grid, you can also see three `Label` elements with data binding set to XPath expressions to display the title, publisher, and ISBN numbers:

```
<Window x:Class="XmlBindingDemo.MainWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        Title="Main Window" Height="240" Width="500">
    <Window.Resources>
        <XmlDataProvider x:Key="books" Source="Books.xml" XPath="Books" />
        <DataTemplate x:Key="listTemplate">
            <TextBlock Text="{Binding XPath=Title}" />
        </DataTemplate>

        <Style x:Key="labelStyle" TargetType="{x:Type Label}">
            <Setter Property="Width" Value="190" />
            <Setter Property="Height" Value="40" />
            <Setter Property="Margin" Value="5" />
        </Style>
    </Window.Resources>

    <Grid DataContext="{Binding Source={StaticResource books}, XPath=Book}">
        <Grid.RowDefinitions>
            <RowDefinition />
            <RowDefinition />
            <RowDefinition />
            <RowDefinition />
        </Grid.RowDefinitions>
        <Grid.ColumnDefinitions>
            <ColumnDefinition />
            <ColumnDefinition />
        </Grid.ColumnDefinitions>
        <ListBox IsSynchronizedWithCurrentItem="True" Margin="5"
          Grid.Column="0" Grid.RowSpan="4" ItemsSource="{Binding}"
          ItemTemplate="{StaticResource listTemplate}" />

        <Label Style="{StaticResource labelStyle}" Content="{Binding XPath=Title}"
          Grid.Row="0" Grid.Column="1" />
        <Label Style="{StaticResource labelStyle}"
          Content="{Binding XPath=Publisher}"
          Grid.Row="1" Grid.Column="1" />
        <Label Style="{StaticResource labelStyle}"
          Content="{Binding XPath=@isbn}"
          Grid.Row="2" Grid.Column="1" />

    </Grid>
</Window>
```

code snippet BooksDemo/MainWindow.xaml

Figure 36-10 shows the result of the XML binding.

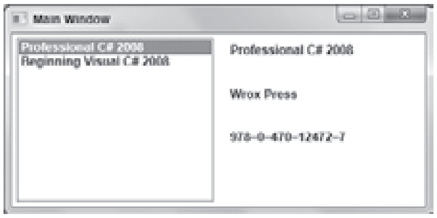

FIGURE 36-10

If XML data should be shown hierarchically, you can use the `TreeView` *control.*

Binding Validation

Several options are available to validate data from the user before it is used with the .NET objects. These options are:

- Handling exceptions
- Data error information
- Custom validation rules

Handling Exceptions

One of the options demonstrated here is that the .NET class throws an exception if an invalid value is set as shown in the class `SomeData`. The property `Value1` accepts only values larger or equal to 5 and smaller than 12:

```
public class SomeData
{
   private int value1;
   public int Value1 {
      get
      {
         return value1;
      }
      set
      {
         if (value < 5 || value > 12)
            throw new ArgumentException(
                  "value must not be less than 5 or greater than 12");
         value1 = value;
      }
   }
}
```

code snippet ValidationDemo/SomeData.cs

In the constructor of the `MainWindow` class, a new object of the class `SomeData` is initialized and passed to the `DataContext` for data binding:

```
public partial class MainWindow: Window
{
   private SomeData p1 = new SomeData { Value1 = 11 };

   public MainWindow()
   {
      InitializeComponent();
      this.DataContext = p1;

   }
```

code snippet ValidationDemo/MainWindow.xaml.cs

The event handler method `OnShowValue` displays a message box to show the actual value of the `SomeData` instance:

```
   private void OnShowValue(object sender, RoutedEventArgs e)
   {
      MessageBox.Show(p1.Value1.ToString());
   }
}
```

With simple data binding, here the `Text` property of a `TextBox` is bound to the `Value1` property. If you run the application now and try to change the value to one that is not valid, you can verify that the value never changed by clicking the Submit button. WPF catches and ignores the exception thrown by the set accessor of the property `Value1`:

```
<Label Margin="5" Grid.Row="0" Grid.Column="0" >Value1:</Label>
<TextBox Margin="5" Grid.Row="0" Grid.Column="1"
      Text="{Binding Path=Value1}" />
```

code snippet ValidationDemo/MainWindow.xaml

To display an error as soon as the context of the input field changes, you can set the `ValidatesOnException` property of the `Binding` markup extension to `True`. With an invalid value (as soon as the exception is thrown when the value should be set), the `TextBox` is surrounded by a red line, as shown in Figure 36-11.

```
<Label Margin="5" Grid.Row="0" Grid.Column="0" >Value1:</Label>
<TextBox Margin="5" Grid.Row="0" Grid.Column="1"
      Text="{Binding Path=Value1, ValidatesOnExceptions=True}" />
```

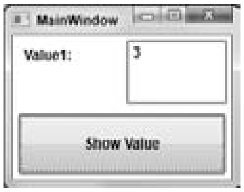

FIGURE 36-11

To return the error information in a different way to the user, you can assign the attached property `ErrorTemplate` that is defined by the `Validation` class to a template defining the UI for errors. The new template to mark the error is shown here with the key `validationTemplate`. The `ControlTemplate` puts a red exclamation point in front of the existing control content:

```
<ControlTemplate x:Key="validationTemplate">
   <DockPanel>
      <TextBlock Foreground="Red" FontSize="20">!</TextBlock>
      <AdornedElementPlaceholder/>
   </DockPanel>
</ControlTemplate>
```

Setting the `validationTemplate` with the `Validation.ErrorTemplate` attached property activates the template with the `TextBox`:

```
<Label Margin="5" Grid.Row="0" Grid.Column="0" >Value1:</Label>
<TextBox Margin="5" Grid.Row="0" Grid.Column="1"
      Text="{Binding Path=Value1, ValidatesOnExceptions=True}"
      Validation.ErrorTemplate="{StaticResource
validationTemplate}" />
```

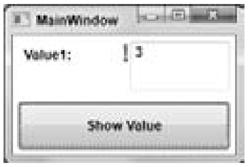

FIGURE 36-12

The new look of the application is shown in Figure 36-12.

Another option for a custom error message is to register to the `Error` *event of the* `Validation` *class. Here the property* `NotifyOnValidationError` *must be set to true.*

The error information itself can be accessed from the `Errors` collection of the `Validation` class. To display the error information in the `ToolTip` of the `TextBox` you can create a property trigger as shown. The trigger is activated as soon as the `HasError` property of the `Validation` class is set to `True`. The trigger sets the `ToolTip` property of the `TextBox`:

```
<Style TargetType="{x:Type TextBox}">
   <Style.Triggers>
      <Trigger Property="Validation.HasError" Value="True">
         <Setter Property="ToolTip"
               Value="{Binding RelativeSource=
                     {x:Static RelativeSource.Self},
               Path=(Validation.Errors)[0].ErrorContent}" />
      </Trigger>
   </Style.Triggers>
</Style>
```

Data Error Information

Another way to deal with errors is if the .NET object implements the interface `IDataErrorInfo`.

The class `SomeData` is now changed to implement the interface `IDataErrorInfo`. This interface defines the property `Error` and an indexer with a string argument. With WPF validation during data binding, the indexer is called and the name of the property to validate is passed as the `columnName` argument. With the implementation the value is verified if it is valid, and an error string is passed otherwise. Here the validation is done on the property `Value2` that is implemented by using the C# 3.0 simple property notation:

```
public class SomeData: IDataErrorInfo
{
   //...

   public int Value2 { get; set; }

   string IDataErrorInfo.Error
   {
      get
      {
         return null;
      }
   }

   string IDataErrorInfo.this[string columnName]
   {
      get
      {
         if (columnName == "Value2")
         {
            if (this.Value2 < 0 || this.Value2 > 80)
               return "age must not be less than 0 or greater than 80";

         }
         return null;
      }
   }
}
```

code snippet ValidationDemo/SomeData.cs

If you set the property `ValidatesOnDataErrors` of the `Binding` class to `true`, the interface `IDataErrorInfo` is used during binding. Here, when the `TextBox` is changed, the binding mechanism invokes the indexer of the interface and passes `Value2` to the `columnName` variable:

```
<Label Margin="5" Grid.Row="1" Grid.Column="0" >Value2:</Label>
<TextBox Margin="5" Grid.Row="1" Grid.Column="1"
      Text="{Binding Path=Value2, ValidatesOnDataErrors=True}" />
```

code snippet ValidationDemo/MainWindow.xaml

Custom Validation Rules

To get more control of the validation you can implement a custom validation rule. A class implementing a custom validation rule needs to derive from the base class `ValidationRule`. With the previous two examples, validation rules have been used as well. Two classes that derive from the abstract base class `ValidationRule` are `DataErrorValidationRule` and `ExceptionValidationRule`. `DataErrorValidationRule` is activated by setting the property `ValidatesOnDataErrors` and uses the interface `IDataErrorInfo`; `ExceptionValidationRule` deals with exceptions and is activated by setting the property `ValidatesOnException`.

Here a validation rule is implemented to verify for a regular expression. The class `RegularExpressionValidationRule` derives from the base class `ValidationRule` and overrides the abstract method `Validate()` that is defined by the base class. With the implementation, the `RegEx` class from the namespace `System.Text.RegularExpressions` is used to validate the expression defined by the `Expression` property:

```
public class RegularExpressionValidationRule: ValidationRule
{
   public string Expression { get; set; }
   public string ErrorMessage { get; set; }

   public override ValidationResult Validate(object value,
         CultureInfo cultureInfo)
   {
      ValidationResult result = null;
      if (value != null)
      {
         Regex regEx = new Regex(Expression);
         bool isMatch = regEx.IsMatch(value.ToString());
         result = new ValidationResult(isMatch, isMatch ?
               null: ErrorMessage);
      }
      return result;
   }
}
```

Instead of using the Binding markup extension, now the binding is done as a child of the TextBox.Text element. The bound object now defines an Email property that is implemented with the simple property syntax. The UpdateSourceTrigger property defines when the source should be updated. Possible options for updating the source are:

- When the property value changes — which is every character typed by the user
- When the focus is lost
- Explicitly

ValidationRules is a property of the Binding class that contains ValidationRule elements. Here the validation rule used is the custom class RegularExpressionValidationRule, where the Expression property is set to a regular expression that verifies if the input is a valid e-mail, and the ErrorMessage property that gives the error message in case the data entered to the TextBox is not valid:

```
<Label Margin="5" Grid.Row="2" Grid.Column="0">Email:</Label>
<TextBox Margin="5" Grid.Row="2" Grid.Column="1">
   <TextBox.Text>
      <Binding Path="Email" UpdateSourceTrigger="LostFocus">
         <Binding.ValidationRules>
            <src:RegularExpressionValidationRule
                  Expression="^([\w-\.]+)@((\[[0-9]{1,3}\.[0-9]{1,3}\.
                              [0-9]{1,3}\.)|(([\w-]+\.)+))([a-zA-Z]{2,4}|
                             [0-9]{1,3})(\]?)$"
                  ErrorMessage="Email is not valid" />
         </Binding.ValidationRules>
      </Binding>
   </TextBox.Text>
</TextBox>
```

COMMANDING

Commanding is a concept of WPF that creates a loose coupling between the source of an action (for example, a button) and the target that does the work (for example, a handler method). Events are strongly coupled (at least with XAML 2006). Compiling the XAML code that includes references to events requires that the code-behind have a handler implemented and available at compile time. With commands, the coupling is loose.

The action that is executed is defined by a command object. Commands implement the interface ICommand. Command classes that are used by WPF are RoutedCommand and a class that derives from it, RoutedUICommand. RoutedUICommand defines an additional text for the user interface that is not defined by ICommand. ICommand defines the methods Execute() and CanExecute(), which are executed on a target object.

The command source is an object that invokes the command. Command sources implement the interface ICommandSource. Examples of such command sources are button classes that derive from ButtonBase, Hyperlink, and InputBinding. KeyBinding and MouseBinding are examples of InputBinding derived classes. Command sources have a Command property where a command object implementing ICommand can be assigned. This fires the command when the control is used, such as with the click of a button.

The command target is an object that implements a handler to perform the action. With command binding, a mapping is defined to map the handler to a command. Command bindings define what handler is invoked on a command. Command bindings are defined by the CommandBinding property that is implemented in the UIElement class. Thus every class that derives from UIElement has the CommandBinding property. This makes the finding of the mapped handler a hierarchical process. For example, a button that is defined within a StackPanel that is inside a ListBox — which itself is inside a Grid — can fire a command. The handler is specified with command bindings somewhere up the tree — such as with command bindings of a Window.

Let's change the implementation of the BooksDemo project to use commands instead of the event model.

Defining Commands

.NET 4 gives you classes that return predefined commands. The `ApplicationCommands` class defines the static properties `New`, `Open`, `Close`, `Print`, `Cut`, `Copy`, `Paste`, and others. These properties return `RoutedUICommand` objects that can be used for a specific purpose. Other classes offering commands are `NavigationCommands` and `MediaCommands`. `NavigationCommands` gives you commands that are common for navigation such as `GoToPage`, `NextPage`, and `PreviousPage`. `MediaCommands` are useful for running a media player with `Play`, `Pause`, `Stop`, `Rewind`, and `Record`.

It's not hard to define custom commands that fulfill application domain–specific actions. For this, the `BooksCommands` class is created that returns a `RoutedUICommand` with the `ShowBooks` property. You can also assign an input gesture to a command, such as `KeyGesture` or `MouseGesture`. Here, a `KeyGesture` is assigned that defines the key B with the ALT modifier. An input gesture is a command source, so clicking the ALT-B key invokes the command:

```
public static class BooksCommands
{
    private static RoutedUICommand showBooks;
    public static ICommand ShowBooks
    {
        get
        {
            if (showBooks == null)
            {
                showBooks = new RoutedUICommand("Show Books", "ShowBooks",
                                                typeof(BooksCommands));
                showBook.InputGestures.Add(
                        new KeyGesture(Key.B, ModifierKeys.Alt));
            }
            return showBooks;
        }
    }
```

code snippet BooksDemo/BooksCommands.cs

Defining Command Sources

Every class that implements the `ICommandSource` interface can be a source of commands, such as `Button` and `MenuItem`. Inside the main window a `Menu` control is added as a child of the `DockPanel`. `MenuItem` elements are contained within the `Menu` control and the `Command` property is assigned to some predefined commands such as `ApplicationCommands.Close`, and the custom command `BooksCommands.ShowBooks`:

```
<DockPanel>
    <Menu DockPanel.Dock="Top">
        <MenuItem Header="_File">
            <MenuItem Header="_Show Books"
                      Command="local:BooksCommands.ShowBooks" />
            <Separator />
            <MenuItem Header="Exit" Command="ApplicationCommands.Close" />
        </MenuItem>
        <MenuItem Header="_Edit">
            <MenuItem Header="Undo" Command="ApplicationCommands.Undo" />
            <Separator />
            <MenuItem Header="Cut" Command="ApplicationCommands.Cut" />
            <MenuItem Header="Copy" Command="ApplicationCommands.Copy" />
            <MenuItem Header="Paste" Command="ApplicationCommands.Paste" />
        </MenuItem>
    </Menu>
```

code snippet BooksDemo/MainWindow.xaml

Command Bindings

Command bindings need to be added to connect them to handler methods. Here, the command bindings are defined within the `Window` element so these bindings are available to all elements within the window. When the command `ApplicationCommands.Close` is executed, the `OnClose()` method gets invoked. When the command `BooksCommands.ShowBooks` is executed, the `OnShowBooks()` method gets called:

```
<Window.CommandBindings>
    <CommandBinding Command="ApplicationCommands.Close" Executed="OnClose" />
    <CommandBinding Command="local:BooksCommands.ShowBooks"
                   Executed="OnShowBooks" />
</Window.CommandBindings>
```

code snippet BooksDemo/MainWindow.xaml

With command binding you can also specify the `CanExecute` property, where a method is invoked to verify whether the command is available. For example, if a file is not changed, the `ApplicationCommands.Save` command could be unavailable.

The handler needs to be defined with an object parameter, for the sender, and `ExecutedRoutedEventArgs`, where information about the command can be accessed:

```
private void OnClose(object sender, ExecutedRoutedEventArgs e)
{
    Application.Current.Shutdown();
}
```

code snippet BooksDemo/MainWindow.xaml.cs

You can also pass parameters with a command. You can do this by specifying the `CommandParameter` *property with a command source, such as the* `MenuItem`*. You can access the parameter with the* `Parameter` *property of* `ExecutedRoutedEventArgs`*.*

Command bindings can also be defined by controls. The `TextBox` control defines bindings for `ApplicationCommands.Cut`, `ApplicationCommands.Copy`, `ApplicationCommands.Paste`, and `ApplicationCommands.Undo`. This way you only need to specify the command source and use the existing functionality within the `TextBox` control.

TREEVIEW

The `TreeView` control is a control to display hierarchical data. Binding to a `TreeView` is very similar to the binding you've seen with the `ListBox`. What's different is the hierarchical data display — a `HierarchicalDataTemplate` can be used.

The next example uses hierarchical displays and the new `DataGrid` control. The `Formula1` sample database is accessed with the ADO.NET Entity Framework. The mapping used is shown in Figure 36-13. The `Race` class contains information about the date of the race and is associated with the `Circuit` class. The `Circuit` class has information about the `Country` and the name of the race circuit. `Race` also has an association with `RaceResult`. A `RaceResult` contains information about the `Racer` and the `Team`.

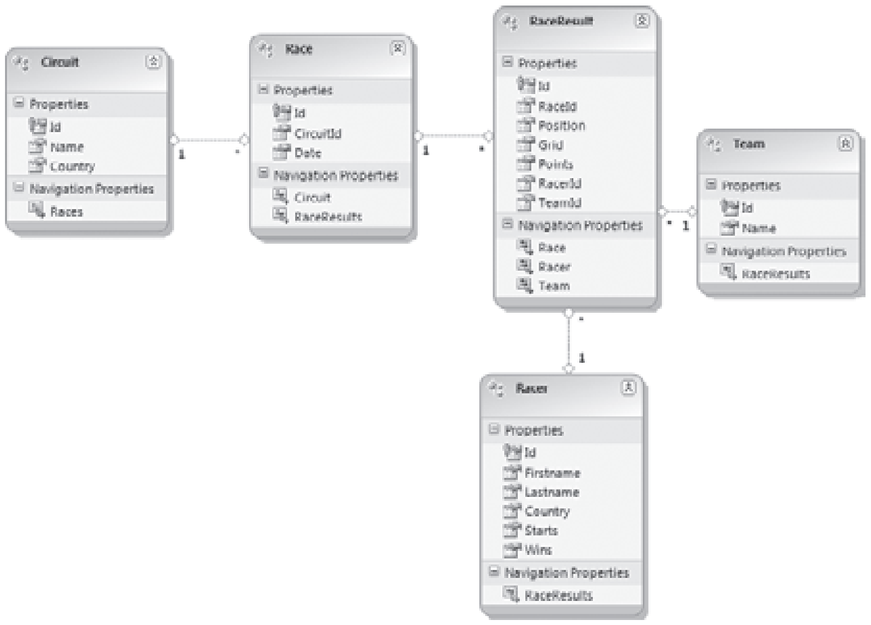

FIGURE 36-13

The ADO.NET Entity Framework is covered in Chapter 31, “ADO.NET Entity Framework.”

With the XAML code a `TreeView` is declared. `TreeView` derives from the base class `ItemsControl` where binding to a list can be done with the `ItemsSource` property. `ItemsSource` is bound to the data context. The data context is assigned in the code-behind, as you will see next. Of course, this could also be done with an `ObjectDataProvider`. To define a custom display for the hierarchical data, `HierarchicalDataTemplate` elements are defined. The data templates here are defined for specific data types with the `DataType` property. The first `HierarchicalDataTemplate` is the template for the `Championship` class and binds the `Year` property of this class to the `Text` property of a `TextBlock`. The `ItemsSource` property defines the binding for the data template itself to define the next level in the data hierarchy. If the `Races` property of the `Championship` class returns a collection, you bind the `ItemsSource` property directly to `Races`. However, because this property returns a `Lazy<T>` object, binding is done to `Races.Value`. The advantages of the `Lazy<T>` class are discussed later in this chapter.

The second `HierarchicalDataTemplate` element defines the template for the `F1Race` class and binds the `Country` and `Date` properties of this class. With the `Date` property a `StringFormat` is defined with the binding. The next level of the hierarchy is defined binding the `ItemsSource` to `Results.Value`.

The class `F1RaceResult` doesn’t have a children collection, so the hierarchy stops here. For this data type, a normal `DataTemplate` is defined to bind `Position`, `Racer`, and `Car` properties:

```
<UserControl x:Class="Formula1Demo.TreeUC"
             xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
             xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
             xmlns:mc="http://schemas.openxmlformats.org/markup-compatibility/2006"
             xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
             xmlns:local="clr-namespace:Formula1Demo"
             mc:Ignorable="d"
             d:DesignHeight="300" d:DesignWidth="300">
    <Grid>
        <TreeView ItemsSource="{Binding}" >
            <TreeView.Resources>
                <HierarchicalDataTemplate DataType="{x:Type local:Championship}"
                                          ItemsSource="{Binding Races.Value}">
                    <TextBlock Text="{Binding Year}" />
                </HierarchicalDataTemplate>

                <HierarchicalDataTemplate DataType="{x:Type local:F1Race}"
                                          ItemsSource="{Binding Results.Value}">
                    <StackPanel Orientation="Horizontal">
                        <TextBlock Text="{Binding Country}" Margin="5,0,5,0" />
                        <TextBlock Text="{Binding Path=Date, StringFormat=d }"
                                          Margin="5,0,5,0" />
                    </StackPanel>
                </HierarchicalDataTemplate>

                <DataTemplate DataType="{x:Type local:F1RaceResult}">
                    <StackPanel Orientation="Horizontal">
                        <TextBlock Text="{Binding Position}" Margin="5,0,5,0" />
                        <TextBlock Text="{Binding Racer}" Margin="5,0,0,0" />
                        <TextBlock Text=", " />
                        <TextBlock Text="{Binding Car}" />
                    </StackPanel>
                </DataTemplate>
            </TreeView.Resources>
        </TreeView>
    </Grid>
</UserControl>
```

code snippet Formula1Demo/TreeUC.xaml

Now for the code that fills the hierarchical control. In the code-behind file of the XAML code, `DataContext` is assigned to the `Years` property. The `Years` property uses a LINQ query, instead of the ADO.NET Entity Framework data context, to get all the years of the Formula-1 races in the database and to create a new `Championship` object for every year. With the instance of the `Championship` class, the `Year` property is set. This class also has a `Races` property to return the races of the year; however, this information is not yet filled in.

```
using System.Collections.Generic;
using System.Linq;
using System.Windows.Controls;

namespace Formula1Demo
{
    public partial class TreeUC : UserControl
    {
        private Formula1Entities data = new Formula1Entities();

        public TreeUC()
        {
            InitializeComponent();
            this.DataContext = Years;
        }
```

```
            public IEnumerable<Championship> Years
            {
                get
                {
                    F1DataContext.Data = data;
                    return (from r in data.Races
                            orderby r.Date ascending
                            select
                            new Championship
                            {
                                Year = r.Date.Year,
                            }).Distinct();
                }
            }
        }
    }
```

code snippet Formula1Demo/TreeUC.xaml.cs

The `Championship` class has a simple automatic property for the year. The `Races` property is of type `Lazy<IEnumerable<F1Race>>`. The `Lazy<T>` class is new with .NET 4 for lazy initialization. With a `TreeView` control, this class comes in very handy. If the data behind the tree is large and you do not want to load the full tree in advance, but only when a user makes a selection, lazy loading can be done. With the constructor of the `Lazy<T>` class, a delegate `Func<IEnumerable<F1Race>>` is used. With this delegate, `IEnumerable<F1Race>` needs to be returned. The implementation of the Lambda expression, assigned to the delegate, uses a LINQ query to create a list of `F1Race` objects that have the `Date` and `Country` property assigned:

```
        public class Championship
        {
            public int Year { get; set; }
            public Lazy<IEnumerable<F1Race>> Races
            {
                get
                {
                    return new Lazy<IEnumerable<F1Race>>(() =>
                    {
                        return from r in F1DataContext.Data.Races
                               where r.Date.Year == Year
                               orderby r.Date
                               select new F1Race
                               {
                                   Date = r.Date,
                                   Country = r.Circuit.Country
                               };
                    });
                }
            }
        }
```

code snippet Formula1Demo/Championship.cs

The `F1Race` class again defines the `Results` property that uses the `Lazy<T>` type to return a list of `F1RaceResult` objects:

```
        public class F1Race
        {
            public string Country { get; set; }
            public DateTime Date { get; set; }
            public Lazy<IEnumerable<F1RaceResult>> Results
            {
                get
                {
                    return new Lazy<IEnumerable<F1RaceResult>>(() =>
                    {
                        return from rr in F1DataContext.Data.RaceResults
                               where rr.Race.Date == this.Date
                               select new F1RaceResult
                               {
                                   Position = rr.Position,
                                   Racer = rr.Racer.Firstname + " " +
                                           rr.Racer.Lastname,
                                   Car = rr.Team.Name
                               };
                    });
                }
            }

        }
```

code snippet Formula1Demo/F1Race.cs

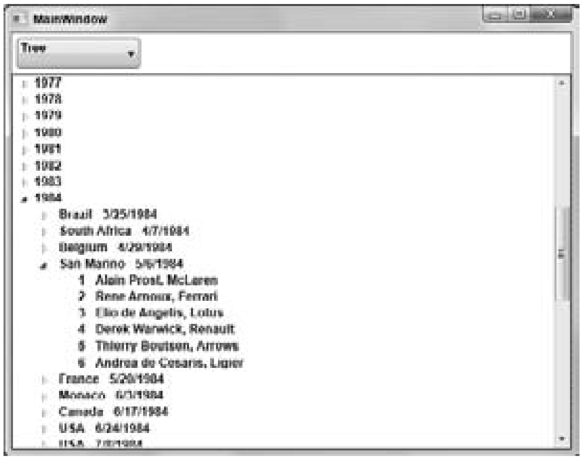
The final class of the hierarchy is `F1RaceResult`, which is a simple data holder for `Position`, `Racer`, and `Car`:

```
        public class F1RaceResult
        {
            public int Position { get; set; }
            public string Racer { get; set; }
            public string Car { get; set; }
        }
```

code snippet Formula1Demo/Championship.cs

When you run the application, you can see at first all the years of the championships in the tree view. Because of binding, the next level is already accessed — every `Championship` object already has the `F1Race` objects associated. The user doesn't need to wait for the first level after the year or an open year with the default look of a small triangle. As you can see in Figure 36-14, the year 1984 is open. As soon as the user clicks on a year to see the second-level binding, the third level is done and the race results are retrieved.

Of course you can also customize the `TreeView` control and define different styles for the complete template or the items in the view.



```
1977
1978
1979
1980
1981
1982
1983
1984
    Brazil   3/25/1984
    South Africa   4/7/1984
    Belgium   4/29/1984
    San Marino   5/6/1984
        1   Alain Prost, McLaren
        2   Rene Arnoux, Ferrari
        3   Elio de Angelis, Lotus
        4   Derek Warwick, Renault
        5   Thierry Boutsen, Arrows
        6   Andrea de Cesaris, Ligier
    France   5/20/1984
    Monaco   6/3/1984
    Canada   6/17/1984
    USA   6/24/1984
    USA   7/8/1984
```

FIGURE 36-14

DATAGRID

Prior to .NET 4, a `DataGrid` control was missing with WPF. Now it's here! With the `DataGrid` control, information is displayed within rows and columns, and can also be edited.

The `DataGrid` control is an `ItemsControl` and defines the `ItemsSource` property that is bound to a collection. The XAML code of this user interface also defines two `RepeatButton` controls that are used for paging functionality. Instead of loading all the race information at once, paging is used so users can step through pages. In a simple scenario, only the `ItemsSource` property of the `DataGrid` needs to be assigned. By default, the `DataGrid` creates columns based on the properties of the bound data:

```
<UserControl x:Class="Formula1Demo.GridUC"
             xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
             xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
             xmlns:mc="http://schemas.openxmlformats.org/markup-compatibility/2006"
             xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
             mc:Ignorable="d"
             d:DesignHeight="300" d:DesignWidth="300">
    <Grid>
        <Grid.RowDefinitions>
            <RepeatButton Margin="5" Click="OnPrevious">Previous</RepeatButton>
            <RepeatButton Margin="5" Click="OnNext">Next</RepeatButton>
        </Grid.RowDefinitions>
        <StackPanel Orientation="Horizontal" Grid.Row="0">
            <Button Click="OnPrevious">Previous</Button>
            <Button Click="OnNext">Next</Button>
        </StackPanel>
        <DataGrid Grid.Row="1" ItemsSource="{Binding}" />
    </Grid>
</UserControl>
```

code snippet Formula1Demo/GridUC.xaml

The code-behind uses the same `Formula1` database as the previous `TreeView` example. The `DataContext` of the `UserControl` is set to the `Races` property. This property returns `IEnumerable<object>`. Instead of assigning a strongly typed enumeration, an `object` is used to make it possible to create an anonymous class with the LINQ query. The LINQ query creates the anonymous class with `Year`, `Country`, `Position`, `Racer`, and `Car` properties and uses a compound to access `Races` and `RaceResults`. It also accesses other associations of `Races` to get country, racer, and team information. With the `Skip()` and `Take()` methods, paging functionality is implemented. The size of a page is fixed to 50 items, and the current page changes with the `OnNext()` and `OnPrevious()` handlers:

```
using System.Collections.Generic;
using System.Linq;
using System.Windows;
using System.Windows.Controls;

namespace Formula1Demo
{
    public partial class GridUC : UserControl
    {
        private int currentPage = 0;
        private int pageSize = 50;
        private Formula1Entities data = new Formula1Entities();
        public GridUC()
        {
            InitializeComponent();
            this.DataContext = Races;
        }

        public IEnumerable<object> Races
        {
            get
            {
                return (from r in data.Races
                        from rr in r.RaceResults
                        orderby r.Date ascending
                        select new
                        {
                            Year = r.Date.Year,
                                    Country = r.Circuit.Country,
                                    Position = rr.Position,
                                    Racer = rr.Racer.Firstname + " " + rr.Racer.Lastname,
                                    Car = rr.Team.Name
                                }).Skip(currentPage * pageSize).Take(pageSize);
            }
        }

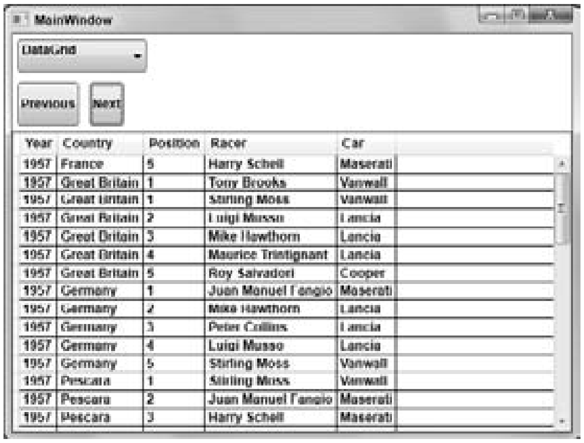
        private void OnPrevious(object sender, RoutedEventArgs e)
        {
            if (currentPage > 0)
            {
                currentPage--;
                this.DataContext = Races;
            }
        }

        private void OnNext(object sender, RoutedEventArgs e)
        {
            currentPage++;
            this.DataContext = Races;
        }
    }
}
```

code snippet Formula1Demo/GridUC.xaml.cs

Figure 36-15 shows the running application with the default grid styles and headers.

In the next DataGrid example, the grid is customized with custom columns and grouping.



Year	Country	Position	Racer	Car
1957	France	5	Harry Schell	Maserati
1957	Great Britain	1	Tony Brooks	Vanwall
1957	Great Britain	1	Stirling Moss	Vanwall
1957	Great Britain	2	Luigi Musso	Lancia
1957	Great Britain	3	Mike Hawthorn	Lancia
1957	Great Britain	4	Maurice Trintignant	Lancia
1957	Great Britain	5	Roy Salvadori	Cooper
1957	Germany	1	Juan Manuel Fangio	Maserati
1957	Germany	2	Mike Hawthorn	Lancia
1957	Germany	3	Peter Collins	Lancia
1957	Germany	4	Luigi Musso	Lancia
1957	Germany	5	Stirling Moss	Vanwall
1957	Pescara	1	Stirling Moss	Vanwall
1957	Pescara	2	Juan Manuel Fangio	Maserati
1957	Pescara	3	Harry Schell	Maserati

FIGURE 36-15

Custom Columns

Setting the property AutoGenerateColumns of the DataGrid to False doesn't generate default columns. You can create custom columns with the Columns property. You can also specify elements that derive from DataGridColumn. Predefined classes exist that can be used. DataGridTextColumn can be used to read and edit text. DataGridHyperlinkColumn is for displaying hyperlinks. DataGridCheckBoxColumn displays a check box for Boolean data. For a list of items in a column you can use the DataGridComboBoxColumn. More DataGridColumn types will be available in the future, but if you need a different representation now, you can use the DataGridTemplateColumn to define and bind any elements you want.

The example code uses DataGridTextColumn elements that are bound to the Position and Racer properties. The Header property is set to a string for display. Of course you can also use a template to define a complete custom header for the column:

```
                <DataGrid ItemsSource="{Binding}" AutoGenerateColumns="False">
                    <DataGrid.Columns>
                        <DataGridTextColumn Binding="{Binding Position, Mode=OneWay}"
```

```
                                    Header="Position" />
                <DataGridTextColumn Binding="{Binding Racer, Mode=OneWay}"
                                    Header="Racer" />
            </DataGrid.Columns>
```

code snippet Formula1Demo/GridUC.xaml.cs

Row Details

When a row is selected, the `DataGrid` can display additional information for the row. This is done by specifying a `RowDetailsTemplate` with the `DataGrid`. A `DataTemplate` is assigned to the `RowDetailsTemplate` which contains several `TextBlock` elements that display the car and points:

```
            <DataGrid.RowDetailsTemplate>
                <DataTemplate>
                    <StackPanel Orientation="Horizontal">
                        <TextBlock Text="Car:" Margin="5,0,0,0" />
                        <TextBlock Text="{Binding Car}" Margin="5,0,0,0" />
                        <TextBlock Text="Points:" Margin="5,0,0,0" />
                        <TextBlock Text="{Binding Points}" />
                    </StackPanel>
                </DataTemplate>
            </DataGrid.RowDetailsTemplate>
```

code snippet Formula1Demo/GridUC.xaml.cs

Grouping with the DataGrid

The Formula-1 races have several rows that contain the same information, such as the year and the country. For such data, grouping can be helpful to organize the information for the user.

For grouping, the `CollectionViewSource` can be used in XAML code that supports grouping, sorting, and filtering. With code-behind you can also use the `ListCollectionView` class, which is used only by the `CollectionViewSource`.

`CollectionViewSource` is defined within a `Resources` collection. The source of `CollectionViewSource` is the result from an `ObjectDataProvider`. The `ObjectDataProvider` invokes the `GetRaces()` method of the `F1Races` type. This method has two `int` parameters that are assigned from the `MethodParameters` collection. The `CollectionViewSource` uses two descriptions for grouping, first by the `Year` property and then by the `Country` property:

```
    <Grid.Resources>
        <ObjectDataProvider x:Key="races" ObjectType="{x:Type local:F1Races}"
                            MethodName="GetRaces">
            <ObjectDataProvider.MethodParameters>
                <sys:Int32>0</sys:Int32>
                <sys:Int32>20</sys:Int32>
            </ObjectDataProvider.MethodParameters>
        </ObjectDataProvider>
        <CollectionViewSource x:Key="viewSource"
                              Source="{StaticResource races}">
            <CollectionViewSource.GroupDescriptions>
                <PropertyGroupDescription PropertyName="Year" />
                <PropertyGroupDescription PropertyName="Country" />
            </CollectionViewSource.GroupDescriptions>
        </CollectionViewSource>
    </Grid.Resources>
```

code snippet Formula1Demo/GridGroupingUC.xaml

How the group is displayed is defined with the DataGrid GroupStyle property. With the GroupStyle element you need to customize the ContainerStyle as well as the HeaderTemplate and the complete panel. To dynamically select the GroupStyle and HeaderStyle, you can also write a container style selector and a header template selector. It is very similar in functionality to the data template selector you've seen earlier.

The GroupStyle in the example sets the ContainerStyle property of the GroupStyle. With this style the GroupItem is customized with a template. The GroupItem appears as the root element of a group when grouping is used. Displayed within the group is the name, using the Name property, and the number of items, using the ItemCount property. The third column of the Grid contains all the normal items using the ItemsPresenter. If the rows are grouped by country, the labels of the Name property would all have a different width, which doesn't look good. Therefore, the SharedSizeGroup property is set with the second column of the grid to make all items the same size. The shared size scope needs to be set with all elements that have the same size. This is done in the DataGrid setting Grid.IsSharedSizeScope="True":

```
<DataGrid.GroupStyle>
    <GroupStyle>
        <GroupStyle.ContainerStyle>
            <Style TargetType="{x:Type GroupItem}">
                <Setter Property="Template">
                    <Setter.Value>
                        <ControlTemplate >
                            <StackPanel Orientation="Horizontal" >
                                <Grid>
                                    <Grid.ColumnDefinitions>
                                        <ColumnDefinition
                                        SharedSizeGroup="LeftColumn"
                                      />
                                        <ColumnDefinition />
                                        <ColumnDefinition />
                                    </Grid.ColumnDefinitions>
                                    <Label Grid.Column="0"
                                      Background="Yellow"
                                      Content="{Binding Name}" />
                                    <Label Grid.Column="1"
                                      Content="{Binding ItemCount}"
                                    />
                                    <Grid Grid.Column="2"
                                      HorizontalAlignment="Center"
                                      VerticalAlignment="Center">
                                        <ItemsPresenter/>
                                    </Grid>
                                </Grid>
                            </StackPanel>
                        </ControlTemplate>
                    </Setter.Value>
                </Setter>
            </Style>
        </GroupStyle.ContainerStyle>
    </GroupStyle>
</DataGrid.GroupStyle>
```

The class F1Races that is used by the ObjectDataProvider uses LINQ to access the Formula1 database and returns a list of anonymous types with Year, Country, Position, Racer, Car, and Points properties. Again, the Skip() and Take() methods are used to access part of the data:

```
using System.Collections.Generic;
using System.Linq;

namespace Formula1Demo
```

```
{
    public class F1Races
    {
        private int lastpageSearched = -1;
        private IEnumerable<object> cache = null;
        private Formula1Entities data = new Formula1Entities();

        public IEnumerable<object> GetRaces(int page, int pageSize)
        {
            if (lastpageSearched == page)
                return cache;
            lastpageSearched = page;

            var q = (from r in data.Races
                     from rr in r.RaceResults
                     orderby r.Date ascending
                     select new
                     {
                         Year = r.Date.Year,
                         Country = r.Circuit.Country,
                         Position = rr.Position,
                         Racer = rr.Racer.Firstname + " " + rr.Racer.Lastname,
                         Car = rr.Team.Name,
                         Points = rr.Points
                     }).Skip(page * pageSize).Take(pageSize);
            cache = q;
            return cache;
        }
    }
}
```

code snippet Formula1Demo/F1Races.cs

Now all that's left is for the user to set the page number and change the parameter of the `ObjectDataProvider`. In the user interface a `TextBox` and a `Button` are defined:

```
<StackPanel Orientation="Horizontal" Grid.Row="0">
    <TextBlock Margin="5" Padding="4"
               VerticalAlignment="Center">Page:</TextBlock>
    <TextBox Margin="5" Padding="4" VerticalAlignment="Center"
             x:Name="textPageNumber" Text="0" />
    <Button Click="OnGetPage">Get Page</Button>
</StackPanel>
```

code snippet Formula1Demo/GridGroupingUC.xaml

The `OnGetPage()` handler of the button in the code-behind accesses the `ObjectDataProvider` and changes the first parameter of the method. It then invokes the `Refresh` method so the `ObjectDataProvider` requests the new page:

```
private void OnGetPage(object sender, RoutedEventArgs e)
{
    int page = int.Parse(textPageNumber.Text);
    var odp = (sender as FrameworkElement).FindResource("races")
                  as ObjectDataProvider;
    odp.MethodParameters[0] = page;
    odp.Refresh();
}
```

code snippet Formula1Demo/GridGroupingUC.xaml.cs

After running the application you can see grouping and row detail information, as shown in Figure 36-16.

FIGURE 36-16

SUMMARY

This chapter covered some features of WPF that are extremely important for business applications.

WPF data binding gives a leap forward. You can bind any property of a .NET class to a property of a WPF element. The binding mode defines the direction of the binding. You can bind .NET objects and lists, and define a data template to create a default look for a .NET class with a data template.

Command binding makes it possible to map handler code to menus and toolbars. You've also seen how easy it is to copy and paste with WPF because a command handler for this technology is already included in the `TextBox` control.

The next chapter goes into another facet of WPF: documents with WPF.

37

Creating Documents with WPF

WHAT'S IN THIS CHAPTER?

- ➤ Creating flow documents
- ➤ Creating fixed documents
- ➤ Creating XPS documents
- ➤ Printing documents

Creating documents is a large part of WPF. The namespace `System.Windows.Documents` supports creating flow and fixed documents. This namespace contains elements with which you can have a rich Word-like experience with flow documents, and create WYSIWYG fixed documents.

Flow documents are geared towards screen reading; the content of the document is arranged based on the size of the window, and the flow of the document changes if the window is resized. *Fixed documents* are mainly used for printing and page-oriented content and the content is always arranged in the same way.

This chapter teaches you how to create and print flow and fixed documents, and covers the namespaces `System.Windows.Documents`, `System.Windows.Xps` and `System.IO.Packaging`.

TEXT ELEMENTS

To build the content of documents, you need document elements. The base class of these elements is `TextElement`. This class defines common properties for font settings, foreground and background, and text effects. `TextElement` is the base class for the classes `Block` and `Inline` whose functionality is explored in the following sections.

Fonts

An important aspect of text is the look of the text and thus the font. With the `TextElement`, the font can be specified with the properties `FontWeight`, `FontStyle`, `FontStretch`, `FontSize`, and `FontFamily`.

- ➤ Predefined `FontWeight` values are defined by the `FontWeights` class, which offers values such as `UltraLight`, `Light`, `Medium`, `Normal`, `Bold`, `UltraBold`, and `Heavy`.

- `FontStyle` values are defined by the `FontStyles` class that offers `Normal`, `Italic`, and `Oblique`.
- With `FontStretch` you can specify the degrees to stretch the font compared to the normal aspect ratio. `FrontStretch` defines predefined stretches that range from 50% (`UltraCondensed`) to 200% (`UltraExpanded`). Predefined values in between the range are `ExtraCondensed` (62.5%), `Condensed` (75%), `SemiCondensed` (87.5%), `Normal` (100%), `SemiExpanded` (112.5%), `Expanded` (125%), `ExtraExpanded` (150%)
- `FontSize` is of type `double` where you can specify the size of the font in device-independent units, inches, centimeters, and points.
- With `FontFamily` you define the name of the preferred font-family, e.g., `Arial` or `Times New Roman`. With this property you can specify a list of font family names so if one font is not available, the next one in the list is used. (If neither the selected font nor the alternate font are available, a flow document falls back to the default `MessageFontFamily`.) You can also reference a font family from a resource or use a URI to reference a font from a server. With fixed documents there's no fallback on a font not available because the font is available with the document.

To give you a feel for the look of different fonts, the following sample WPF application includes a `ListBox`. The `ListBox` defines an `ItemTemplate` for every item in the list. This template uses four `TextBlock` elements where the `FontFamily` is bound to the `Source` property of a `FontFamily` object. With different `TextBlock` elements `FontWeight` and `FontStyle` are set:

```
<ListBox ItemsSource="{Binding}">
    <ListBox.ItemTemplate>
        <DataTemplate>
            <StackPanel Orientation="Horizontal" >
                <TextBlock Margin="3, 0, 3, 0"
                    FontFamily="{Binding Path=Source}"
                    FontSize="18" Text="{Binding Path=Source}" />
                <TextBlock Margin="3, 0, 3, 0"
                    FontFamily="{Binding Path=Source}"
                    FontSize="18" FontStyle="Italic" Text="Italic" />
                <TextBlock Margin="3, 0, 3, 0"
                    FontFamily="{Binding Path=Source}"
                    FontSize="18" FontWeight="UltraBold"
                    Text="UltraBold" />
                <TextBlock Margin="3, 0, 3, 0"
                    FontFamily="{Binding Path=Source}"
                    FontSize="18" FontWeight="UltraLight"
                    Text="UltraLight" />
            </StackPanel>
        </DataTemplate>
    </ListBox.ItemTemplate>
</ListBox>
```

code snippet ShowFonts/ShowFontsWindow.xaml

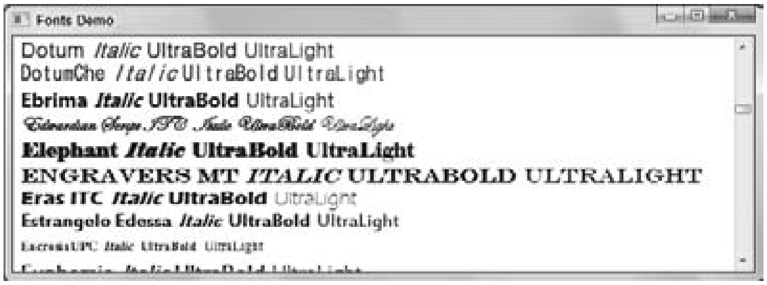
In the code-behind, the data context is set to the result of the `SystemFontFamilies` property of the `System.Windows.Media.Font` class:

```
public partial class ShowFontsWindow : Window
{
    public ShowFontsWindow()
    {
        InitializeComponent();

        this.DataContext=Fonts.SystemFontFamilies;
    }
}
```

code snippet ShowFonts/ShowFontsWindow.xaml.cs

Running the application, you get a large list of system font families with italic, bold, ultrabold, and ultralight characteristics, as shown in Figure 37-1.



```
Dotum Italic UltraBold UltraLight
DotumChe Italic UltraBold UltraLight
Ebrima Italic UltraBold UltraLight
Edwardian Script ITC Italic UltraBold UltraLight
Elephant Italic UltraBold UltraLight
ENGRAVERS MT ITALIC ULTRABOLD ULTRALIGHT
Eras ITC Italic UltraBold UltraLight
Estrangelo Edessa Italic UltraBold UltraLight
EucrosiaUPC Italic UltraBold UltraLight
```

FIGURE 37-1

TextEffect

Next let's have a look into `TextEffect`, as it is also common to all document elements. `TextEffect` is defined in the namespace `System.Windows.Media` and derives from the base class `Animatable` that allows animation of text.

`TextEffect` allows you to animate a clipping region, the foreground brush, and a transformation. With the properties `PositionStart` and `PositionCount` you specify the position in the text the animation applies to.

For applying the text effects, the `TextEffects` property of a `Run` element is set. The `TextEffect` element specified within the property defines a foreground and a transformation. For the foreground, a `SolidColorBrush` with the name `brush1` is used that is animated with a `ColorAnimation` element. The transformation makes use of `ScaleTransformation` with the name `scale1` that is animated from two `DoubleAnimation` elements:

```
<TextBlock>
    <TextBlock.Triggers>
         <EventTrigger RoutedEvent="TextBlock.Loaded">
            <BeginStoryboard>
                <Storyboard>
                    <ColorAnimation AutoReverse="True" RepeatBehavior="Forever"
                                    From="Red" To="Yellow" Duration="0:0:3"
                                    Storyboard.TargetName="brush1"
                                    Storyboard.TargetProperty="Color" />
                    <DoubleAnimation AutoReverse="True"
                                     RepeatBehavior="Forever"
                                     From="0.2" To="12" Duration="0:0:6"
                                     Storyboard.TargetName="scale1"
                                     Storyboard.TargetProperty="ScaleX" />
                    <DoubleAnimation AutoReverse="True"
                                     RepeatBehavior="Forever"
                                     From="0.2" To="12" Duration="0:0:6"
                                     Storyboard.TargetName="scale1"
                                     Storyboard.TargetProperty="ScaleY" />
                </Storyboard>
            </BeginStoryboard>
        </EventTrigger>
    </TextBlock.Triggers>
    <Run FontFamily="Mangal">
        cn|elements
        <Run.TextEffects>
            <TextEffect PositionStart="0" PositionCount="30" >
```

```
                    <TextEffect.Foreground>
                        <SolidColorBrush x:Name="brush1" Color="Blue" />
                    </TextEffect.Foreground>
                    <TextEffect.Transform>
                        <ScaleTransform x:Name="scale1" ScaleX="3" ScaleY="3" />
                    </TextEffect.Transform>
                </TextEffect>
            </Run.TextEffects>
        </Run>
    </TextBlock>
```

code snippet TextEffectsDemo/MainWindow.xaml

Running the application, you can see the changes in size and color as shown in Figures 37-2 and 37-3.

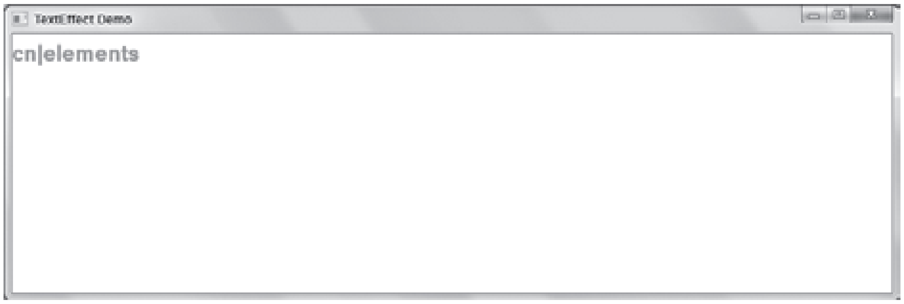


FIGURE 37-2

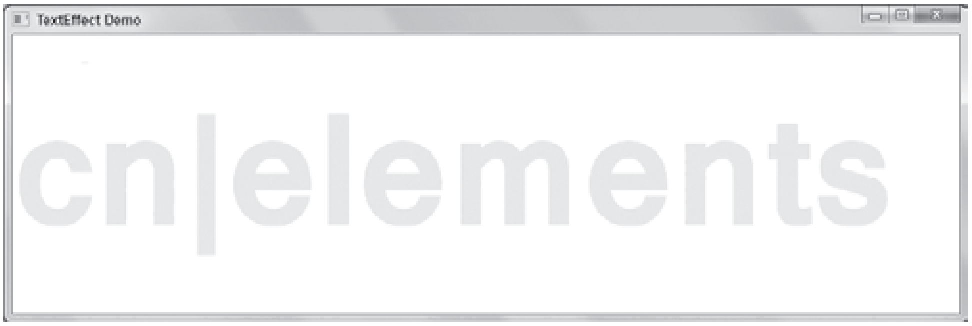

FIGURE 37-3

Inline

The base class for all inline flow content elements is `Inline`. You can use `Inline` elements within a paragraph of a flow document. Because within a paragraph one `Inline` element can be after another, the `Inline` class provides the `PreviousInline` and `NextInline` properties to navigate from one element to another. You can also get a collection of all peer inlines with `SiblingInlines`.

The `Run` element that was used earlier to write some text is an `Inline` element for formatted or unformatted text, but there are many more. A new line after a `Run` element can be done with the `LineBreak` element.

The Span element derives from the Inline class and allows grouping of Inline elements. Only Inline elements are allowed within the content of Span. The self-explanatory Bold, Hyperlink, Italic, and Underline classes all derive from Span and thus have the same functionality to allow Inline elements as its content, but act on these elements differently. The following XAML code demonstrates using Bold, Italic, Underline, and LineBreak, as shown in Figure 37-4.

```
<Paragraph FontWeight="Normal">
    <Span>
        <Span>Normal</Span>
        <Bold>Bold</Bold>
        <Italic>Italic</Italic>
        <LineBreak />
        <Underline>Underline</Underline>
    </Span>
</Paragraph>
```

code snippet FlowDocumentsDemo/FlowDocument1.xaml

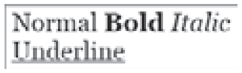

FIGURE 37-4

AnchoredBlock is an abstract class that derives from Inline and is used to anchor Block elements to flow content. Figure and Floater are concrete classes that derive from AnchoredBlock. Because these two inline elements become interesting in relation to blocks, these elements are discussed later in this chapter.

Another Inline element that maps UI elements that have been used in the previous chapters is InlineUIContainer. InlineUIContainer allows adding all UIElement objects (for example, a Button) to the document. The following code segment adds an InlineUIContainer with ComboBox, RadioButton, and TextBox elements to the document. The result is shown in Figure 37-5.

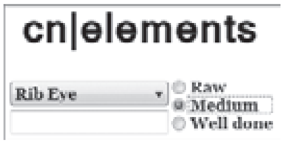

FIGURE 37-5

```
<Paragraph TextAlignment="Center" >
    <Span FontSize="36">
        <Italic>cn|elements</Italic>
    </Span>
    <LineBreak />
    <LineBreak />
    <InlineUIContainer>
        <Grid>
            <Grid.RowDefinitions>
                <RowDefinition />
                <RowDefinition />
            </Grid.RowDefinitions>
            <Grid.ColumnDefinitions>
                <ColumnDefinition />
                <ColumnDefinition />
            </Grid.ColumnDefinitions>
            <ComboBox Width="140"  Margin="3"  Grid.Row="0">
                <ComboBoxItem>Filet Mignon</ComboBoxItem>
                <ComboBoxItem>Rib Eye</ComboBoxItem>
                <ComboBoxItem>Sirloin</ComboBoxItem>
            </ComboBox>

            <StackPanel Grid.Row="0" Grid.RowSpan="2" Grid.Column="1">
                <RadioButton>Raw</RadioButton>
                <RadioButton>Medium</RadioButton>
                <RadioButton>Well done</RadioButton>
                </StackPanel>
                <TextBox Grid.Row="1" Grid.Column="0" Width="140"></TextBox>
            </Grid>
        </InlineUIContainer>
    </Paragraph>
```

code snippet FlowDocumentsDemo/FlowDocument2.xaml

Block

`Block` is an abstract base class for block-level elements. Blocks allow grouping elements contained to specific views. Common with all blocks are the properties `PreviousBlock`, `NextBlock`, and `SiblingBlocks` that allow you to navigate from block to block. Setting `BreakPageBefore` and `BreakColumnBefore` page and column breaks are done before the block starts. A `Block` also defines a border with the `BorderBrush` and `BorderThickness` properties.

Classes that derive from `Block` are `Paragraph`, `Section`, `List`, `Table`, and `BlockUIContainer`. `BlockUIContainer` is similar to `InlineUIContainer` in that you can add elements that derive from `UIElement`.

`Paragraph` and `Section` are simple blocks where `Paragraph` contains inline elements; `Section` is used to group other `Block` elements. With the `Paragraph` block you can determine whether a page or column break is allowed within the paragraph or between paragraphs. `KeepTogether` can be used to disallow breaking within the paragraph; `KeepWithNext` tries to keep one paragraph and the next together. If a paragraph is broken by a page or column break, `MinWidowLines` defines the minimum number of lines that are placed after the break and `MinOrphanLines` defines the minimum number of lines before the break.

The `Paragraph` block also allows decorating the text within the paragraph with `TextDecoration` elements. Predefined text decorations are defined by `TextDecorations`: `Baseline`, `Overline`, `Strikethrough`, and `Underline`.

The following XAML code shows multiple `Paragraph` elements. One `Paragraph` element with a title follows another with the content belonging to this title. These two paragraphs are connected with the attribute `KeepWithNext`. It's also assured that the paragraph with the content is not broken by setting `KeepTogether` to `True`. The result is shown in Figure 37-6.

```
<FlowDocument xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
              ColumnWidth="300" FontSize="16" FontFamily="Georgia">
    <Paragraph FontSize="36">
        <Run>Lyrics</Run>
    </Paragraph>

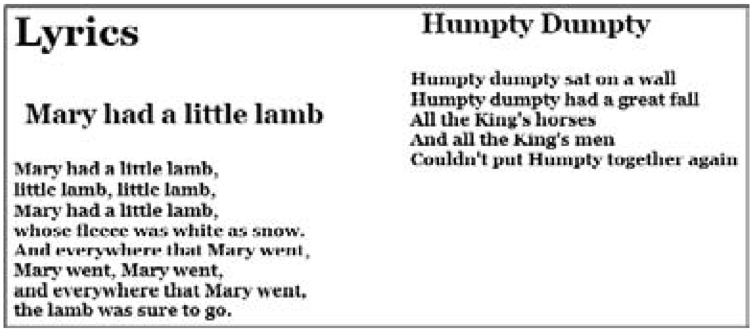
    <Paragraph TextIndent="10"  FontSize="24" KeepWithNext="True">
        <Bold>
            <Run>Mary had a little lamb</Run>
        </Bold>
    </Paragraph>

    <Paragraph KeepTogether="True">
        <Run>
            Mary had a little lamb,
        </Run>
        <LineBreak />
        <Run>
            little lamb, little lamb,
        </Run>
        <LineBreak />
        <Run>
            Mary had a little lamb,
        </Run>
        <LineBreak />
        <Run>
            whose fleece was white as snow.
        </Run>
```

```
            <LineBreak />
            <Run>
                And everywhere that Mary went,
            </Run>
            <LineBreak />
            <Run>
                Mary went, Mary went,
            </Run>
            <LineBreak />
            <Run>
                and everywhere that Mary went,
            </Run>
            <LineBreak />
            <Run>
                the lamb was sure to go.
            </Run>
        </Paragraph>

        <Paragraph TextIndent="10" FontSize="24" KeepWithNext="True">
            <Bold>
                <Run>Humpty Dumpty</Run>
            </Bold>
        </Paragraph>
        <Paragraph KeepTogether="True">
            <Run>Humpty dumpty sat on a wall</Run>
            <LineBreak />
            <Run>
                Humpty dumpty had a great fall</Run>
            <LineBreak />
            <Run>
                All the King's horses</Run>
            <LineBreak />
            <Run>
                And all the King's men</Run>
            <LineBreak />
            <Run>
                Couldn't put Humpty together again
            </Run>
        </Paragraph>
    </FlowDocument>
```

code snippet FlowDocumentsDemo/ParagraphDemo.xaml



Lyrics

Mary had a little lamb

Mary had a little lamb,
little lamb, little lamb,
Mary had a little lamb,
whose fleece was white as snow.
And everywhere that Mary went,
Mary went, Mary went,
and everywhere that Mary went,
the lamb was sure to go.

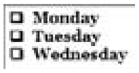
Humpty Dumpty

Humpty dumpty sat on a wall
Humpty dumpty had a great fall
All the King's horses
And all the King's men
Couldn't put Humpty together again

FIGURE 37-6

Lists

The `List` class is used to create textual unordered or ordered lists. `List` defines the bullet style of its items by setting the `MarkerStyle` property. `MarkerStyle` is of type `TextMarkerStyle` and can be a number (`Decimal`), a letter (`LowerLatin` and `UpperLatin`), a roman numeral (`LowerRoman` and UpperRoman), or a graphic (Disc, Circle, Square, Box). List can only contain ListItem elements which in turn can only contain Block elements.



❑ Monday
❑ Tuesday
❑ Wednesday

FIGURE 37-7

Defining the following list with XAML results in the output shown in Figure 37-7.

```
<List MarkerStyle="Square">
    <ListItem>
        <Paragraph>Monday</Paragraph>
    </ListItem>
    <ListItem>
        <Paragraph>Tuesday</Paragraph>
    </ListItem>
    <ListItem>
        <Paragraph>Wednesday</Paragraph>
    </ListItem>
</List>
```

code snippet FlowDocumentsDemo/ListDemo.xaml

Tables

The Table class is very similar to the Grid class that was presented in Chapter 35 to define rows and columns. The following example demonstrates creating a FlowDocument with a Table. To create tables you can add TableColumn objects to the Columns property. With TableColumn you can specify the width and background.

The Table also contains TableRowGroup objects. The TableRowGroup has a Rows property where TableRow objects can be added. The TableRow class defines a Cells property where TableCell objects can be added. TableCell objects can contain any Block element. Here a Paragraph is used that contains the Inline element Run:

```
var doc = new FlowDocument();
var t1 = new Table();
t1.Columns.Add(new TableColumn
    { Width = new GridLength(50, GridUnitType.Pixel) });
t1.Columns.Add(new TableColumn
    { Width = new GridLength(1, GridUnitType.Auto) });
t1.Columns.Add(new TableColumn
    { Width = new GridLength(1, GridUnitType.Auto) });

var titleRow = new TableRow();
titleRow.Background = new SolidColorBrush(Colors.LightBlue);
var titleCell = new TableCell
    { ColumnSpan = 3, TextAlignment = TextAlignment.Center };
titleCell.Blocks.Add(
    new Paragraph(new Run("Formula 1 Championship 2009")
        { FontSize=24, FontWeight = FontWeights.Bold }));
titleRow.Cells.Add(titleCell);

var headerRow = new TableRow
    { Background = new SolidColorBrush(Colors.LightGoldenrodYellow) };
headerRow.Cells.Add(new TableCell(new Paragraph(new Run("Pos"))
    { FontSize = 14, FontWeight=FontWeights.Bold}));
headerRow.Cells.Add(new TableCell(new Paragraph(new Run("Name"))
    { FontSize = 14, FontWeight = FontWeights.Bold }));
headerRow.Cells.Add(new TableCell(new Paragraph(new Run("Points"))
    { FontSize = 14, FontWeight = FontWeights.Bold }));

var row1 = new TableRow();
row1.Cells.Add(new TableCell(new Paragraph(new Run("1."))));
row1.Cells.Add(new TableCell(new Paragraph(
                                new Run("Jenson Button"))));
row1.Cells.Add(new TableCell(new Paragraph(new Run("95"))));

var row2 = new TableRow { Background =
                              new SolidColorBrush(Colors.LightGray)};
row2.Cells.Add(new TableCell(new Paragraph(new Run("2."))));
row2.Cells.Add(new TableCell(new Paragraph(new Run("Sebastian Vettel"))));
row2.Cells.Add(new TableCell(new Paragraph(new Run("84"))));

var row3 = new TableRow();
row3.Cells.Add(new TableCell(new Paragraph(new Run("3."))));
row3.Cells.Add(new TableCell(new Paragraph(
                                 new Run("Rubens Barrichello"))));
row3.Cells.Add(new TableCell(new Paragraph(new Run("77"))));

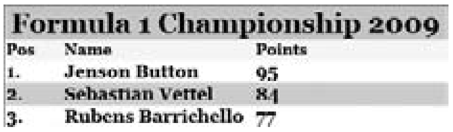
var rowGroup = new TableRowGroup();
rowGroup.Rows.Add(titleRow);
rowGroup.Rows.Add(headerRow);
rowGroup.Rows.Add(row1);
rowGroup.Rows.Add(row2);
rowGroup.Rows.Add(row3);
t1.RowGroups.Add(rowGroup);

doc.Blocks.Add(t1);

reader.Document = doc;
```

code snippet TableDemo/MainWindow.xaml

Running the application, you can see the nicely formatted table as shown in Figure 37-8.



Formula 1 Championship 2009		
Pos	Name	Points
1.	Jenson Button	95
2.	Sebastian Vettel	84
3.	Rubens Barrichello	77

FIGURE 37-8

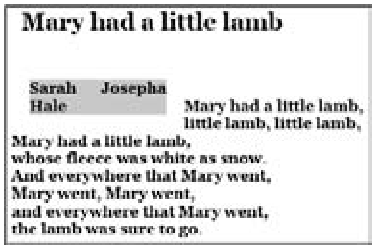
Anchor to Blocks

Now that you've learned about the `Inline` and `Block` elements, you can combine the two by using the `Inline` elements of type `AnchoredBlock`. `AnchoredBlock` is an abstract base class with two concrete implementations, `Figure` and `Floater`.

The `Floater` displays its content parallel to the main content with the properties `HorizontalAlignment` and `Width`.

Starting from the earlier example, a new paragraph is added that contains a `Floater`. This `Floater` is aligned to the left and has a width of 160. As you can see in Figure 37-9, the next paragraph flows around it.

```
<Paragraph TextIndent="10" FontSize="24" KeepWithNext="True">
    <Bold>
        <Run>Mary had a little lamb</Run>
    </Bold>
</Paragraph>
<Paragraph>
    <Floater HorizontalAlignment="Left" Width="160">
        <Paragraph Background="LightGray">
            <Run>Sarah Josepha Hale</Run>
        </Paragraph>
    </Floater>
</Paragraph>
<Paragraph KeepTogether="True">
    <Run>
        Mary had a little lamb
    </Run>
    <LineBreak />
    <!-- ... -->
</Paragraph>
```



Mary had a little lamb

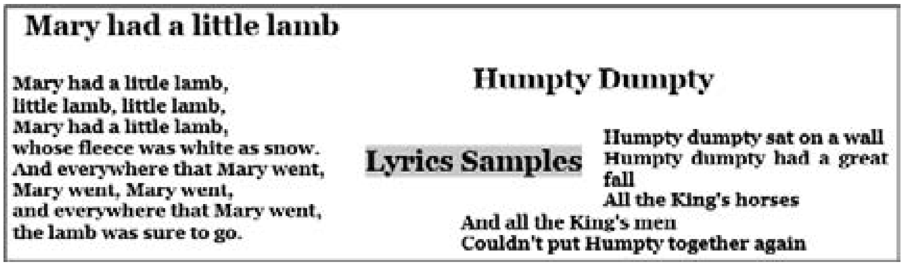
Sarah Hale | Josepha

Mary had a little lamb,
little lamb, little lamb,
Mary had a little lamb,
whose fleece was white as snow.
And everywhere that Mary went,
Mary went, Mary went,
and everywhere that Mary went,
the lamb was sure to go.

FIGURE 37-9

A `Figure` aligns horizontally and vertically and can be anchored to the page, content, a column, or a paragraph. The `Figure` in the following code is anchored to the page center but with a horizontal and vertical offset. The `WrapDirection` is set so that both left and right columns wrap around the figure. Figure 37-10 shows the result of the wrap:

```
<Paragraph>
    <Figure HorizontalAnchor="PageCenter" HorizontalOffset="20"
        VerticalAnchor="PageCenter" VerticalOffset="20" WrapDirection="Both" >
        <Paragraph Background="LightGray" FontSize="24">
            <Run>Lyrics Samples</Run>
        </Paragraph>
    </Figure>
</Paragraph>
```



Mary had a little lamb

Mary had a little lamb,
little lamb, little lamb,
Mary had a little lamb,
whose fleece was white as snow.
And everywhere that Mary went,
Mary went, Mary went,
and everywhere that Mary went,
the lamb was sure to go.

Humpty Dumpty

Lyrics Samples

Humpty dumpty sat on a wall
Humpty dumpty had a great fall
All the King's horses
And all the King's men
Couldn't put Humpty together again

FIGURE 37-10

`Floater` and `Figure` are both used to add content that is not in the main flow. Although these two features seem similar, the characteristics of these elements are quite different. The following table explains the differences between `Floater` and `Figure`.

CHARACTERISTICS	FLOATER	FIGURE
Position	A floater cannot be positioned. It is rendered where space is available.	A figure can be positioned with horizontal and vertical anchors. It can be docked relative to the page, content, column, or paragraph.
Width	A floater can be placed only within one column. If the width is set larger than the column size, it is ignored.	A figure can be sized across multiple columns. The width of a figure can be set to 0.5 pages or 2 columns.
Pagination	If a floater is larger than a column height, the floater breaks and paginates to the next column or page.	If a figure is larger than a column height, only the part of the figure that fits in the column is rendered; the other content is lost.

FLOW DOCUMENTS

With all the `Inline` and `Block` elements, now you know what should be put into a flow document. The class `FlowDocument` can contain `Block` elements, and the `Block` elements can contain `Block` or `Inline` elements, depending on the type of the `Block`.

A major functionality of the `FlowDocument` class is that it is used to break up the flow into multiple pages. This is done via the `IDocumentPaginatorSource` interface that is implemented by `FlowDocument`.

Other options with a `FlowDocument` are to set up the default font and foreground and background brushes, and to configure the page and column sizes.

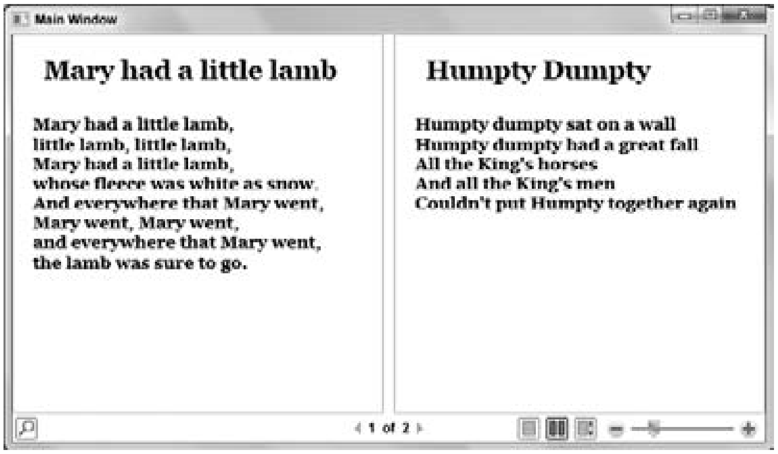
The following XAML code for the `FlowDocument` defines a default font and font size, a column width, and also a ruler between columns:

```
<FlowDocument xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
              ColumnWidth="300" FontSize="16" FontFamily="Georgia"
              ColumnRuleWidth="3" ColumnRuleBrush="Violet">
```

Now you just need a way to view the documents. The following list describes several viewers:

- `RichTextBox` — A simple viewer that also allows editing (as long as the `IsReadOnly` property is not set to `true`). The `RichTextBox` doesn't display the document with multiple columns but instead in scroll mode. This is similar to the Web layout in Microsoft Word. The scrollbar can be enabled by setting the `HorizontalScrollbarVisibility` to `ScrollbarVisibility.Auto`.
- `FlowDocumentsScrollViewer` — A reader that is meant only to read but not edit documents. This reader allows zooming into the document. There's also a toolbar with a slider for zooming that can be enabled with the property `IsToolbarEnabled`. Settings such as `CanIncreaseZoom`, `CanDecreaseZoom`, `MinZoom`, and `MaxZoom` allow setting the zoom features.
- `FlowDocumentPageViewer` — A viewer that paginates the document. With this viewer you not only have a toolbar to zoom into the document, but can also switch from page to page.
- `FlowDocumentReader` — A viewer that combines the functionality of `FlowDocumentScrollViewer` and `FlowDocumentPageViewer`. This viewer supports different viewing modes that can be set from the toolbar or with the property `ViewingMode` that is of type `FlowDocumentReaderViewingMode`. This enumeration has the possible values `Page`, `TwoPage`, and `Scroll`. The viewing modes can also be disabled according to your needs.

Figure 37-11 shows the previously created flow document with the `FlowDocumentReader` in `TwoPage` mode.



Mary had a little lamb

Mary had a little lamb,
little lamb, little lamb,
Mary had a little lamb,
whose fleece was white as snow.
And everywhere that Mary went,
Mary went, Mary went,
and everywhere that Mary went,
the lamb was sure to go.

Humpty Dumpty

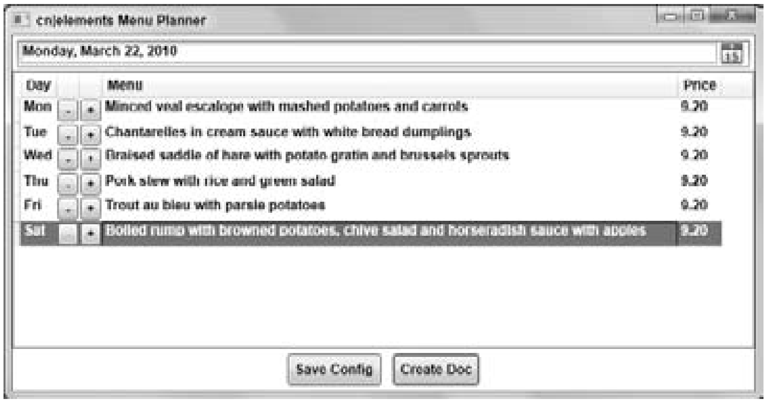
Humpty dumpty sat on a wall
Humpty dumpty had a great fall
All the King's horses
And all the King's men
Couldn't put Humpty together again

FIGURE 37-11

FIXED DOCUMENTS

Fixed documents always define the same look, the same pagination, and use the same fonts — no matter where the document is copied or used. WPF defines the class `FixedDocument` that can be used to create fixed documents, and the class `DocumentViewer` to view fixed documents.

This chapter uses a sample application to create a fixed document programmatically by requesting user input for a menu plan which is used to create a fixed document. Figure 37-12 shows the main user interface of this application, where the user can select a day with the `DatePicker` class, enter menus for a week in a `DataGrid`, and click the Create Doc button to create a new `FixedDocument`. This application uses `Page` objects that are navigated within a `NavigationWindow`. Clicking the Create Doc button navigates to a new page that contains the fixed document.



Monday, March 22, 2010

Day			Menu	Price
Mon	-	+	Minced veal escalope with mashed potatoes and carrots	9.20
Tue	-	+	Chantarelles in cream sauce with white bread dumplings	9.20
Wed	-	+	Braised saddle of hare with potato gratin and brussels sprouts	9.20
Thu	-	+	Pork stew with rice and green salad	9.20
Fri	-	+	Trout au bleu with parsle potatoes	9.20
Sat	-	+	Boiled rump with browned potatoes, chive salad and horseradish sauce with apples	9.20

FIGURE 37-12

The event handler for the Create Doc button, `OnCreateDoc()`, navigates to a new page. To do this, the handler instantiates the new page, `DocumentPage`. This page includes a handler, `NavigationService_LoadCompleted()`, that is assigned to the `LoadCompleted` event of the `NavigationService`. Within this handler the new page can access the content that is passed to the page. Then the navigation is done by invoking the `Navigate()` method to `page2`. The new page receives the object `menus` that contain all the menu information that is needed to build up the fixed page. The `menus` variable is of type `ObservableCollection<MenuEntry>`:

```
private void OnCreateDoc(object sender, RoutedEventArgs e)
{
    if (menus.Count == 0)
    {
        MessageBox.Show("Select a date first", "Menu Planner",
            MessageBoxButton.OK);
        return;
    }
    var page2 = new DocumentPage();
    NavigationService.LoadCompleted +=
        page2.NavigationService_LoadCompleted;
    NavigationService.Navigate(page2, menus);
}
```

code snippet CreateXps/MenuPlannerPage.xaml.cs

Within the `DocumentPage`, a `DocumentViewer` is used to give read access to the fixed document. The fixed document is created in the method `NavigationService_LoadCompleted`. With the event handler, the data that is passed from the first page is received with the `ExtraData` property of `NavigationEventArgs`.

The received `ObservableCollection<MenuEntry>` is assigned to the `menus` variable that is used to build up the fixed page:

```
internal void NavigationService_LoadCompleted(object sender,
                                              NavigationEventArgs e)
{
    menus = e.ExtraData as ObservableCollection<MenuEntry>;

    fixedDocument = new FixedDocument();
    var pageContent1 = new PageContent();
    fixedDocument.Pages.Add(pageContent1);
    var page1 = new FixedPage();
    pageContent1.Child = page1;
    page1.Children.Add(GetHeaderContent());
    page1.Children.Add(GetLogoContent());
    page1.Children.Add(GetDateContent());
    page1.Children.Add(GetMenuContent());

    viewer.Document = fixedDocument;

    NavigationService.LoadCompleted -= NavigationService_LoadCompleted;
}
```

code snippet CreateXps/DocumentPage.xaml.cs

Fixed documents are created with the `FixedDocument` class. The `FixedDocument` element only contains `PageContent` elements that are accessible via the `Pages` property. The `PageContent` elements must be added to the document in the order they should appear on the page. `PageContent` defines the content of a single page.

`PageContent` has a `Child` property such that a `FixedPage` can be associated with it. To the `FixedPage` you can add elements of type `UIElement` to the `Children` collection. This is where you can add all the elements you've learned about in the last two chapters, including a `TextBlock` element that itself can contain `Inline` and `Block` elements.

In the sample code, the children to the `FixedPage` are created with helper methods `GetHeaderContent()`, `GetLogoContent()`, `GetDateContent()`, and `GetMenuContent()`.

The method `GetHeaderContent()` creates a `TextBlock` that is returned. The `TextBlock` has the `Inline` element `Bold` added, which in turn has the `Run` element added. The `Run` element then contains the header text for the document. With `FixedPage.SetLeft()` and `FixedPage.SetTop()` the position of the `TextBox` within the fixed page is defined:

```
private UIElement GetHeaderContent()
{
    var text1 = new TextBlock();
    text1.FontFamily = new FontFamily("Mangal");
    text1.FontSize = 34;
    text1.HorizontalAlignment = HorizontalAlignment.Center;
    text1.Inlines.Add(new Bold(new Run("cn|elements")));
    FixedPage.SetLeft(text1, 170);
    FixedPage.SetTop(text1, 40);
    return text1;
}
```

The method `GetLogoContent()` adds a logo in the form of an `Ellipse` with a `RadialGradientBrush` to the fixed document:

```
private UIElement GetLogoContent()
{
    var ellipse = new Ellipse
    {
        Width = 90,
            Height = 40,
            Fill = new RadialGradientBrush(Colors.Yellow, Colors.DarkRed)
        };

        FixedPage.SetLeft(ellipse, 500);
        FixedPage.SetTop(ellipse, 50);
        return ellipse;
    }
```

The method `GetDateContent()` accesses the `menus` collection to add a date range to the document:

```
    private UIElement GetDateContent()
    {
        string dateString = String.Format("{0:d} to {1:d}",
            menus[0].Day, menus[menus.Count - 1].Day);
        var text1 = new TextBlock
        {
            FontSize = 24,
            HorizontalAlignment = HorizontalAlignment.Center
        };
        text1.Inlines.Add(new Bold(new Run(dateString)));
        FixedPage.SetLeft(text1, 130);
        FixedPage.SetTop(text1, 90);
        return text1;
    }
```

Finally the method `GetMenuContent()` creates and returns a `Grid` control. This grid contains columns and rows that contain the date, menu, and price information:

```
    private UIElement GetMenuContent()
    {
        var grid1 = new Grid { ShowGridLines = true };

        grid1.ColumnDefinitions.Add(new ColumnDefinition
                                    { Width= new GridLength(50)});
        grid1.ColumnDefinitions.Add(new ColumnDefinition
                                    { Width = new GridLength(300)});
        grid1.ColumnDefinitions.Add(new ColumnDefinition
                                    { Width = new GridLength(70) });

        for (int i = 0; i < menus.Count; i++)
        {
            grid1.RowDefinitions.Add(new RowDefinition
                                     { Height = new GridLength(40) });

            var t1 = new TextBlock(
                new Run(String.Format("{0:ddd}", menus[i].Day)));
            t1.VerticalAlignment = VerticalAlignment.Center;
            t1.Margin = new Thickness(5, 2, 5, 2);
            Grid.SetColumn(t1, 0);
            Grid.SetRow(t1, i);
            grid1.Children.Add(t1);

            var t2 = new TextBlock(new Run(menus[i].Menu));
            t2.VerticalAlignment = VerticalAlignment.Center;
            t2.Margin = new Thickness(5, 2, 5, 2);
            Grid.SetColumn(t2, 1);
            Grid.SetRow(t2, i);
            grid1.Children.Add(t2);

            var t3 = new TextBlock(new Run(menus[i].Price.ToString()));
            t3.VerticalAlignment = VerticalAlignment.Center;
            t3.Margin = new Thickness(5, 2, 5, 2);
            Grid.SetColumn(t3, 2);
```

```
                Grid.SetRow(t3, i);
                grid1.Children.Add(t3);
            }

            FixedPage.SetLeft(grid1, 100);
            FixedPage.SetTop(grid1, 140);
            return grid1;
        }
```

Run the application to see the created fixed document shown in Figure 37-13.

FIGURE 37-13

XPS DOCUMENTS

With Microsoft Word you can save a document as a PDF or XPS file. Since Word 2007 SP2 this feature is included with Microsoft Word. If you have Word 2007 but didn't install SP2 yet you can download the add-on for free. XPS is the *XML Paper Specification*, a subset of WPF. Windows includes an XPS reader.

.NET includes classes and interfaces to read and write XPS documents with the namespaces `System.Windows.Xps`, `System.Windows.Xps.Packaging`, and `System.IO.Packaging`.

XPS is packaged within the ZIP file format, so you can easily analyze an XPS document by renaming a file with an `.xps` extension to `.zip` and opening the archive..

An XPS file requires a specific structure in the zipped document that is defined by the XML Paper Specifications (which you can download from `http://www.microsoft.com/whdc/xps/xpsspec.mspx`). The structure is based on the Open Packaging Convention (OPC) that Word documents (OOXML or Office Open XML) are based on as well. Within such a file you can find different folders for metadata, resources (such as fonts and pictures), and the document itself. Within the document folder of an XPS document you can find the XAML code representing the XPS subset of XAML.

To create an XPS document, you use the `XpsDocument` class from the namespace `System.Windows.Xps.Packaging`. To use this class, you will need to reference the assembly `ReachFramework` as well. With this class you can add a thumbnail (`AddThumbnail()`) and fixed document sequences (`AddFixedDocumentSequence()`) to the document, as well as digitally sign the document. A fixed document sequence is written by using the interface `IXpsFixedDocumentSequenceWriter` that in turn uses an `IXpsFixedDocumentWriter` to write the document within the sequence.

If a `FixedDocument` already exists, there's an easier way to write the XPS document. Instead of adding every resource and every document page, you can use the class `XpsDocumentWriter` from the namespace `System.Windows.Xps`. For this class the assembly `System.Printing` must be referenced.

With the following code snippet you can see the handler to create the XPS document. First, a filename for the menu plan is created that uses a week number in addition to the name `menuplan`. The week number is calculated with the help of the `GregorianCalendar` class. Then the `SaveFileDialog` is opened to let the user overwrite the created filename and select the directory where the file should be stored. The `SaveFileDialog` class is defined in the namespace `Microsoft.Win32` and wraps the native file dialog. Then a new `XpsDocument` is created where the filename is passed to the constructor. Recall that the XPS file uses a ZIP format to compress the content. With the `CompressionOption` you can specify whether the compression should be optimized on time or space.

Next, an `XpsDocumentWriter` is created with the help of the static method `XpsDocument.CreateXpsDocumentWriter()`. The Write method of the `XpsDocumentWriter` is overloaded to accept different content or content parts to write the document. Examples of acceptable options with the `Write()` method are `FixedDocumentSequence`, `FixedDocument`, `FixedPage`, `string`, and a `DocumentPaginator`. In the sample code, only the `fixedDocument` that was created earlier is passed:

```
private void OnCreateXPS(object sender, RoutedEventArgs e)
{
    var c = new GregorianCalendar();
    int weekNumber = c.GetWeekOfYear(menus[0].Day,
        CalendarWeekRule.FirstFourDayWeek, DayOfWeek.Monday);
    string fileName = String.Format("menuplan{0}", weekNumber);

    var dlg = new SaveFileDialog
    {
        FileName = fileName,
        DefaultExt = "xps",
        Filter = "XPS Documents|*.xps|All Files|*.*",
        AddExtension = true
    };

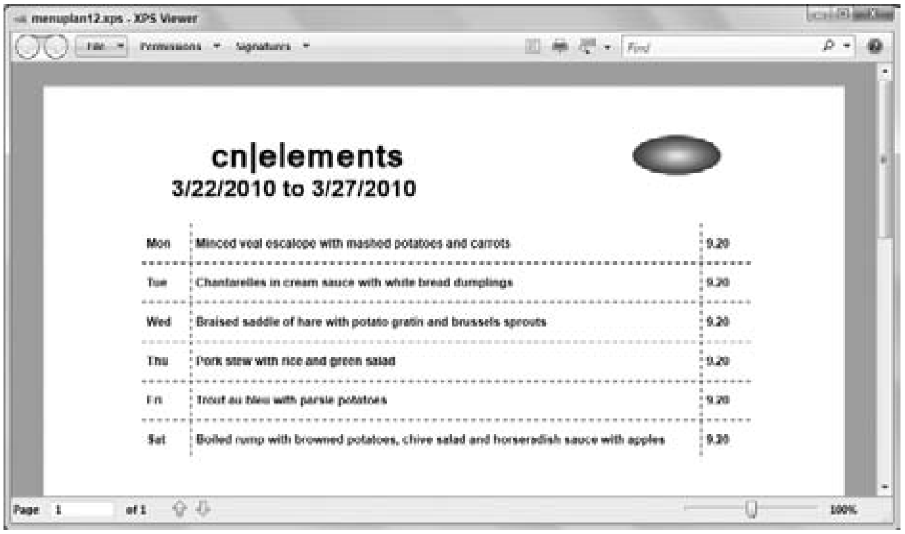
    if (dlg.ShowDialog() == true)
    {

        XpsDocument doc = new XpsDocument(dlg.FileName, FileAccess.Write,
                                          CompressionOption.Fast);
        XpsDocumentWriter writer = XpsDocument.CreateXpsDocumentWriter(doc);
        writer.Write(fixedDocument);
        doc.Close();

    }
}
```

code snippet CreateXps/DocumentPage.xaml.cs

By running the application to store the XPS document, you can view the document with an XPS viewer, as shown in Figure 37-14.



cn|elements
3/22/2010 to 3/27/2010

Mon	Minced veal escalope with mashed potatoes and carrots	9.20
Tue	Chantarelles in cream sauce with white bread dumplings	9.20
Wed	Braised saddle of hare with potato gratin and brussels sprouts	9.20
Thu	Pork stew with rice and green salad	9.20
Fri	Trout au bleu with parsle potatoes	9.20
Sat	Boiled rump with browned potatoes, chive salad and horseradish sauce with apples	9.20

FIGURE 37-14

To one overload of the `Write()` method of the `XpsDocumentWriter` you can also pass a `Visual`, which is the base class of `UIElement`, and thus you can pass any `UIElement` to the writer to create an XPS document easily. This functionality will be used in the following printing example.

PRINTING

The simplest way to print a `FixedDocument` that is shown on the screen with the `DocumentViewer` is to invoke the `Print()` method of the `DocumentViewer` that has the document associated. This is all that needs to be done with the menu planner application in an `OnPrint()` handler. The `Print()` method of the `DocumentViewer` opens up the `PrintDialog` and sends the associated `FixedDocument` to the selected printer:

```
private void OnPrint(object sender, RoutedEventArgs e)
{
    viewer.Print();
}
```

code snippet CreateXps/DocumentPage.xaml.cs

Printing with the PrintDialog

If you want more control over the printing process, the `PrintDialog` can be instantiated, and the document printed with the `PrintDocument()` method. The `PrintDocument()` method requires a `DocumentPaginator` with the first argument. The `FixedDocument` returns a `DocumentPaginator` object with the `DocumentPaginator` property. The second argument defines the string that shows up with the current printer and in the printer dialogs for the print job:

```
var dlg = new PrintDialog();
if (dlg.ShowDialog() == true)
{
    dlg.PrintDocument(fixedDocument.DocumentPaginator, "Menu Plan");
}
```

code snippet CreateXps/DocumentPage.xaml.cs

Printing Visuals

It's also simple to create `UIElement` objects. The following XAML code defines an `Ellipse`, a `Rectangle`, and a `Button` that is visually represented with two `Ellipse` elements. With the `Button` there's a `Click` handler `OnPrint()` that starts the print job of the visual elements:

```
<Canvas x:Name="canvas1">
    <Ellipse Canvas.Left="10" Canvas.Top="20" Width="180" Height="60"
             Stroke="Red" StrokeThickness="3" >
        <Ellipse.Fill>
            <RadialGradientBrush>
                <GradientStop Offset="0" Color="LightBlue" />
                <GradientStop Offset="1" Color="DarkBlue" />
            </RadialGradientBrush>
        </Ellipse.Fill>
    </Ellipse>
    <Rectangle Width="180" Height="90" Canvas.Left="50" Canvas.Top="50">
        <Rectangle.LayoutTransform>
            <RotateTransform Angle="30" />
        </Rectangle.LayoutTransform>
        <Rectangle.Fill>
            <LinearGradientBrush>
                <GradientStop Offset="0" Color="Aquamarine" />
                <GradientStop Offset="1" Color="ForestGreen" />
            </LinearGradientBrush>
        </Rectangle.Fill>
        <Rectangle.Stroke>
            <LinearGradientBrush>
                <GradientStop Offset="0" Color="LawnGreen" />
                <GradientStop Offset="1" Color="SeaGreen" />
            </LinearGradientBrush>
        </Rectangle.Stroke>
    </Rectangle>
    <Button Canvas.Left="90" Canvas.Top="190" Content="Print" Click="OnPrint">
        <Button.Template>
            <ControlTemplate TargetType="Button">
                <Grid>
                    <Grid.RowDefinitions>
                        <RowDefinition />
                        <RowDefinition />
                    </Grid.RowDefinitions>
                    <Ellipse Grid.Row="0" Grid.RowSpan="2" Width="60"
                             Height="40" Fill="Yellow" />
                    <Ellipse Grid.Row="0" Width="52" Height="20"
                            HorizontalAlignment="Center">
                        <Ellipse.Fill>
                            <LinearGradientBrush StartPoint="0.5,0"
                                                 EndPoint="0.5,1">
                                <GradientStop Color="White" Offset="0" />
                                <GradientStop Color="Transparent"
                                              Offset="0.9" />
                            </LinearGradientBrush>
                        </Ellipse.Fill>
                    </Ellipse>
                    <ContentPresenter Grid.Row="0" Grid.RowSpan="2"
                            HorizontalAlignment="Center"
                            VerticalAlignment="Center" />
                </Grid>

            </ControlTemplate>
```

```
                </Button.Template>
            </Button>
        </Canvas>
```

code snippet PrintingDemo/MainWindow.xaml

In the `OnPrint()` handler the print job can be started by invoking the `PrintVisual()` method of the `PrintDialog`. `PrintVisual()` accepts any object that derives from the base class `Visual`:

```
private void OnPrint(object sender, RoutedEventArgs e)
{
    PrintDialog dlg = new PrintDialog();
    if (dlg.ShowDialog() == true)
    {
        dlg.PrintVisual(canvas1, "Print Demo");

    }
}
```

code snippet PrintingDemo/MainWindow.xaml.cs

For programmatically printing without user intervention, the `PrintDialog` classes from the namespace `System.Printing` can be used to create a print job and adjust print settings. The class `LocalPrintServer` gives information about print queues and returns the default `PrintQueue` with the `DefaultPrintQueue` property. You can configure the print job with a `PrintTicket`. `PrintQueue.DefaultPrintTicket` returns a default `PrintTicket` that is associated with the queue. The `PrintQueue` method `GetPrintCapabilities()` returns the capabilities of a printer, and depending on the capabilities you can configure the `PrintTicket` as shown in the following code segment. After configuration of the print ticket is complete, the static method `PrintQueue.CreateXpsDocumentWriter()` returns an `XpsDocumentWriter` object. The `XpsDocumentWriter` class was used previously to create a XPS document. You can also use it to start a print job. The `Write()` method of the `XpsDocumentWriter` not only accepts a `Visual` or `FixedDocument` as the first argument but also a `PrintTicket` as the second argument. If a `PrintTicket` is passed with the second argument, the target of the writer is the printer that is associated with the ticket and thus the writer sends the print job to the printer.

```
LocalPrintServer printServer = new LocalPrintServer();

PrintQueue queue = printServer.DefaultPrintQueue;

PrintTicket ticket = queue.DefaultPrintTicket;
PrintCapabilities capabilities = queue.GetPrintCapabilities(ticket);
if (capabilities.DuplexingCapability.Contains(
        Duplexing.TwoSidedLongEdge))
    ticket.Duplexing = Duplexing.TwoSidedLongEdge;
if (capabilities.InputBinCapability.Contains(InputBin.AutoSelect))
    ticket.InputBin = InputBin.AutoSelect;
if (capabilities.MaxCopyCount > 3)
    ticket.CopyCount = 3;
if (capabilities.PageOrientationCapability.Contains(
    PageOrientation.Landscape))
    ticket.PageOrientation = PageOrientation.Landscape;
if (capabilities.PagesPerSheetCapability.Contains(2))
    ticket.PagesPerSheet = 2;
if (capabilities.StaplingCapability.Contains(
        Stapling.StapleBottomLeft))
    ticket.Stapling = Stapling.StapleBottomLeft;

XpsDocumentWriter writer = PrintQueue.CreateXpsDocumentWriter(queue);
writer.Write(canvas1, ticket);
```

SUMMARY

In this chapter you learned how WPF capabilities can be used with documents, how to create flow documents that adjust automatically depending on the screen sizes, and fixed documents that always look the same. You've also seen how to print documents and how to send visual elements to the printer.

The next chapter continues with the WPF technology and shows the capabilities of Silverlight.

38 Silverlight

WHAT'S IN THIS CHAPTER?

➤ Differences between WPF and Silverlight
➤ Creating Silverlight projects
➤ Navigation between pages
➤ Networking with System.Net, WCF, and data services
➤ Integration with the browser

In the last few chapters, you've read about creating WPF applications. Silverlight is a subset of WPF and offers applications running in a web browser. Since version 3.0, the applications can also run in a standalone fashion. The advantage of Silverlight is that you don't have to run it on a Windows operating system; it is also available on other platforms. All that's needed is an add-in in the browser that includes the Silverlight runtime. The Silverlight runtime contains a subset of the .NET Framework and a subset of WPF.

Before going through this chapter, you should be knowledgeable about XAML and WPF, as discussed in Chapters 27 and 35.

COMPARING WPF AND SILVERLIGHT

Silverlight and WPF are similar in many aspects, but there are also important differences. Silverlight consists of a core presentation framework (a subset of WPF), the .NET Framework for Silverlight (a subset of the .NET Framework), and installers and updaters. WPF applications run on a Windows system and require at least the .NET Client Profile. Silverlight uses a plugin model and is hosted in a web browser.

Silverlight is available for use with a wide range of browsers and operating systems. Beside Internet Explorer, Silverlight can also be used in Firefox, Safari, Opera, and Google Chrome. Not all of these browsers are supported yet. `http://go.microsoft.com/fwlink/?LinkId=128526` contains a list of supported operating systems and browsers.

You can use Moonlight to run Silverlight applications on a Linux system. You can download Moonlight at `http://www.gomono.com/moonlight`*. Check this page for the current status of supported features with Moonlight.*

When you compile a WPF application, you get an executable assembly that contains XAML code in a binary form, named BAML, as a resource. With a Silverlight application, the compiler creates an XAP file that is a ZIP package containing the assembly and configuration.

In the .NET Framework for Silverlight, you will find the same classes as in the full .NET Framework but, of course, not all of them. Some classes are missing and also several methods and properties from classes that are available with Silverlight.

What's completely unavailable with Silverlight 3 that you have with WPF is support for flow and fixed documents (see Chapter 37, "Creating Documents with WPF") and 3-D (3-D is covered in Chapter 35, "Core WPF"). You can simulate 3-D with 2-D in Silverlight but, of course, this is completely different from the 3-D functionality of WPF. Interoperability to Windows Forms is not available either. In any case, it's better to write the UI new with XAML instead of integrating Windows Forms controls.

There are also some smaller differences that can be frustrating if you write applications both for WPF and Silverlight:

➤ **Mouse clicks and events** — In Silverlight, the right mouse click is always caught by the browser and doesn't get to the Silverlight control. That's why there's no right button down/up event. There's also no double-click event. Silverlight doesn't have events for the mouse wheel. When reading the properties of `RoutedEventArgs`, with Silverlight just the properties `Handled` and `OriginalSource` are used. This changes with Silverlight 4 with the right mouse click and mouse wheel support.

➤ **Brushes** — Silverlight doesn't have the `DrawingBrush`, `VisualBrush`, and `TileBrush` brushes. However, you have the `VideoBrush` brush available to add videos to the brush.

➤ **Fonts** — Because not all the fonts are available on all platforms, Silverlight is limited in the fonts it offers.

➤ **Controls** — Silverlight doesn't have `Menu`, `Toolbar`, `Window`, and `WebBrowser` controls. However, there are some controls that Silverlight has that are not available with WPF. Over time, these differences will disappear. `Calendar`, `DatePicker`, `DataGrid` controls first appeared in Silverlight and are now available with WPF as well. `AutoCompleteBox` and `NumericUpDown` are controls that are currently missing from WPF.

➤ **Networking** — To avoid blocking the UI thread, only asynchronous calls are available. With Silverlight 3, you're limited to the `BasicHttpBinding` and `PollingDuplexHttpBinding` with WCF. However, you can also use binary encoding.

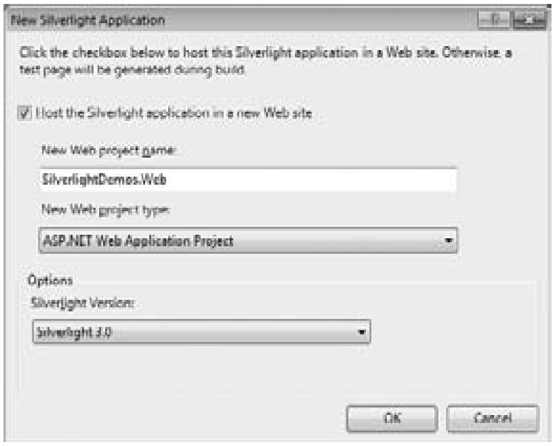
➤ **File system access** — Silverlight 3 applications are not allowed to read and write anywhere from the client system. You can read and write from isolated storage. `IsolatedStorageFile` and `IsolatedStorageFileStream` are available. Isolated storage is covered in Chapter 29, "Manipulating Files and the Registry." On a running Silverlight control you can click the right mouse button to get into the Silverlight menu, where several tabs are available with information and configuration options. The Application Storage tab gives information about the applications using data with isolated storage, and you have control to remove it. You can compare this with cookies of web applications; just the quotas are very different between cookies and the isolated storage. With Silverlight 4 more control on the file system is available.

➤ **Browser integration** — Because Silverlight controls typically run within a web browser, integration with the browser is important. You can define .NET classes that can be called from JavaScript, and also call into HTML and JavaScript from Silverlight .NET code with classes from the namespace `System.Windows.Browser`.

- **Media** — This is an important aspect of web applications that has special support in Silverlight. With streaming, you can use features such as progressive downloading and smooth streaming, and add timeline markers to streams. With the DeepZoom technology and the `MultiScaleImage` control, you can create an impressive user experience, allowing users to zoom into large images that are built up from several image files. To create DeepZoom images, you use the DeepZoom composer, which creates the Silverlight code to use the `MultiScaleImage` control.

CREATING A SILVERLIGHT PROJECT

When creating a new Silverlight project with Visual Studio, you're asked if a Web project should be created as well (see Figure 38-1). The Web project contains test pages to test the Silverlight application and contains the binary files from the Silverlight project. With the Web project type, you can choose between an ASP.NET Web Application Project and an ASP.NET MVC Web Project. ASP.NET MVC is shown in Chapter 42.



New Silverlight Application

Click the checkbox below to host this Silverlight application in a Web site. Otherwise, a test page will be generated during build.

☑ Host the Silverlight application in a new Web site

New Web project name:
SilverlightDemos.Web

New Web project type:
ASP.NET Web Application Project

Options
Silverlight Version:
Silverlight 3.0

FIGURE 38-1

The project that is created for this chapter is `SilverlightDemos`, with the Web project `SilverlightDemos.Web`. In the Visual Studio 2010 Web Project project settings is a tab labeled SilverlightApplications, which contains references to the Silverlight project in the solution and the path to the location that the binaries of the Silverlight project (the XAP file) should be copied to, usually the directory `ClientBin`.

The HTML test page contains an `object` tag that references the binary of a Silverlight control with the `source` parameter. The parameter `minRuntimeVersion` defines what version of the Silverlight runtime is needed on the client system. If the client system doesn't have the Silverlight runtime installed, a hyperlink is specified with a default image from a Microsoft site, as shown in Figure 38-2, to inform the user about the Microsoft Silverlight installation. When this test page starts, the Silverlight control is loaded in the web browser.

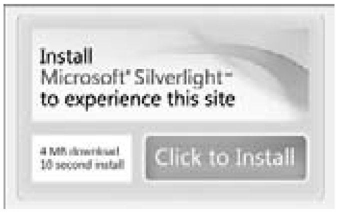


FIGURE 38-2

```
<object data="data:application/x-silverlight-2,"
        type="application/x-silverlight-2" width="100%" height="100%">
    <param name="source" value="ClientBin/SilverlightDemos.xap"/>
    <param name="onError" value="onSilverlightError" />
    <param name="background" value="white" />
    <param name="minRuntimeVersion" value="3.0.40818.0" />
    <param name="autoUpgrade" value="true" />
    <a href="http://go.microsoft.com/fwlink/?LinkID=149156&v=3.0.40818.0"
       style="text-decoration:none">
        <img src="http://go.microsoft.com/fwlink/?LinkId=161376"
             alt="Get Microsoft Silverlight" style="border-style:none"/>
    </a>
</object>
```

code snippet SilverlightDemos.Web/SilverlightDemosTestPage.html

NAVIGATION

One difference between Silverlight and WPF projects is how navigation between pages is handled. Of course, in web applications, navigation between pages is a common task.

To see navigation in action, create a new Visual Studio 2010 project of type Silverlight Navigation Application, named EventRegistration. This project template contains predefined styles, a main page, and a few pages in the Views folder that are navigated to.

`MainPage.xaml` contains a `Frame` element. This element is prefixed with the `navigation` alias, which references the .NET namespace `System.Windows.Controls` in the assembly `System.Windows.Controls.Navigation`. Another alias that is used here is `uriMapper`, which references the .NET namespace `System.Windows.Navigation` in the same assembly. The `Frame` element is used as a parent of the different pages. The first page that is loaded is changed from the default to the `/Welcome` page by setting the `Source` property. The `UriMapper` class converts a URI to an object. So instead of specifying `/Views/Welcome.xaml` as the navigation source page, just `/Welcome` is enough and is translated to the `Welcome.xaml` file in the Views directory.

All the styles that are referenced here are defined as resources in the file `Styles.xaml` file. This file is added to the application resource files in the file `App.xaml`.

```
<Border x:Name="ContentBorder" Style="{StaticResource ContentBorderStyle}">
    <navigation:Frame x:Name="ContentFrame"
                      Style="{StaticResource ContentFrameStyle}"
                      Source="/Welcome" Navigated="ContentFrame_Navigated"
                      NavigationFailed="ContentFrame_NavigationFailed">
        <navigation:Frame.UriMapper>
          <uriMapper:UriMapper>
            <uriMapper:UriMapping Uri="" MappedUri="/Views/Home.xaml"/>
            <uriMapper:UriMapping Uri="/{pageName}"
                                  MappedUri="/Views/{pageName}.xaml"/>
          </uriMapper:UriMapper>
        </navigation:Frame.UriMapper>
    </navigation:Frame>
</Border>
```

code snippet WCFRegistration/MainPage.xaml

`MainPage.xaml` contains a logo and application name section as well as `HyperlinkButton` controls to let the user navigate between the main pages of the application. The logo is specified with the resource `LogoIcon`, which is defined with a `Path` element in the file `Styles.xaml`. The style of the `HyperlinkButton` elements is also defined in the styles file. The `NavigateUri` property is set to a `Uri` that is mapped with the `UriMapper` definitions shown earlier.

```
<Grid x:Name="NavigationGrid" Style="{StaticResource NavigationGridStyle}">
    <Border x:Name="BrandingBorder"
            Style="{StaticResource BrandingBorderStyle}">
        <StackPanel x:Name="BrandingStackPanel"
                    Style="{StaticResource BrandingStackPanelStyle}">
            <ContentControl Style="{StaticResource LogoIcon}"/>
            <TextBlock x:Name="ApplicationNameTextBlock"
                       Style="{StaticResource ApplicationNameStyle}"
                       Text="CN innovation"/>
        </StackPanel>
    </Border>
    <Border x:Name="LinksBorder" Style="{StaticResource LinksBorderStyle}">
        <StackPanel x:Name="LinksStackPanel"
                    Style="{StaticResource LinksStackPanelStyle}">
            <HyperlinkButton x:Name="Link1"
                             Style="{StaticResource LinkStyle}"
                             NavigateUri="/Home" TargetName="ContentFrame"
                             Content="home"/>
            <Rectangle x:Name="Divider1"
                       Style="{StaticResource DividerStyle}"/>
            <HyperlinkButton x:Name="Link2"
                             Style="{StaticResource LinkStyle}"
```

```
                                          NavigateUri="/About" TargetName="ContentFrame"
                                          Content="about"/>
                </StackPanel>
            </Border>
        </Grid>
```

The Welcome page is shown with loading the Silverlight control because it is referenced directly with the `Source` property from the `Frame` element. This `Page` just contains a `TextBlock` element with information about the application, which is contained within a `Border` element for defining some visual effects that is contained within a `Canvas` element for positioning.

```
<navigation:Page x:Class="Wrox.ProCSharp.Silverlight.Views.Welcome"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
        xmlns:mc="http://schemas.openxmlformats.org/markup-compatibility/2006"
        xmlns:navigation="clr-namespace:System.Windows.Controls;
                          assembly=System.Windows.Controls.Navigation"
        Title="Welcome Page">
    <Canvas x:Name="LayoutRoot">
        <Canvas.Resources>
            <!-- Storyboard Resources -->
        </Canvas.Resources>

        <Border x:Name="border1" Canvas.Left="0" Canvas.Top="0" Width="240"
                Height="80" CornerRadius="9">
            <Border.Effect>
                <DropShadowEffect ShadowDepth="7" BlurRadius="3"
                                  Color="DarkGreen" />
            </Border.Effect>
            <Border.Background>
                <LinearGradientBrush StartPoint="0.5,0" EndPoint="0.5,1">
                    <GradientStop x:Name="gradient1" Offset="0"
                                  Color="DarkGreen" />
                    <GradientStop x:Name="gradient2" Offset="0.4" Color="Green" />
                    <GradientStop x:Name="gradient3" Offset="0.7"
                                  Color="MediumSeaGreen" />
                    <GradientStop x:Name="gradient4" Offset="0.9"
                                  Color="LightGreen" />
                </LinearGradientBrush>
            </Border.Background>

            <TextBlock HorizontalAlignment="Center" VerticalAlignment="Center"
                       Text="Event Registration" FontFamily="Comic Sans MS"
                       FontSize="24" Foreground="Wheat" />
        </Border>
    </Canvas>
</navigation:Page>
```

code snippet WCFRegistration/Views/Welcome.xaml

Within the `Resources` section of the `Canvas` element, two `Storyboard` elements are defined to do an animation. This is very similar to the animations you saw in Chapter 35 for WPF. Minor differences can be detected between these technologies with animations; for example, the animations with Silverlight don't define the `AccelerationRatio` and `DecelerationRatio` properties you know from WPF. However, you can get the same features using key-frame animations or with ease functions. Ease functions were in Silverlight before they became available in WPF, which was extended in .NET 4 to include this feature.

```
        <Canvas.Resources>
            <Storyboard x:Name="startStoryboard">
                <DoubleAnimation From="0" To="400" Duration="00:00:4"
```

```
                         Storyboard.TargetName="border1"
                         Storyboard.TargetProperty="(Canvas.Left)">
            <DoubleAnimation.EasingFunction>
                <CircleEase EasingMode="EaseIn" />
            </DoubleAnimation.EasingFunction>
        </DoubleAnimation>
        <DoubleAnimation From="0" To="300" Duration="00:00:4"
                         Storyboard.TargetName="border1"
                         Storyboard.TargetProperty="(Canvas.Top)">
            <DoubleAnimation.EasingFunction>
                <BounceEase Bounces="4" EasingMode="EaseIn" />
            </DoubleAnimation.EasingFunction>
        </DoubleAnimation>
    </Storyboard>
    <Storyboard x:Name="endStoryboard">
        <DoubleAnimation To="50" Duration="00:00:4"
                         Storyboard.TargetName="border1"
                         Storyboard.TargetProperty="(Canvas.Left)">
            <DoubleAnimation.EasingFunction>
                <CircleEase EasingMode="EaseOut" />
            </DoubleAnimation.EasingFunction>
        </DoubleAnimation>
        <DoubleAnimation To="50" Duration="00:00:4"
                         Storyboard.TargetName="border1"
                         Storyboard.TargetProperty="(Canvas.Top)">
            <DoubleAnimation.EasingFunction>
                <ElasticEase EasingMode="EaseOut" Springiness="4"
                             Oscillations="3" />
            </DoubleAnimation.EasingFunction>
        </DoubleAnimation>
        <ColorAnimation Duration="00:00:4"
                        Storyboard.TargetName="gradient1"
                        Storyboard.TargetProperty="Color" To="DarkBlue" />
        <ColorAnimation Duration="00:00:4"
                        Storyboard.TargetName="gradient2"
                        Storyboard.TargetProperty="Color" To="Blue" />
        <ColorAnimation Duration="00:00:4"
                        Storyboard.TargetName="gradient3"
                        Storyboard.TargetProperty="Color"
                        To="MediumBlue" />
        <ColorAnimation Duration="00:00:4"
                        Storyboard.TargetName="gradient4"
                        Storyboard.TargetProperty="Color" To="LightBlue" />
        <DoubleAnimation Duration="00:00:4" BeginTime="00:00:2"
                         Storyboard.TargetName="border1"
                         Storyboard.TargetProperty="Width" To="500" />
        <DoubleAnimation Duration="00:00:4" BeginTime="00:00:2"
                         Storyboard.TargetName="border1"
                         Storyboard.TargetProperty="Height" To="300" />
    </Storyboard>
</Canvas.Resources>
```

The first storyboard animation, `startStoryboard`, is started in the `OnNavigateTo` event handler by invoking the `Begin()` method. The `Completed` event of the first storyboard animation is set to a Lambda expression to start the second storyboard, `endStoryboard`, when the first is completed. When the second storyboard is completed, `NavigationService.Navigate()` is used to navigate to the Home page.

```
using System;
using System.Windows.Controls;
using System.Windows.Navigation;

namespace Wrox.ProCSharp.Silverlight.Views
{
    public partial class Welcome : Page
    {
        public Welcome()
        {
            InitializeComponent();
        }

        protected override void OnNavigatedTo(NavigationEventArgs e)
        {
            startStoryboard.Completed += (sender1, e1) =>
                {
                    endStoryboard.Completed += (sender2, e2) =>
                        NavigationService.Navigate(
                                new Uri("/Home", UriKind.Relative));
                    endStoryboard.Begin();
                };
            startStoryboard.Begin();
        }
    }
}
```

code snippet WCFRegistration/Views/Welcome.xaml.cs

When you run the application, you can see an animation and the hyperlink buttons, as shown in Figure 38-3.

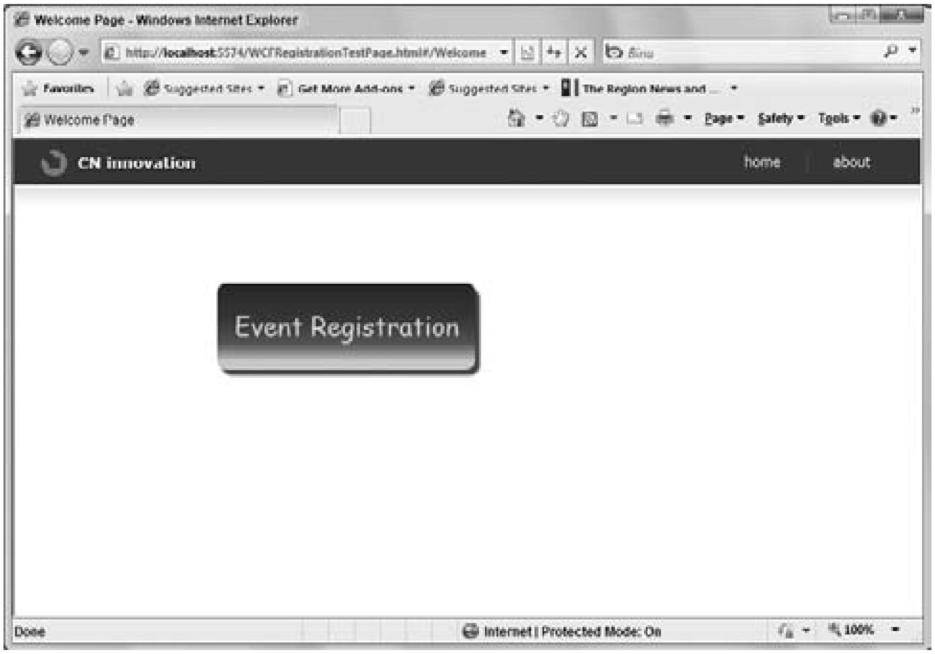

FIGURE 38-3

NETWORKING

With Silverlight, networking is in some ways the same as from the .NET Framework stack, but it is also different in important aspects. You have the socket classes `HttpRequest` and `WebClient` that you are familiar with from Chapter 24. WCF (Chapter 43) and WCF Data Services (Chapter 32) are available as well. However, only asynchronous methods are available to send and receive requests to and from the network. The UI thread shouldn't be blocked, as this can have a fatal effect for the user.

Before Silverlight 3.0, the only networking stack that could be used from Silverlight was the one that was offered by the browser. Since Silverlight 3.0, this is different; you can use a different HTTP stack as well.

One important restriction for applications running inside a browser on the client was that the client could only access networking services from the same server that the control came from. This has changed since Adobe's Flash technology, but the target server must support this. The Silverlight networking stack checks to see if a Silverlight Policy File named `clientaccesspolicy.xml` exists on the server. If such a file does not exist, Silverlight also accepts the file `crossdomain.xml`, which is the same file used with Adobe Flash. The second file is not checked if the first exists, and Silverlight doesn't use all entries from the `crossdomain.xml` file and requires that the entire domain be marked as public if this file is used.

A sample Silverlight Policy File, `clientaccesspolicy.xml`, is shown here. For the client domain `www.cninnovation.com`, access is granted to all subpaths. You can restrict the resources that the grant applies to, and also use an `*` for the domain URI to allow clients to come from anywhere.

```
<?xml version="1.0" encoding="utf-8"?>
<access-policy>
  <cross-domain-access>
    <policy>
      <allow-from http-request-headers="*">
        <domain uri="http://www.cninnovation.com"/>
      </allow-from>
      <grant-to>
        <resource path="/" include-subpaths="true"/>
      </grant-to>
    </policy>
  </cross-domain-access>
</access-policy>
```

Let's look at an example that uses networking stacks from Silverlight. For this, an ADO.NET Entity Data Model is created first, to read and write to and from a database across the network.

Creating an ADO.NET Entity Data Model

The sample Silverlight control is used to write attendee registration information to a database. First, the user must select from a list of events before he can register for an event. The database `EventRegistration` defines three tables: Events, Attendees, and RegistrationCodes, which are mapped to the ADO.NET Entity Data Model entity classes `Event`, `Attendee`, and `RegistrationCode`, as shown in Figure 38-4.

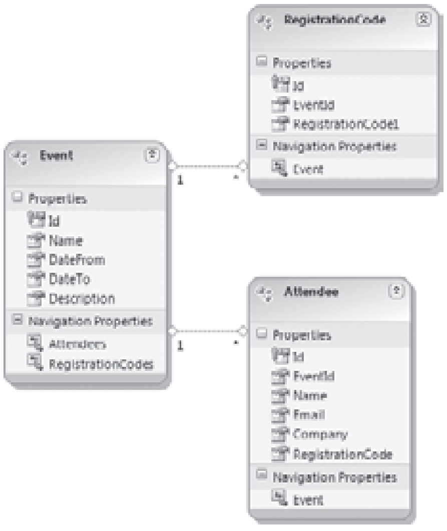

FIGURE 38-4

Creating a WCF Service for Silverlight Clients

To access the generated entity classes, a WCF service is created. The contract for the service is defined by the interface `IRegistrationService`. This service contract defines the operations `GetEvents()` and `RegisterAttendee()`. `GetEvents()` accepts a date range for the event selection and returns an array of `Event` objects as defined by the Entity Data Model. The operation `RegisterAttendee()` requires an `Attendee` object as argument and returns `true` or `false`, depending on the success or failure of the registration.

```
using System;
using System.ServiceModel;

namespace Wrox.ProCSharp.Silverlight.Web
{
    [ServiceContract]
    public interface IRegistrationService
    {
        [OperationContract]
        Event[] GetEvents(DateTime fromTime, DateTime toTime);

        [OperationContract]
        bool RegisterAttendee(Attendee attendee);
    }
}
```

code snippet SilverlightDemos.Web/IRegistrationService.cs

You can read information on WCF and defining service contracts in Chapter 43, "Windows Communication Foundation."

The service contract is implemented with the class `RegistrationService`. The method `GetEvents()` uses a LINQ query that accesses the entity framework's data context to get all events from a specific timeframe and returns an array of `Event` objects. The method `RegisterAttendee()` first verifies that the registration code is valid and adds the `Attendee` object to the database with the `SaveChanges()` method of the data context.

```
using System;
using System.Linq;
using System.ServiceModel.Activation;

namespace Wrox.ProCSharp.Silverlight.Web
{
    public class RegistrationService : IRegistrationService
    {
        public Event[] GetEvents(DateTime fromTime, DateTime toTime)
        {
            Event[] events = null;
            using (var data = new EventRegistrationEntities())
            {
                events = (from e in data.Events
                          where e.DateFrom >= fromTime && e.DateFrom <= toTime
                          select e).ToArray();

                foreach (var ev in events)
                {
                    data.Detach(ev);
                }
            }
            return events;
        }
```

```
            public bool RegisterAttendee(Attendee attendee)
            {
                using (EventRegistrationEntities data =
                        new EventRegistrationEntities())
                {
                    if ((from rc in data.RegistrationCodes
                            where rc.RegistrationCode1 == attendee.RegistrationCode
                            select rc).Count() < 1)
                    {
                        return false;
                    }
                    else
                    {
                        data.Attendees.AddObject(attendee);
                        if (data.SaveChanges() == 1)
                        {
                            return true;
                        }
                        else
                        {
                            return false;
                        }
                    }
                }
            }
        }
    }
```

code snippet SilverlightDemos.Web/RegistrationService.svc.cs

The default `BasicHttpBinding` that is used with WCF hosting in the ASP.NET web application is okay for use by Silverlight clients, and thus doesn't need any configuration. The only configuration needed to make it possible to add a service reference from Visual Studio is to allow the publishing of metadata with the `HTTP GET` protocol as shown.

```
<system.serviceModel>
  <behaviors>
    <serviceBehaviors>
      <behavior name="">
        <serviceMetadata httpGetEnabled="true" />
        <serviceDebug includeExceptionDetailInFaults="false" />
      </behavior>
    </serviceBehaviors>
  </behaviors>
</system.serviceModel>
```

code snippet SilverlightDemos.Web/Web.config

Starting with Silverlight 3, it is possible to configure a binary encoding with the HTTP transport. Silverlight 3 implements this encoding to allow for better performance. This custom binding is used by default if you add a Silverlight-enabled WCF Service.

Calling WCF Services

Before calling the service, a UI needs to be created. In the same Silverlight project as before, where the animation was done, the `Home.xaml` page is changed to include `ComboBox` and `TextBox` controls to allow entering information for an event and registering for the event. The design view of the application is shown in Figure 38-5.

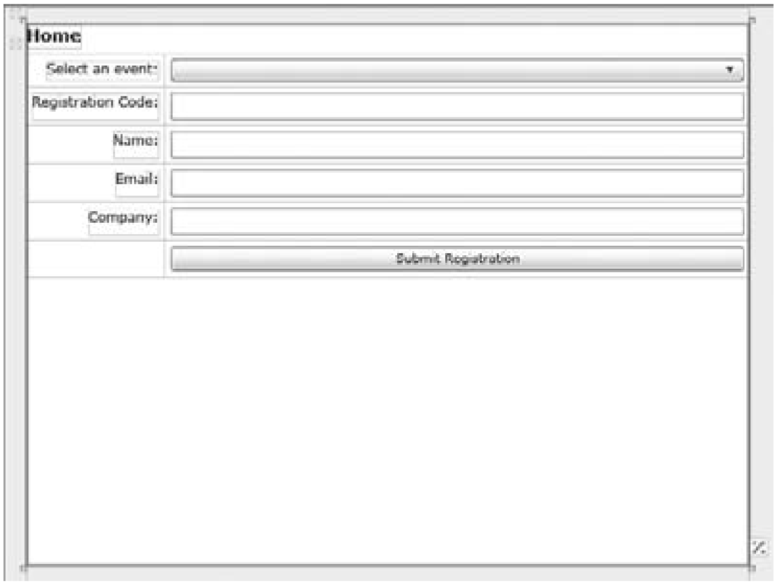

FIGURE 38-5

The `ComboBox` binds to the `EventList` property of the data context and uses a `DataTemplate` with two `TextBlock` elements that bind to the `Name` and `DateFrom` properties of the items.

```
<ComboBox x:Name="comboEvents"
          ItemsSource="{Binding Path=EventList, Mode=OneWay}"
          Grid.Row="0" Grid.Column="1" Margin="5"
          VerticalAlignment="Center">
    <ComboBox.ItemTemplate>
        <DataTemplate>
            <StackPanel Orientation="Vertical">
                <TextBlock Text="{Binding Path=Name}" />
                <TextBlock Text="{Binding Path=DateFrom}" />
            </StackPanel>
        </DataTemplate>
    </ComboBox.ItemTemplate>
</ComboBox>
```

code snippet WCFRegistration/Views/Home.xaml

For data input, the control uses several `TextBox` elements that bind to properties of the `Attendee` object that is returned by the `CurrentAttendee` property. With WPF, the default binding mode depends on the control where it is used; with Silverlight, the default binding mode is `OneWay` and thus needs to be changed for two-way bindings. The `Button` element has the handler method `OnRegistration()` associated to the `Click` event.

```
<TextBox Grid.Row="1" Grid.Column="1" Margin="5"
         Text="{Binding Path=CurrentAttendee.RegistrationCode,
                        Mode=TwoWay}" />
<TextBox Grid.Row="2" Grid.Column="1" Margin="5"
         Text="{Binding Path=CurrentAttendee.Name,
                        Mode=TwoWay}" />
<TextBox Grid.Row="3" Grid.Column="1" Margin="5"
         Text="{Binding Path=CurrentAttendee.Email,
                        Mode=TwoWay}" />
```

```
                    <TextBox Grid.Row="4" Grid.Column="1" Margin="5"
                             Text="{Binding Path=CurrentAttendee.Company,
                                            Mode=TwoWay}" />
                    <Button Grid.Row="5" Grid.Column="1"
                            Content="Submit Registration" Margin="5"
                            Click="OnRegistration" />
```

In the code-behind, the `DataContext` of the Silverlight page is set to this to map the `EventList` and `CurrentAttendee` properties.

```
using System.Collections.ObjectModel;
using System.Windows;
using System.Windows.Controls;
using System.Windows.Navigation;
using  Wrox.ProCSharp.Silverlight.RegistrationService;

namespace Wrox.ProCSharp.Silverlight
{
    public partial class Home : Page
    {
        public Home()
        {
            CurrentAttendee = new Attendee();
            EventList = new ObservableCollection<Event>();
            InitializeComponent();

            this.DataContext = this;
        }

        public ObservableCollection<Event> EventList { get; private set; }
        public Attendee CurrentAttendee { get; private set; }
```

code snippet WCFRegistration/Views/Home.xaml.cs

By adding a service reference to the `RegistrationService`, only the asynchronous methods are created with the proxy class. This proxy class uses the async component pattern.

The overridden method `OnNavigatedTo()` is invoked on navigation to the page. Here, the operation `GetEvents` of the WCF service is invoked by calling the method `GetEventsAsync()`. On completion of the asynchronous operation, the event `GetEventsCompleted` is fired. A Lambda expression is assigned to this event to add the returned events to the `eventList` collection. Because `eventList` is an `ObservableCollection<T>`, the user interface is updated about changes of this list.

```
        protected override void OnNavigatedTo(NavigationEventArgs e)
        {
            var client = new RegistrationServiceClient();
            client.GetEventsCompleted += (sender, e1) =>
                {
                    if (e1.Error != null)
                    {

                    }
                    else
                    {
                        foreach (var ev in e1.Result)
                    {
                        EventList.Add(ev);
                    }
                }
            };
        client.GetEventsAsync(DateTime.Today, DateTime.Today.AddMonths(2));
    }
```

The method `OnRegistration()` is invoked when the `Click` event of the Submit Registration button is fired. Here again, an asynchronous method is invoked: `RegisterAttendeeAsync()` to register the attendee. On completion of this method, `NavigationService.Navigate()` is used to navigate the user to a different page.

```
    private void OnRegistration(object sender, RoutedEventArgs e)
    {
        var client = new RegistrationServiceClient();
        CurrentAttendee.EventId = (comboEvents.SelectedItem as Event).Id;
        client.RegisterAttendeeCompleted += (sender1, e1) =>
            {
                if (e1.Error == null)
                {
                    if (e1.Result)
                    {
                        NavigationService.Navigate(
                                new Uri("/Success", UriKind.Relative));
                    }
                    else
                    {
                        NavigationService.Navigate(
                                new Uri("/ErrorPage", UriKind.Relative));
                    }
                }
                else
                {
                    // display error
                }
            };
        client.RegisterAttendeeAsync(CurrentAttendee);
    }
```

Now the Silverlight application can be started to invoke the WCF Web service.

Using WCF Data Services

Silverlight also gives you access to the client part of WCF Data Services. With this, you can use HTTP requests to retrieve and update data from the Silverlight control without the need to manually define service methods. Retrieving, updating, and adding new data can be done with simple HTTP requests.

WCF Data Services is covered in Chapter 32, "Data Services."

To offer a service using WCF Data Services for the Silverlight application, a new WCF Data Service item named `EventRegistrationDataService` is added to the Web project. The implementation derives from `DataService<EventRegistrationEntities>`. The generic parameter for the base class `DataService<T>` is the entity data context that was created by the template for the ADO.NET Entity Framework. With `config.SetEntitySetAccessRule()`, access rules are defined to allow read and all access to the Events entity set and the Attendees entity set.

```
using System.Collections.Generic;
using System.Data.Services;
using System.Data.Services.Common;
using System.Linq;
using System.ServiceModel.Web;

namespace Wrox.ProCSharp.Silverlight.Web
{
    public class EventRegistrationDataService :
            DataService<EventRegistrationEntities>
    {
        public static void InitializeService(DataServiceConfiguration config)
        {
            config.SetEntitySetAccessRule("Events", EntitySetRights.AllRead);
            config.SetEntitySetAccessRule("Attendees", EntitySetRights.All);
            config.SetServiceOperationAccessRule("AddAttendee",
                    ServiceOperationRights.All);
            config.DataServiceBehavior.MaxProtocolVersion =
                    DataServiceProtocolVersion.V2;
        }
```

code snippet SilverlightDemos.Web/EventRegistrationDataService.svc.cs

To make an operation available for registration of an attendee using WCF Data Services that is more complex than just adding a new record, the method `AddAttendee()` is added to the class `EventRegistrationDataService`. The `WebGet` attribute specifies that the method can be accessed with an `HTTP GET` request. For `POST`, `PUT`, or `DELETE` requests, the `WebInvoke` attribute can be used. Within the `InitializeService()` method, access is given to this operation with the method `SetServiceOperationAccessRule()`. `AddAttendee()` receives attendee information with separate parameters and first verifies that the `registrationCode` exists before writing the attendee to the `Attendees` table that is mapped from the Entity Data Model. Using separate parameters with this method instead of using an `Attendee` object is required to call this method with an `HTTP GET` request.

```
        [WebGet]
        public bool AddAttendee(string name, string email, string company,
                                string registrationCode, int eventId)
        {
            if ((from rc in this.CurrentDataSource.RegistrationCodes
                 where rc.RegistrationCode1 == registrationCode
                 select rc).Count() < 1)
            {
                return false;
            }
            else
            {
                var attendee = new Attendee {
                    Name = name,
                    Email = email,
                    Company = company,
                    RegistrationCode = registrationCode,
                    EventId = eventId
                };
                this.CurrentDataSource.Attendees.AddObject(attendee);
                return !(this.CurrentDataSource.SaveChanges() < 1);
            }
        }
    }
}
```

Adding a service reference to the Silverlight control project `EventRegistration` makes it possible to use the WCF Data Services client classes to access the service. The method `OnNavigatedTo()` is now changed to use the generated proxy from the Data Services client instead of the pure WCF proxy used earlier.

EventRegistrationEntities is a class generated from adding the service reference and derives from DataServiceContext in the namespace System.Data.Services.Client. This class defines a context for the client to keep tracking and changing information and to create HTTP requests out of LINQ queries. A LINQ query is defined to get all the events from a specific date range. What's different here compared to WCF Data Services is that synchronous methods are not available, but this is to be expected. Calling the query as it is defined by the variable q results in a NotSupportedException. Instead, you must invoke the BeginExecute() method of the DataServiceQuery<T> class. This method uses the async pattern and accepts an AsyncCallback delegate as a first parameter. Here, a Lambda expression is passed to this delegate parameter, which is invoked as soon as the data is returned from the service. Calling EndExecute() retrieves the returned data and writes it to the ObservableCollection<T>.

```
protected override void OnNavigatedTo(NavigationEventArgs e)
{
    Uri serviceRoot =
            new Uri("EventRegistrationDataService.svc", UriKind.Relative);
    var data = new EventRegistrationEntities(serviceRoot);
    var q = from ev in data.Events
            where ev.DateFrom >= DateTime.Today &&
                  ev.DateFrom <= DateTime.Today.AddMonths(2)
            select ev;

    DataServiceQuery<Event> query = (DataServiceQuery<Event>)q;
    query.BeginExecute(ar =>
        {
            var query1 = ar.AsyncState as DataServiceQuery<Event>;
            var events = query1.EndExecute(ar);
            foreach (var ev in events)
            {
                EventList.Add(ev);
            }
        }, query);
}
```

code snippet EventRegistration/Home.xaml.cs

Calling the method AddAttendee() is done with the WebClient class from the System.Net namespace, shown next.

Using System.Net to Access the Service

As the AddAttendee method offered by the service can be directly accessed with an HTTP GET request, this request can easily be done with classes from the System.Net namespace such as WebClient or HttpWebRequest. Of course, with Silverlight only async methods are available. The WebClient class implements the async component pattern; the HttpWebRequest class implements the async pattern.

The System.Net *namespace is covered in Chapter 24, "Networking."*

The changed implementation of the OnRegistration event handler method now makes use of the WebClient class. Calling the method DownloadStringAsync() starts the request passing the URL string to the method. With a GET request, all parameters are defined with the URL string. As soon as the data is returned from the services, the event DownloadStringCompleted is fired with the WebClient class. Here, a Lamba expression is created to parse the Boolean return value from the XML message. Depending on the result, navigation either goes to the Success or ErrorPage.

```
            private void OnRegistration(object sender, RoutedEventArgs e)
             {
                 CurrentAttendee.EventId = (comboEvents.SelectedItem as Event).Id;

                 var client = new WebClient();
                 client.DownloadStringCompleted += (sender1, e1) =>
                     {
                         if (e1.Error != null)
                         {
                             NavigationService.Navigate(
                                     new Uri("/ErrorPage", UriKind.Relative));
                         }

                         bool result = bool.Parse(XElement.Parse(e1.Result).Value);
                         if (result)
                             NavigationService.Navigate(
                                     new Uri("/Success", UriKind.Relative));
                         else
                             NavigationService.Navigate(
                                     new Uri("/ErrorPage", UriKind.Relative));

                     };
                 Uri requestUri = new Uri(String.Format(
                     "../../EventRegistrationDataService.svc/AddAttendee?name='{0}'" +
                     "&email='{1}'&company='{2}'&registrationCode='{3}'&eventid={4}",
                     CurrentAttendee.Name, CurrentAttendee.Email,
                     CurrentAttendee.Company, CurrentAttendee.RegistrationCode,
                     CurrentAttendee.EventId), UriKind.Relative);
                 client.DownloadStringAsync(requestUri);
             }
         }
     }
```

code snippet EventRegistration/Home.xaml.cs

When you run the application, you can register for an event.

Since version 3 of Silverlight, the Silverlight application does not have to use the networking stack from the browser. The networking stack from the browser is limited in the methods of the HTTP requests it can perform and returns only limited information on the response status codes. However, now it's possible to use a different networking stack that can be selected with the `WebRequestCreator` class from the `System.Net.Browser` namespace. The following code snippet changes the networking stack to `ClientHttp`. `BrowserHttp` is the second option in `WebRequestCreator`. This change switches the networking stack to use all the networking options you've seen.

```
    bool result = WebRequest.RegisterPrefix("http://", WebRequestCreator.ClientHttp);
```

BROWSER INTEGRATION

Integration with a web browser often is an important part of using Silverlight. Silverlight 1.0 could only be programmed using JavaScript. Luckily, this changed with Silverlight 2.0, but there are still many scenarios where you might want to control HTML and JavaScript code from within the Silverlight control or invoke .NET methods from JavaScript. Both are possible with the help of the namespace `System.Windows.Browser`.

To demonstrate this integration by using the existing web solution, the following example creates a new Silverlight project named `JavaScriptInterop`. This control is used to demonstrate both calling out to the HTML code from within the Silverlight control and to invoke .NET methods from JavaScript.

Calling out to JavaScript

To call into the HTML page from the Silverlight control, the HTML test page `JavaScriptInteropTestPage.html` gets an HTML `Button` control with the name `button1`. This button will be changed from within the Silverlight control.

```
<form id="form1" runat="server" style="height: 100%">
  <input id="button1" type="button" value="Click me!" />
```

code snippet SilverlightDemos.Web/JavaScripInteropTestPage.html

The XAML code from the Silverlight control has a `TextBox` and a `Button` control. The `TextBox` allows you to enter text that will show up on the HTML button.

```
<TextBox Grid.Row="0" Grid.Column="0" x:Name="text1" Margin="5" />
<Button Grid.Row="0" Grid.Column="1" Content="Set value for HTML button"
        Click="OnChangeHtml" Margin="5" />
<TextBlock Grid.Row="1" Grid.Column="0" Grid.ColumnSpan="2" Margin="5"
           Text="" x:Name="text2" />
```

code snippet JavaScriptInterop/MainPage.xaml

In the handler of the `Click` event of the `Button`, the method `OnChangeHtml()`, the `button1` HTML element is accessed by invoking the `GetElementById()` method of the `HtmlDocument`. If you're used to the DOM model of HTML, the code here looks very similar. Using the `HtmlElement`, attributes from the HTML element can be changed; for example, the value attribute can be changed to `text1.Text` to set it to the text input from the user.

```
private void OnChangeHtml(object sender, RoutedEventArgs e)
{
    HtmlDocument doc = HtmlPage.Document;
    HtmlElement element = doc.GetElementById("button1");
    element.SetAttribute("value", text1.Text);
}
```

code snippet JavaScriptInterop/MainPage.xaml.cs

You can also add event handlers to HTML elements by invoking the `AttachEvent()` method on an `HtmlElement`, as shown next. Here, the method `OnChangeHtmlButtonClick()` is assigned to the `onclick` event of the HTML button `button1`.

```
public MainPage()
{
    InitializeComponent();
    HtmlDocument doc = HtmlPage.Document;
    HtmlElement element = doc.GetElementById("button1");
    element.AttachEvent("onclick", OnHtmlButtonClick);
}

private void OnHtmlButtonClick(object sender, HtmlEventArgs e)
{
    text2.Text = "HTML button onclick fired";
}
```

With the classes from the namespace `System.Windows.Browser`, you can access all the information from HTML. `HtmlPage`, `HtmlDocument`, `HtmlWindow`, `HtmlPage`, and `HtmlObject` are the most important classes for accessing browser information, cookies, elements from the page, and style sheets, and reading and changing content. It also works the other way around; calling from JavaScript into Silverlight is shown next.

JavaScript Calling Silverlight

To make a .NET method available from JavaScript, the attribute `ScriptableMember` must be applied. If you would like to make all members of a class available from JavaScript, you can apply the attribute `ScriptableType` instead. Here, the attribute `ScriptableMember` is applied to the method `ToUpper()`, which changes the input string to uppercase.

```
[ScriptableMember]
public string ToUpper(string s)
{
    return s.ToUpper();
}
```

code snippet JavaScriptInterop/MainPage.xaml.cs

The type containing scriptable members must be registered with the HTML page so that it can be found by scripting. This is done by invoking the `RegisterScriptableObject()` method from the `HtmlPage` class. The first argument of this method is a key name that is used by JavaScript to find the object. The second argument defines the instance that is used to access the scriptable members.

```
public MainPage()
{
    InitializeComponent();
    //...

    HtmlPage.RegisterScriptableObject("ScriptKey", this);
}
```

Now it is possible to access the .NET code from JavaScript. To find the scriptable object from JavaScript, the Silverlight control must be accessed. To make this easier, an `id` attribute is added to the `object` tag that references the Silverlight package. Also, text and button elements are added to the HTML code. The button has the JavaScript function `callDotnet()` assigned to the `onclick` event where the call to managed code happens.

```
<input id="text1" type="text" />
<input id="button2" type="button" value="Convert with a .NET method"
       onclick="callDotnet()" />
<div id="silverlightControlHost">
    <object id="plugin" data="data:application/x-silverlight-2,"
            type="application/x-silverlight-2"
        width="30%" height="30%">
        <param name="source" value="ClientBin/JavaScriptInterop.xap" />
        <param name="onError" value="onSilverlightError" />
        <param name="background" value="white" />
        <param name="minRuntimeVersion" value="3.0.40818.0" />
        <param name="autoUpgrade" value="true" />
        <a href="http://go.microsoft.com/fwlink/?LinkID=149156&v=3.0.40818.0"
           style="text-decoration: none">
            <img src="http://go.microsoft.com/fwlink/?LinkId=161376"
                alt="Get Microsoft Silverlight" style="border-style: none" />
        </a>
    </object>
```

code snippet SilverlightDemos.Web/JavaScripInteropTestPage.html

The JavaScript function `callDotnet()` uses the plugin identifier to find the Silverlight control with `getElementById()`. By using the `ScriptKey` defined earlier with the registration, the scriptable type can now be accessed. Using this scriptable type, the method `ToUpper()` is now available to change the input to uppercase.

```
function callDotnet() {
    var plugin = document.getElementById("plugin");
```

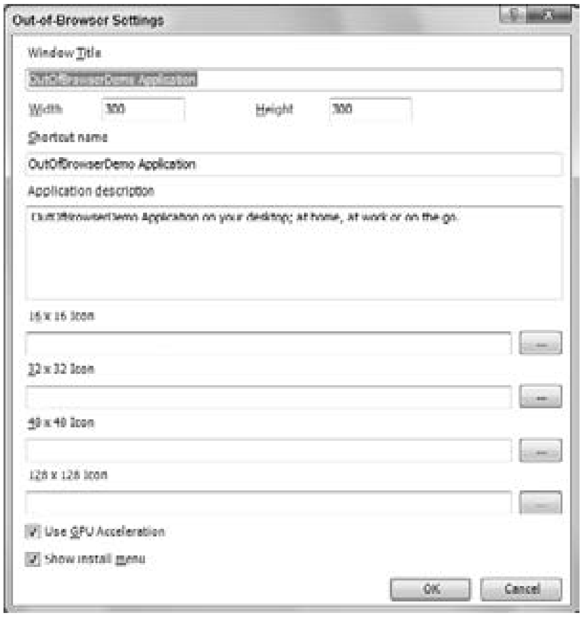
```
            var dotnet = plugin.content.ScriptKey;
            var input = document.getElementById("text1").value;
            var output = dotnet.ToUpper(input);
            document.getElementById("text1").value = output;
        }
```

If you don't plan to make your web site solely with Silverlight but want to mix in ASP.NET or HTML features and enhance it with Silverlight, the browser integration features come in very handy.

SILVERLIGHT OUT-OF-BROWSER APPLICATIONS

Since version 3 of Silverlight, Silverlight applications can also run out of browser. The application can be installed from a user without administrator privileges. However, the application is still restricted to a security sandbox and doesn't have full trust on the client system. What is the advantage of a Silverlight out-of-browser application compared to WPF? With Silverlight, it's not necessary to install the .NET Framework, only the Silverlight runtime that's installed with the browser plugin is necessary. Because this plugin is available on different platforms, out-of-browser applications can run on many more platforms than WPF applications.

With the Silverlight project settings of Visual Studio 2010, you can click the check box to enable running the application out of the browser and change out-of-browser settings as shown in Figure 38-6. With these settings, you can define application icons, title, description, and also if GPU acceleration should be used, which can be a great performance advantage with special graphics. By marking the check box for Show install menu, an installation option for the user is available on clicking the right mouse button on the Silverlight control.



Out-of-Browser Settings

Window Title: OutOfBrowserDemo Application

Width: 300   Height: 300

Shortcut name: OutOfBrowserDemo Application

Application description: OutOfBrowserDemo Application on your desktop; at home, at work or on the go.

16 x 16 Icon:

32 x 32 Icon:

48 x 48 Icon:

128 x 128 Icon:

☑ Use GPU Acceleration

☑ Show install menu

FIGURE 38-6

You can control installation and updates from the Silverlight application, as demonstrated next with the project `OutOfBrowserDemo` and a user interface that contains two `Button` and a `TextBlock` control. The first button, `installButton`, has the event handler method `OnInstall()` associated with it so that the user can install the application on the client system, and the button `updateButton` with the event handler `OnUpdate()` to check for available updates.

```
<Grid x:Name="LayoutRoot" Background="White">
    <Grid.RowDefinitions>
        <RowDefinition />
        <RowDefinition />
        <RowDefinition />
    </Grid.RowDefinitions>
    <Button x:Name="installButton" Grid.Row="0"
        Content="Install Out-of-Browser" Click="OnInstall" Margin="5" />
    <TextBlock x:Name="text1" Grid.Row="1" FontSize="24"
        HorizontalAlignment="Center" VerticalAlignment="Center" />
        <Button x:Name="updateButton" Grid.Row="2" Content="Check for Updates"
            Click="OnUpdate" Margin="5" />
    </Grid>
```

code snippet OutOfBrowserDemo/MainPage.xaml

The constructor `MainPage` checks whether the application is running out of browser or within the browser and sets the text of the `TextBlock` control accordingly. To check if the application is running out of browser, you can use the `IsRunningOutOfBrowser` property of the `Application` class. This class also provides information about the installation state of the application with the `InstallState` property. Possible values are `NotInstalled`, `Installing`, `Installed`, and `InstallFailed` with the `InstallState` enumeration. Using this information, the `installButton` and `updateButton` controls are visible or collapsed.

```
public MainPage()
{
    InitializeComponent();
    if (App.Current.IsRunningOutOfBrowser)
    {
        text1.Text = "running out of browser";
    }
    else
    {
        text1.Text = "running in the browser";
        updateButton.Visibility = Visibility.Collapsed;
    }
    if (App.Current.InstallState == InstallState.Installed)
    {
        installButton.Visibility = Visibility.Collapsed;
    }
}
```

code snippet OutOfBrowserDemo/MainPage.xaml.cs

The event handler `OnInstall()` is invoked by clicking the associated button. An installation happens just by invoking the `Install()` method of the `Application` class.

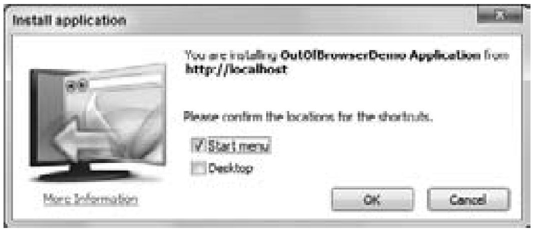
```
private void OnInstall(object sender, RoutedEventArgs e)
{
    if (App.Current.InstallState == InstallState.NotInstalled)
    {
        bool result = App.Current.Install();
        if (result)
            text1.Text = "installation successful";
    }
}
```

Checking for an update on the server can be done programmatically with the `Application` class as well. Here, the update is done in the event handler method `OnUpdate()`. `CheckAndDownloadUpdateAsync()` checks for an available update and installs the update. This is an asynchronous operation using the async component pattern that fires the event `CheckAndDownloadUpdateCompleted` on completion of the update. Success or error information is written in the handler of this event. After a successful update, the new version is available on the next start.

```
private void OnUpdate(object sender, RoutedEventArgs e)
{
    App.Current.CheckAndDownloadUpdateCompleted += (sender1, e1) =>
        {
            if (e1.Error != null)
            {
                text1.Text = e1.Error.Message;
            }
```

```
                    else
                    {
                        if (e1.UpdateAvailable)
                            text1.Text =
                                "Update successful and will be used with the next start";
                    }
                };
            App.Current.CheckAndDownloadUpdateAsync();
        }
```

Running the application — first in the browser — you can click the Install button, which opens the dialog shown in Figure 38-7. The user can choose to have an application shortcut available in the start menu and on the desktop. After installation, the application can also be started out of browser.



You are installing **OutOfBrowserDemo Application** from **http://localhost**

Please confirm the locations for the shortcuts.

[✓] Start menu
[ ] Desktop

FIGURE 38-7

After you make some changes in the Silverlight project, you can check for updates by clicking the Update button. To get rid of the application, click the right mouse button to open the context menu and remove the application.

SUMMARY

In this chapter, you've seen the rich Silverlight framework, which includes a subset of the functionality of WPF applications and also some enhancements based on the functionality needed for applications running on the Web.

You've seen how to create Silverlight projects and how they differ from WPF, and how to integrate with the browser, run Silverlight applications out of the browser, and use networking features to access resources on the server.

In the next chapter, you read about a traditional technology for user interfaces: Windows Forms.

39 Windows Forms

WHAT'S IN THIS CHAPTER?

- The Form class
- The class hierarchy of Windows Forms
- The controls and components that are part of the System.Windows.Forms namespace
- Menus and toolbars
- Creating user controls

Web-based applications have taken off over the past several years and are fast becoming the standard. The ability to have all of your application logic reside on a centralized server is very appealing from an administrator's viewpoint. The downside of Web-based applications is that they typically don't provide a rich user experience. The .NET Framework has given developers the ability to create rich, smart client applications and eliminate the deployment problems and "DLL Hell" that existed before. Whether you choose to use Windows Forms or Windows Presentation Foundation (see Chapter 35, "Core WPF"), client applications are no longer difficult to develop or deploy.

Windows Forms will seem familiar if you are a Visual Basic developer. You create new forms (also known as windows or dialogs) in much the same way that you drag and drop controls from a toolbox onto the Form Designer. However, if your background is in the classic C style of Windows programming, where you create the message pump and monitor messages, or if you're an MFC programmer, you will find that you're able to get to the lower-level internals if you need to. You can override the window procedure and catch messages, but you might be surprised that you really won't need to very often.

CREATING A WINDOWS FORMS APPLICATION

In this example, you'll create a very simple Windows Forms application (the rest of the chapter uses a single example application, which can be found in the `03 MainExample` folder in the download code zip file.). This first example does not use Visual Studio .NET. It has been entered in a text editor and compiled using the command-line compiler.

```
using System;
using System.Windows.Forms;
namespace NotepadForms
{
  public class MyForm: System.Windows.Forms.Form
  {
    public MyForm()
    {
    }
    [STAThread]
    static void Main()
    {
      Application.Run(new MyForm());
    }
  }
}
```

code snippet 01 MyForm/NotepadForms.cs

When you compile and run this example, you will get a small blank form without a caption. The application is not terribly useful, but it serves to show a minimal implementation.

As you look at the code two items deserve attention. The first is the fact that you have used inheritance to create the `MyForm` class. The following line declares that `MyForm` is derived from the `System.Windows.Forms.Form` class:

```
public class MyForm: System.Windows.Forms.Form
```

The `Form` class is one of the main classes in the `System.Windows.Forms` namespace. The other section of code that you want to look at is:

```
[STAThread]
static void Main()
{
  Application.Run(new MyForm());
}
```

`Main` is the default entry point into any C# client application. Typically in larger applications, the `Main()` method would not be in a form, but instead would be in a separate class. In this case, you would set the startup class name in the project properties dialog box. Notice the attribute `[STAThread]`. This sets the COM threading model to single-threaded apartment (STA). The STA threading model is required for COM interop and is added by default to a Windows Forms project.

The `Application.Run()` method is responsible for starting the standard application message loop. `ApplicationRun()` has three overloads: the first takes no parameter, the second takes an `ApplicationContext` object as a parameter, and the one you see in the example takes a form object as a parameter. In the example, the `MyForm` object will become the main form of the application. This means that when this form is closed, the application ends. By using the `ApplicationContext` class, you can gain a little more control over when the main message loop ends and the application exits.

The `Application` class contains some very useful functionality. It provides a handful of static methods and properties for controlling the application's starting and stopping process and to gain access to the Windows messages that are being processed by the application. The following table lists some of the more useful of these methods and properties.

METHOD/PROPERTY	DESCRIPTION
`CommonAppDataPath`	The path for the data that is common for all users of the application. Typically, this is `BasePath\Company Name\Product Name\Version`, where `BasePath` is `C:\Documents and Settings\username\ApplicationData`. If it does not exist, the path will be created.
`ExecutablePath`	This is the path and filename of the executable file that starts the application.
`LocalUserAppDataPath`	Similar to `CommonAppDataPath` with the exception that this property supports roaming.

METHOD/PROPERTY	DESCRIPTION
`MessageLoop`	Returns `true` if a message loop exists on the current thread; `false` otherwise.
`StartupPath`	Similar to `ExecutablePath`, except that the filename is not returned.
`AddMessageFilter`	Used to preprocess messages. By implementing an `IMessageFilter`-based object, the messages can be filtered from the message loop, or special processing can take place prior to the message being passed to the loop.
`DoEvents`	Similar to the Visual Basic `DoEvents` statement. Allows messages in the queue to be processed.
`EnableVisualStyles`	Enables XP visual styles for the various visual elements of the application. There are two overloads that will accept manifest information. One is a stream of the manifest, and the other is the full name and path of the location where the manifest exists.
`Exit and ExitThread`	`Exit` ends all currently running message loops and exits the application. `ExitThread` ends the message loop and closes all windows on the current thread.

Now, what does this sample application look like when it is generated in Visual Studio? The first thing to notice is that two files are created because Visual Studio takes advantage of the partial class feature of the Framework and separates all of the Designer-generated code into a separate file. Using the default name of Form1, the two files are `Form1.cs` and `Form1.Designer.cs`. (Unless you have the Show All Files option checked on the Project menu, you won't see `Form1.Designer.cs` in Solution Explorer.) Following is the code that Visual Studio generates for the two files. First is `Form1.cs`:

```
using System;
using System.Collections.Generic;
using System.ComponentModel;
using System.Data;
using System.Drawing;
using System.Linq;
using System.Text;
using System.Windows.Forms;
namespace VisualStudioForm
{
  public partial class Form1: Form
  {
    public Form1()
    {
      InitializeComponent();
    }
  }
}
```

code snippet Form1.cs

This is pretty simple, a handful of using statements and a simple constructor. Here is the code in `Form1.Designer.cs`:

```
namespace VisualStudioForm
{
  partial class Form1
  {
    /// <summary>
    /// Required designer variable.
    /// </summary>
    private System.ComponentModel.IContainer components = null;
    /// <summary>
    /// Clean up any resources being used.
    /// </summary>
    /// <param name="disposing">true if managed resources
 /// should be disposed; otherwise, false.</param>
```

```
        protected override void Dispose(bool disposing)
        {
          if (disposing && (components != null))
          {
            components.Dispose();
          }
          base.Dispose(disposing);
        }
        #region Windows Form Designer generated code
        /// <summary>
        /// Required method for Designer support—do not modify
        /// the contents of this method with the code editor.
        /// </summary>
        private void InitializeComponent()
        {
          this.components =
         new System.ComponentModel.Container();
          this.AutoScaleMode =
           System.Windows.Forms.AutoScaleMode.Font;
          this.Text = "Form1";
        }
        #endregion
      }
    }
```

code snippet Form1.Designer.cs

The Designer file of a form should rarely be edited directly. The only exception is if there is any special processing that needs to take place in the `Dispose` method. The `InitializeComponent` method is discussed later in this chapter.

Looking at the code as a whole for this sample application, you can see it is much longer than the simple command-line example. There are several `using` statements at the start of the class; most are not necessary for this example. There is no penalty for keeping them there. The class `Form1` is derived from `System.Windows.Forms.Form` just like the earlier Notepad example, but things start to get different at this point. First, there is this line in the `Form1.Designer` file:

```
private System.ComponentModel.IContainer components = null;
```

In the example, this line of code doesn't really do anything. When you add a component to a form, you can also add it to the `components` object, which is a container. The reason for adding to this container has to do with disposing of the form. The form class supports the `IDisposable` interface because it is implemented in the `Component` class. When a component is added to the `components` object, this container will make sure that the components are tracked properly and disposed of when the form is disposed of. You can see this if you look at the `Dispose` method in the code:

```
protected override void Dispose(bool disposing)
{
  if (disposing && (components != null))
  {
    components.Dispose();
  }
  base.Dispose(disposing);
}
```

Here you can see that when the `Dispose` method is called, the `Dispose` method of the `components` object is also called, and because the `component` object contains the other components, they are also disposed of.

The constructor of the `Form1` class, which is in the `Form1.cs` file, looks like this:

```
public Form1()
{
  InitializeComponent();
}
```

Notice the call to InitializeComponent(). InitializeComponent() is located in Form1.Designer.cs and does pretty much what it describes, and that is to initialize any controls that might have been added to the form. It also initializes the form properties. For this example, InitializeComponent() looks like the following:

```
private void InitializeComponent()
{
this.components = new System.ComponentModel.Container();
this.AutoScaleMode = System.Windows.Forms.AutoScaleMode.Font;
this.Text = "Form1";
}
```

As you can see, it is basic initialization code. This method is tied to the Designer in Visual Studio. When you make changes to the form by using the Designer, the changes are reflected in InitializeComponent(). If you make any type of code change in InitializeComponent(), the next time you make a change in the Designer, your changes will be lost. InitializeComponent() gets regenerated after each change in the Designer. If you need to add additional initialization code for the form or controls and components on the form, be sure to add it after InitializeComponent() is called. InitializeComponent() is also responsible for instantiating the controls so any call that references a control prior to InitializeComponent() will fail with a null reference exception.

To add a control or component to the form, press Ctrl+Alt+X or select Toolbox from the View menu in Visual Studio .NET to display the Toolbox. Form1 should be in design mode. Right-click Form1.cs in Solution Explorer and select View Designer from the context menu. Select the Button control, and drag it to the form in the Designer. You can also double-click the control to add it to the form. Do the same with the TextBox control.

Now that you have added a TextBox control and a Button control to the form, InitializeComponent() expands to include the following code:

```
private void InitializeComponent()
{
  this.button1 = new System.Windows.Forms.Button();
  this.textBox1 = new System.Windows.Forms.TextBox();
  this.SuspendLayout();
  //
  // button1
  //
  this.button1.Location = new System.Drawing.Point(77, 137);
  this.button1.Name = "button1";
  this.button1.Size = new System.Drawing.Size(75, 23);
  this.button1.TabIndex = 0;
  this.button1.Text = "button1";
  this.button1.UseVisualStyleBackColor = true;
  //
  // textBox1
  //
  this.textBox1.Location = new System.Drawing.Point(67, 75);
  this.textBox1.Name = "textBox1";
  this.textBox1.Size = new System.Drawing.Size(100, 20);
  this.textBox1.TabIndex = 1;
  //
  // Form1
  //
  this.AutoScaleDimensions = new System.Drawing.SizeF(6F, 13F);
  this.AutoScaleMode = System.Windows.Forms.AutoScaleMode.Font;
  this.ClientSize = new System.Drawing.Size(284, 264);
  this.Controls.Add(this.textBox1);
  this.Controls.Add(this.button1);
  this.Name = "Form1";
  this.Text = "Form1";
  this.ResumeLayout(false);
  this.PerformLayout();
}
```

If you look at the first three lines of code in the method, you can see the Button and TextBox controls are instantiated. Notice the names given to the controls, textBox1 and button1. By default, the Designer uses the name of the control and adds an integer value to the name. When you add another button, the Designer adds the name button2, and so on. Typically, you would change these names to suit your application. The next line is part of the SuspendLayout and ResumeLayout pair., SuspendLayout() temporarily suspends the layout events that take place when a control is first initialized. At the end of the method the ResumeLayout() method is called to set things back to normal. This process can be used to optimize form initialization by avoiding redrawing the screen while it is set up. In a complex form with many controls, the InitializeComponent() method can get quite large.

To change a property value of a control, either press F4 or select Properties Window from the View menu. The Properties window enables you to modify most of the properties for a control or component. When a change is made in the Properties window, the InitializeComponent() method is rewritten to reflect the new property value. For example, if the Text property is changed to My Button in the Properties window, InitializeComponent() will contain this code:

```
//
// button1
//
this.button1.Location = new System.Drawing.Point(77, 137);
this.button1.Name = "button1";
this.button1.Size = new System.Drawing.Size(75, 23);
this.button1.TabIndex = 0;
this.button1.Text = "My Button";
this.button1.UseVisualStyleBackColor = true;
```

If you are using an editor other than Visual Studio .NET, you will want to include an InitializeComponent() *type function in your designs. Keeping all of this initialization code in one spot will help keep the constructor cleaner, not to mention that if you have multiple constructors you can make sure that the initialization code is called from each constructor.*

Class Hierarchy

The importance of understanding the hierarchy becomes apparent during the design and construction of custom controls. If your custom control is a derivative of a current control — for example, a text box with some added properties and methods — you will want to inherit from the text box control and then override and add the properties and methods to suit your needs. However, if you are creating a control that doesn't match up to any of the controls included with the .NET Framework, you will have to inherit from one of the three base control classes — Control or ScrollableControl if you need autoscrolling capabilities, and ContainerControl if your control needs to be a container of other controls.

The rest of this chapter is devoted to looking at many of these classes — how they work together and how they can be used to build professional-looking client applications.

CONTROL CLASS

The System.Windows.Forms namespace has one particular class that is the base class for virtually every control and form that is created. This class is the System.Windows.Forms.Control class. The Control class implements the core functionality to create the display that the user sees. The Control class is derived from the System.ComponentModel.Component class. The Component class provides the Control class with the necessary infrastructure that is required to be dropped on a design surface and to be contained by another object. The Control class provides a large list of functionality to the classes that are derived from it. The list is too long to itemize here, so this section looks at the more important items that are provided by the Control class. Later in the chapter, when you look at the specific controls based on the Control class, you will see the properties and methods in some sample code. The following subsections group the methods and properties by functionality, so related items can be looked at together.

Size and Location

The size and location of a control are determined by the properties Height, Width, Top, Bottom, Left, and Right along with the complementary properties Size and Location. The difference is that Height, Width, Top, Bottom, Left, and Right all take single integers as their value. Size takes a Size structure and Location takes a Point structure as their values. The Size and Point structures are a contained version of X,Y coordinates. Point generally relates to a location and Size is the height and width of an object. Size and Point are in the System.Drawing namespace. Both are very similar in that they provide an X,Y coordinate pair but also have overridden operators for easy comparison and conversion. You can, for example, add two Size structures together. In the case of the Point structure, the Addition operator is overridden so that you can add a Size structure to a Point and get a new Point in return. This has the effect of adding distance to a location and getting a new location. This is very handy if you have to dynamically create forms or controls.

The Bounds property returns a Rectangle object that represents the area of a control. This area includes scroll bars and title bars. Rectangle is also part of the System.Drawing namespace. The ClientSize property is a Size structure that represents the client area of the control, minus the scroll bars and title bar.

The PointToClient and PointToScreen methods are handy conversion methods that take a Point and return a Point. PointToClient takes a Point that represents screen coordinates and translates it to coordinates based on the current client object. This is handy for drag-and-drop actions. PointToScreen does just the opposite — it takes coordinates of a client object and translates them to screen coordinates. The RectangleToScreen and ScreenToRectangle methods perform the same functionality with Rectangle structures instead of Points.

The Dock property determines which edge of the parent control the control will be docked to. A DockStyle enumeration value is used as the property's value. This value can be Top, Bottom, Right, Left, Fill, or None. Fill sets the control's size to match the client area of the parent control.

The Anchor property anchors an edge of the control to the edge of the parent control. This is different from docking in that it does not set the edge to the parent control but sets the current distance from the edge so that it is constant. For example, if you anchor the right edge of the control to the right edge of the parent and the parent is resized, the right edge of the control will maintain the same distance from the parent's right edge. The Anchor property takes a value of the AnchorStyles enumeration. The values are Top, Bottom, Left, Right, and None. By setting the values, you can make the control resize dynamically with the parent as the parent is resized. This way, buttons and text boxes will not be cut off or hidden as the form is resized by the user.

The Dock and Anchor properties used in conjunction with the Flow and Table layout controls (discussed later in this chapter) enable you to create very sophisticated user windows. Window resizing can be difficult with complex forms with many controls. These tools help make that process much easier.

Appearance

Properties that relate to the appearance of the control are BackColor and ForeColor, which take a System.Drawing.Color object as a value. The BackGroundImage property takes an Image-based object as a value. The System.Drawing.Image class is an abstract class that is used as the base for the Bitmap and Metafile classes. The BackgroundImageLayout property uses the ImageLayout enumeration to set how the image is displayed on the control. Valid values are Center, Tile, Stretch, Zoom, and None.

The Font and Text properties deal with displaying the written word. In order to change the Font you will need to create a Font object. When you create the Font object, you specify the font name, size, and style.

User Interaction

User interaction is best described as the various events that a control creates and responds to. Some of the more common events are `Click`, `DoubleClick`, `KeyDown`, `KeyPress`, `Validating`, and `Paint`.

The `Mouse` events — `Click`, `DoubleClick`, `MouseDown`, `MouseUp`, `MouseEnter`, `MouseLeave`, and `MouseHover` — deal with the interaction of the mouse and the control. If you are handling both the `Click` and the `DoubleClick` events, every time you catch a `DoubleClick` event, the `Click` event is raised as well. This can result in undesired results if not handled properly. Also, `Click` and `DoubleClick` receive `EventArgs` as an argument, whereas the `MouseDown` and `MouseUp` events receive `MouseEventArgs`. The `MouseEventArgs` contain several pieces of useful information such as the button that was clicked, the number of times the button was clicked, the number of mouse wheel detents (notches in the mouse wheel), and the current X and Y coordinates of the mouse. If you have access to any of this information, you will have to handle either the `MouseDown` or `MouseUp` events, not the `Click` or `DoubleClick` events.

The keyboard events work in a similar fashion: The amount of information needed determines the event that is handled. For simple situations, the `KeyPress` event receives `KeyPressEventArgs`. This contains `KeyChar`, which is a `char` value that represents the key pressed. The `Handled` property is used to determine whether or not the event was handled. If you set the `Handled` property to `true`, the event is not passed on for default handling by the operating system. If you need more information about the key that was pressed, the `KeyDown` or `KeyUp` event is more appropriate to handle this. They both receive `KeyEventArgs`. Properties in `KeyEventArgs` include whether the Ctrl, Alt, or Shift key was pressed. The `KeyCode` property returns a `Keys` enumeration value that identifies the key that was pressed. Unlike the `KeyPressEventArgs.KeyChar` property, the `KeyCode` property tells you about every key on the keyboard, not just the alphanumeric keys. The `KeyData` property returns a `Keys` value and will also set the modifier. The modifiers are `OR`'d with the value. This tells you that the Shift key or the Ctrl key was pressed as well. The `KeyValue` property is the `int` value of the `Keys` enumeration. The `Modifiers` property contains a `Keys` value that represents the modifier keys that were pressed. If more than one has been selected, the values are `OR`'d together. The key events are raised in the following order:

1. `KeyDown`
2. `KeyPress`
3. `KeyUp`

The `Validating`, `Validated`, `Enter`, `Leave`, `GotFocus`, and `LostFocus` events all deal with a control gaining focus (or becoming active) or losing focus. This happens when the user tabs into a control or selects the control with the mouse. `Enter`, `Leave`, `GotFocus`, and `LostFocus` seem to be very similar in what they do. The `GotFocus` and `LostFocus` events are lower-level events that are tied to the `WM_SETFOCUS` and the `WM_KILLFOCUS` Windows messages. Generally, you should use the `Enter` and `Leave` events if possible. The `Validating` and `Validated` events are raised when the control is validating. These events receive `CancelEventArgs`. With this, you can cancel the following events by setting the `Cancel` property to `true`. If you have custom validation code, and validation fails, you can set `Cancel` to `true` and the control will not lose focus. `Validating` occurs during validation; `Validated` occurs after validation. The order in which these events are raised is:

1. `Enter`
2. `GotFocus`
3. `Leave`
4. `Validating`
5. `Validated`
6. `LostFocus`

Understanding the order of these events is important so that you don't inadvertently create a recursive situation. For example, trying to set the focus of a control from the control's `LostFocus` event creates a loop so the user would not be able to exit from your application.

Windows Functionality

The System.Windows.Forms namespace is one of the few namespaces that relies on Windows functionality. The Control class is a good example of that. If you were to do a disassembly of the System.Windows.Forms.dll, you would see a list of references to the UnsafeNativeMethods class. The .NET Framework uses this class to wrap many of the standard Win32 API calls. By using interop to the Win32 API, the look and feel of a standard Windows application can still be achieved with the System.Windows.Forms namespace.

Functionality that supports the interaction with Windows includes the Handle and IsHandleCreated properties. Handle returns an IntPtr that contains the HWND (windows handle) for the control. The window handle is an opaque value that uniquely identifies the window. A control can be considered a window, so it has a corresponding HWND. You can use the Handle property to call any number of Win32 API calls.

To gain access to the Windows messages, you can override the WndProc method. The WndProc method takes a Message object as a parameter. The Message object is a simple wrapper for a Windows message. It contains the HWnd, LParam, WParam, Msg, and Result properties. If you want to have the message processed by the system, you must make sure that you pass the message to the base.WndProc(msg) method. Failing to pass the message on to Windows can have drastic effects, as the normal event processing will no longer run and you'll most likely make your application fail spectacularly. If you want to handle the message, you don't want to pass the message on.

Miscellaneous Functionality

Some items that are a little more difficult to classify are the data-binding capabilities. The BindingContext property returns a BindingManagerBase object. The DataBindings collection maintains a ControlBindingsCollection, which is a collection of binding objects for the control. Data binding is discussed later in this chapter.

The CompanyName, ProductName, and Product versions provide data on the origination of the control and its current version.

The Invalidate method allows you to invalidate a region of the control for repainting. You can invalidate the entire control or specify a region or rectangle to invalidate. This causes a paint message to be sent to the control's WndProc. You also have the option to invalidate any child controls at the same time.

Dozens of other properties, methods, and events make up the Control class. This list represents some of the more commonly used ones and is meant to give you an idea of the functionality available.

STANDARD CONTROLS AND COMPONENTS

The previous section covered some of the common methods and properties for controls. This section looks at the various controls that ship with the .NET Framework and explains what each of them offers in added functionality.

This example is available in the Chapter39Code example in the download for the book.

Button

The Button class represents the simple command button and is derived from the ButtonBase class. The most common thing to do is to write code to handle the Click event of the button. The following code snippet implements an event handler for the Click event. When the button is clicked, a message box pops up that displays the button's name:

```
private void btnTest_Click(object sender, System.EventArgs e)
{
   MessageBox.Show(((Button)sender).Name + " was clicked.");
}
```

With the PerformClick method, you can simulate the Click event on a button without the user actually clicking the button, which could be useful when testing your UI. A window also has the notion of a default button, which is automatically clicked if the user presses the Enter key in that window. To identify the button as default, you set the AcceptButton property on the form that contains the button to the button object. Then, when the user presses the Enter key, the button Click event for the default button is raised. Figure 39-1 shows that the button with the caption Default is the default button (notice the dark border). You can also define a button as the CancelButton which indicates that this button will receive a click event if the user presses the Escape key.

FIGURE 39-1

Buttons can have images as well as text. Images are supplied by way of an ImageList object or the Image property. ImageList objects are exactly what they sound like: a list of images managed by a component placed on a form. They are explained in detail later in this chapter.

Both Text and Image have an Align property to align the text or image on the Button. The Align property takes a ContentAlignment enumeration value. The text or image can be aligned in combinations of left and right and top and bottom.

CheckBox

The CheckBox control is also derived from ButtonBase and is used to accept a two-state or three-state response from the user. If you set the ThreeState property to true, the CheckBox's CheckState property can be one of the three CheckState enum values in the following table.

VALUE	DESCRIPTION
Checked	The check box has a check mark.
Unchecked	The check box does not have a check mark.
Indeterminate	In this state the check box becomes gray.

The Indeterminate state is useful if you need to convey to the user that an option has not been set. You can also check the Checked property if you want a Boolean value.
The CheckedChanged and CheckStateChanged events occur when the CheckState or Checked properties change. For a three-state check box, you need to attach to the CheckStateChanged event. Catching these events can be useful for setting other values based on the new state of the CheckBox. The example includes the following code to show the state of the three-state check box:

```
private void threeState_CheckStateChanged(object sender, EventArgs e)
{
    CheckBox cb = sender as CheckBox;

    if (null != cb)
        threeStateState.Text =
          string.Format("State is {0}", cb.CheckState);
}
```

code snippet 03 MainExample/ButtonExample.cs

As the state of the check box changes, a label is updated with the new state.

RadioButton

The last control derived from ButtonBase is the radio button. Radio buttons are generally used as a group. Sometimes referred to as option buttons, radio buttons allow the user to choose one of several options. When you have multiple RadioButton controls in the same container, only one at a time may be selected. So, if you have three options — for example, Red, Green, and Blue — if the Red option is selected and the user clicks the Blue option, Red is automatically deselected.

The Appearance property takes an Appearance enumeration value. This can be either Button or Normal. When you choose Normal, the radio button looks like a small circle with a label beside it. Selecting the button fills the circle; selecting another button deselects the currently selected button and makes the circle look empty. When you choose Button, the control looks like a standard button, but it works like a toggle — selected is the in position, and deselected is the normal, or out, position.

The CheckedAlign property determines where the circle is in relation to the label text. It could be on top of the label, on either side, or below it.

The CheckedChanged event is raised whenever the value of the Checked property changes. This way, you can perform other actions based on the new value of the control.

ComboBox, ListBox, and CheckedListBox

ComboBox, ListBox, and CheckedListBox are all derived from the ListControl class. This class provides some of the basic list management functionality. The most important aspects of using list controls are adding data to and selecting data from the list. Which list is used is generally determined by how the list is used and the type of data that is going to be in the list. If there is a need to have multiple selections or if the user needs to be able to see several items in the list at any time, the ListBox or CheckedListBox is the best choice. If only a single item is ever selected in the list at any time, a ComboBox may be a good choice.

Data must be added to a list box before it can be useful. You add data by adding objects to the ListBox .ObjectCollection. This collection is exposed by the list's Items property. Because the collection stores objects, any valid .NET type can be added to the list. In order to identify the items, two important properties need to be set. The first is the DisplayMember property. This setting tells the ListControl what property of your object should be displayed in the list. The other is ValueMember, which is the property of your object that you want to return as the value. If strings have been added to the list, by default the string value is used for both of these properties. The ListExample form in the sample application shows how data can be loaded into a list box. The example uses Vendor objects for the list data. The Vendor object contains just two properties: Name and Id. The DisplayMember property is set to the Name property. This tells the list control to display the value from the Name property in the list to the user.

Once the data is loaded in the list, the SelectedItem and SelectedIndex properties can be used to get at the data. The SelectedItem property returns the object that is currently selected. If the list is set to allow multiple selections, there is no guarantee which of the selected items will be returned. In this case, the SelectedItems collection should be used. This contains a list of all of the currently selected items in the list.

If the item at a specific index is needed, the Items property can be used to access the ListBox .ObjectCollection. Because this is a standard .NET collection class, the items in the collection can be accessed in the same way as any other collection class.

If DataBinding is used to populate the list, the SelectedValue property will return the property value of the selected object that was set to the ValueMember property. If Id is set to ValueMember, the SelectedValue will return the Id value from the selected item. In order to use ValueMember and SelectedValue the list must be loaded by way of the DataSource property. An ArrayList or any other IList-based collection must be loaded with the objects first, and then the list can be assigned to the DataSource property.

The Items property of the ComboBox returns ComboBox.ObjectCollection. A ComboBox is a combination of an edit control and a list box. You set the style of the ComboBox by passing a DropDownStyle enumeration value to the DropDownStyle property. The following table lists the various DropDownStyle values.

VALUE	DESCRIPTION
DropDown	The text portion of the combo box is editable, and users can enter a value. They can also click the arrow button to show the drop-down list of values.
DropDownList	The text portion is not editable. Users must make a selection from the list.
Simple	This is similar to DropDown except that the list is always visible.

If the values in the list are wide, you can change the width of the drop-down portion of the control with the `DropDownWidth` property. The `MaxDropDownItems` property sets the number of items to show when the drop-down portion of the list is displayed.

The `FindString` and `FindStringExact` methods are two other useful methods of the list controls. `FindString` finds the first string in the list that starts with the passed-in string. `FindStringExact` finds the first string that matches the passed-in string. Both return the index of the value that is found or `-1` if the value is not found. They can also take an integer that is the starting index to search from.

Lastly, the `CheckedListBox` control is similar to the `ListBox`; however, the `DisplayMember` and `ValueMember` properties do not show up in IntelliSense, nor do they display in the property grid. They are available on the actual control, but an attribute has been added to them to indicate that they are not used. This is not the case — you can use `DisplayMember` to determine what will show up on the user interface, or as an alternative, you can simply override the `ToString()` method on the objects you are adding into this list to display whatever you like onscreen.

The DataGridView Control

The `DataGrid` control that has been available from the initial release of .NET was functional, but it had many aspects that made it unsuitable for use in a commercial application — such as an inability to display images, drop-down controls, or lock columns, to name but a few. The control always felt half-completed, so many control vendors provided custom grid controls that overcame these deficiencies and also provided much more functionality.

.NET 2.0 introduced an additional `Grid` control — the `DataGridView`. This addressed many of the deficiencies of the original control, and added significant functionality that previously was available only with add-on products.

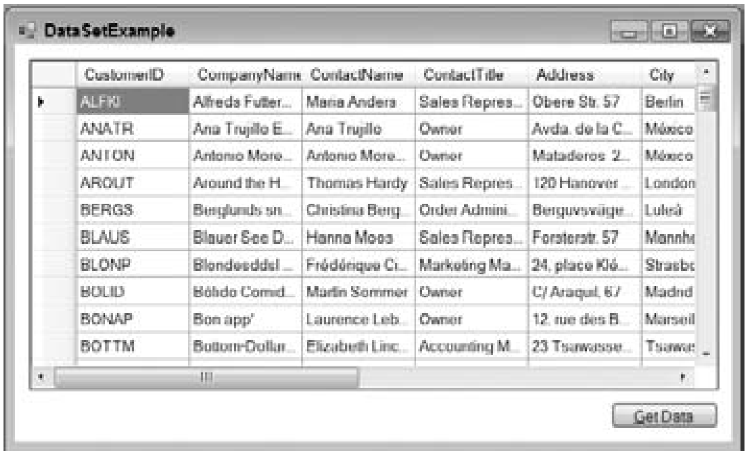
The `DataGridView` control has binding capabilities similar to the old `DataGrid`, so it can bind to an `Array`, `DataTable`, `DataView`, or `DataSet` class, or a component that implements either the `IListSource` or `IList` interface. It gives you a variety of views of the same data. In its simplest guise, data can be displayed (as in a `DataSet` class) by setting the `DataSource` and `DataMember` properties — note that this control is not a plugin replacement for the `DataGrid`, so the programmatic interface to it is entirely different from that of the `DataGrid`. This control also provides more complex capabilities, which are discussed in the course of this chapter.

In this section we use the Northwind sample database. If you don't already have it installed, please download the installer from the Web and create a database called Northwind in your SQL Server or SQL Express instance. You can find the installation scripts for Northwind at `http://msdn.microsoft.com/enus/library/ms143221.aspx`.

Displaying Tabular Data

Chapter 20, "Threads, Tasks, and Synchronization," introduced numerous ways of selecting data and reading it into a data table, although the data was displayed in a very basic fashion using `Console.WriteLine()`.

The following example demonstrates how to retrieve some data and display it in a `DataGridView` control. For this purpose, you will build a new application, `DisplayTabularData`, shown in Figure 39-2.



CustomerID	CompanyName	ContactName	ContactTitle	Address	City
ALFKI	Alfreds Futter...	Maria Anders	Sales Repres...	Obere Str. 57	Berlin
ANATR	Ana Trujillo E...	Ana Trujillo	Owner	Avda. de la C...	México
ANTON	Antonio More...	Antonio More...	Owner	Mataderos 2...	México
AROUT	Around the H...	Thomas Hardy	Sales Repres...	120 Hanover ...	London
BERGS	Berglunds sn...	Christina Berg...	Order Admini...	Berguvsväge...	Luleå
BLAUS	Blauer See D...	Hanna Moos	Sales Repres...	Forsterstr. 57	Mannh
BLONP	Blondesddsl ...	Frédérique Ci...	Marketing Ma...	24, place Klé...	Strasbo
BOLID	Bólido Comid...	Martín Sommer	Owner	C/ Araquil, 67	Madrid
BONAP	Bon app'	Laurence Leb...	Owner	12, rue des B...	Marseil
BOTTM	Bottom-Dollar...	Elizabeth Linc...	Accounting M...	23 Tsawasse...	Tsawa

FIGURE 39-2

This simple application selects every record from the `Customer` table in the Northwind database and displays these records to the user in the `DataGridView` control. The following snippet shows the code for this example (excluding the form and control definition code):

```
using System;
using System.Configuration;
using System.Data;
using System.Data.Common;
using System.Data.SqlClient;
using System.Windows.Forms;

namespace DisplayTabularData
{
  partial class Form1: Form
  {
    public Form1()
    {
      InitializeComponent();
    }

    private void getData_Click(object sender, EventArgs e)
    {
      string customers = "SELECT * FROM Customers";

      using (SqlConnection con =
               new SqlConnection (ConfigurationManager.
                 ConnectionStrings["northwind"].ConnectionString))
      {
        DataSet ds = new DataSet();

        SqlDataAdapter da = new SqlDataAdapter(customers, con);

        da.Fill(ds, "Customers");

        dataGridView.AutoGenerateColumns = true;
        dataGridView.DataSource = ds;
        dataGridView.DataMember = "Customers";
      }
    }
  }
}
```

The form consists of the `getData` button, which when clicked calls the `getData_Click()` method shown in the example code.

This constructs a `SqlConnection` object, using the `ConnectionStrings` property of the `ConfigurationManager` class. Subsequently, a data set is constructed and filled from the database table, using a `DataAdapter` object. The data is then displayed by the `DataGridView` control by setting the `DataSource` and `DataMember` properties. Note that the `AutoGenerateColumns` property is also set to `true` because this ensures that something is displayed to the user. If this flag is not specified, you need to create all the columns yourself.

Data Sources

The `DataGridView` control provides a flexible way to display data; in addition to setting the `DataSource` to a `DataSet` and the `DataMember` to the name of the table to display, the `DataSource` property can be set to any of the following sources:

- An array (the grid can bind to any one-dimensional array)
- `DataTable`
- `DataView`
- `DataSet` or `DataViewManager`
- Components that implement the `IListSource` interface
- Components that implement the `IList` interface
- Any generic collection class or object derived from a generic collection class

The following sections give an example of each of these data sources.

Displaying Data from an Array

At first glance, displaying data from an array seems to be easy. Create an array, fill it with some data, and set the `DataSource` property on the `DataGridView` control. Here's some example code:

```
string[] stuff = new string[] {"One", "Two", "Three"};
dataGridView.DataSource = stuff;
```

If the data source contains multiple possible candidate tables (such as when using a `DataSet` or `DataViewManager`), you need to also set the `DataMember` property.

You could replace the code in the previous example's `getData_Click` event handler with the preceding array code. The problem with this code is the resulting display (see Figure 39-3).

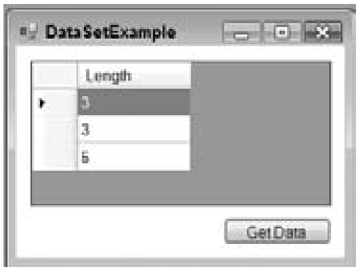


FIGURE 39-3

Instead of displaying the strings defined within the array, the grid displays the length of those strings. That's because when using an array as the source of data for a `DataGridView` control, the grid looks for the first public property of the object within the array and displays this value rather than the string value. The first (and only) public property of a string is its length, so that is what is displayed. The list of properties for any class can be obtained by using the `GetProperties` method of the `TypeDescriptor` class. This returns a collection of `PropertyDescriptor` objects, which can then be used when displaying data. The .NET `PropertyGrid` control uses this method when displaying arbitrary objects.

One way to rectify the problem with displaying strings in the `DataGridView` is to create a wrapper class:

```
protected class Item
{
   public Item(string text)
   {
      _text = text;
   }
```

```
        public string Text
        {
           get{return _text;}
        }
        private string _text;
    }
```

Figure 39-4 shows the output when an array of this `Item` class (which could just as well be a `struct` for all the processing that it does) is added to your data source array code.

	Text
▸	One
	Two
	Three

FIGURE 39-4

DataTable

You can display a `DataTable` within a `DataGridView` control in two ways:

- ➤ If you have a standalone `DataTable`, simply set the `DataSource` property of the control to the table.
- ➤ If your `DataTable` is contained within a `DataSet`, you need to set the `DataSource` to the data set and the `DataMember` property should be set to the name of the `DataTable` within the data set.

Figure 39-5 shows the result of running the `DataSourceDataTable` sample code.

	ProductID	ProductName	SupplierID	CategoryID	Quant
▸	1	Chai	1	1	10 box
	2	Chang	1	1	24 - 12
	3	Aniseed Syrup	1	2	12 - 55
	4	Chef Anton's ...	2	2	48 - 6 c
	5	Chef Anton's ...	2	2	36 box
	6	Grandma's B...	3	2	12 - 8 c

FIGURE 39-5

The last column shows a check box instead of the more common edit control. The `DataGridView` control, in the absence of any other information, will read the schema from the data source (which in this case is the `Products` table), and infer from the column types what control is to be displayed. Unlike the original `DataGrid` control, the `DataGridView` control has built-in support for image columns, buttons, and combo boxes.

The data in the database does not change when fields are altered in the data grid because the data is stored only locally on the client computer — there is no active connection to the database. Updating data in the database is discussed later in this chapter.

Displaying Data from a DataView

A `DataView` provides a means to filter and sort data within a `DataTable`. When data has been selected from the database, it is common to permit the user to sort that data, for example, by clicking on column headings. In addition, the user might want to filter the data to show only certain rows, such as all those that have been altered. A `DataView` can be filtered so that only selected rows are shown to the user; however, you cannot filter the columns from the `DataTable`.

A `DataView` does not permit the filtering of columns, only rows.

To create a `DataView` based on an existing `DataTable`, use the following code:

```
DataView dv = new DataView(dataTable);
```

Once the DataView is created, further settings can be altered on it, which affect the data and operations permitted on that data when it is displayed within the data grid. For example:

- ➤ Setting `AllowEdit = false` disables all column edit functionality for rows.
- ➤ Setting `AllowNew = false` disables the new row functionality.

- Setting `AllowDelete = false` disables the delete row capability.
- Setting the `RowStateFilter` displays only rows of a given state.
- Setting the `RowFilter` enables you to filter rows.

The next section explains how to use the `RowStateFilter` setting; the other options are fairly self-explanatory.

Filtering Rows by Data

After the `DataView` has been created, the data displayed by that view can be altered by setting the `RowFilter` property. This property, typed as a string, is used as a means of filtering based on certain criteria defined by the value of the string. Its syntax is similar to a `WHERE` clause in regular SQL, but it is issued against data already selected from the database.

The following table shows some examples of filter clauses.

CLAUSE	DESCRIPTION
`UnitsInStock > 50`	Shows only those rows where the value in the `UnitsInStock` column is greater than 50.
`Client = 'Smith'`	Returns only the records for a given client.
`County LIKE 'C*'`	Returns all records where the `County` field begins with a C — in this example, the rows for Cornwall, Cumbria, Cheshire, and Cambridgeshire would be returned. The `%` character can be used as a single-character wildcard, whereas the `*` denotes a general wildcard that will match zero or more characters.

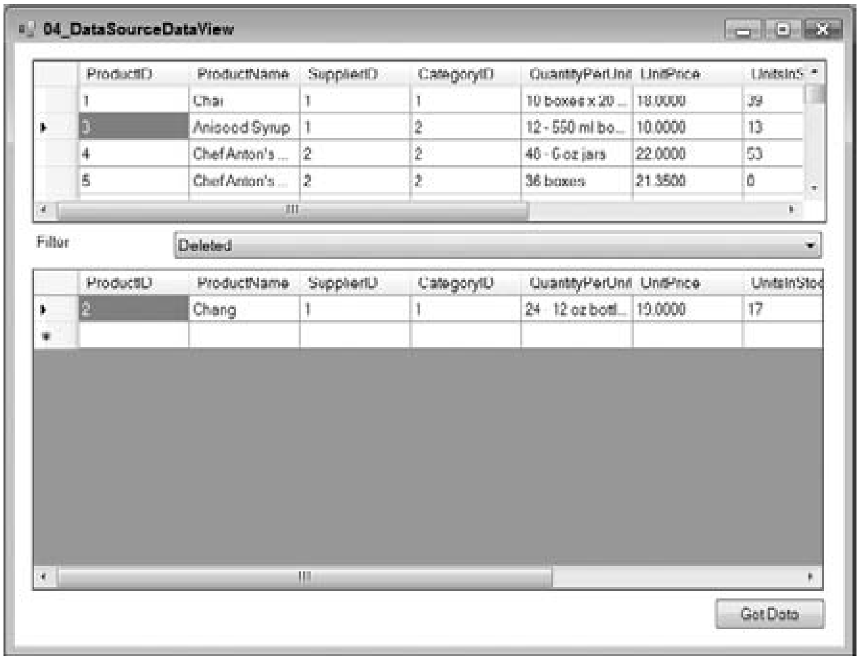
The runtime will do its best to coerce the data types used within the filter expression into the appropriate types for the source columns. For instance, it is perfectly legal to write `"UnitsInStock > '50'"` in the earlier example, even though the column is an integer. If an invalid filter string is provided, an `EvaluateException` will be thrown.

Filtering Rows on State

Each row within a `DataView` has a defined row state, which has one of the values shown in the following table. This state can also be used to filter the rows viewed by the user.

DATAVIEWROWSTATE	DESCRIPTION
`Added`	Lists all rows that have been newly created.
`CurrentRows`	Lists all rows except those that have been deleted.
`Deleted`	Lists all rows that were originally selected and have been deleted; does not show newly created rows that have been deleted.
`ModifiedCurrent`	Lists all rows that have been modified and shows the current value of each column.
`ModifiedOriginal`	Lists all rows that have been modified but shows the original value of the column and not the current value.
`OriginalRows`	Lists all rows that were originally selected from a data source. Does not include new rows. Shows the original values of the columns (that is, not the current values if changes have been made).
`Unchanged`	Lists all rows that have not changed in any way.

Figure 39-6 shows a grid that can have rows added, deleted, or amended, and a second grid that lists rows in one of the preceding states.



04_DataSourceDataView

ProductID	ProductName	SupplierID	CategoryID	QuantityPerUnit	UnitPrice	UnitsInS
1	Chai	1	1	10 boxes x 20 ...	18.0000	39
3	Aniseed Syrup	1	2	12 - 550 ml bo...	10.0000	13
4	Chef Anton's ...	2	2	48 - 6 oz jars	22.0000	53
5	Chef Anton's ...	2	2	36 boxes	21.3500	0

Filter: Deleted

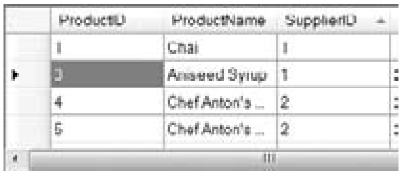
ProductID	ProductName	SupplierID	CategoryID	QuantityPerUnit	UnitPrice	UnitsInStoc
2	Chang	1	1	24 - 12 oz bottl...	19.0000	17

FIGURE 39-6

The filter not only applies to the visible rows but also to the state of the columns within those rows. This is evident when choosing the `ModifiedOriginal` or `ModifiedCurrent` selections. These states are based on the `DataRowVersion` enumeration. For example, when the user has updated a column in the row, the row will be displayed when either `ModifiedOriginal` or `ModifiedCurrent` is chosen; however, the actual value will be either the `Original` value selected from the database (if `ModifiedOriginal` is chosen) or the current value in the `DataColumn` (if `ModifiedCurrent` is chosen).

Sorting Rows

Apart from filtering data, you might also have to sort the data within a `DataView`. To sort data in ascending or descending order, simply click the column header in the `DataGridView` control (see Figure 39-7). The only trouble is that the control can sort by only one column, whereas the underlying `DataView` control can sort by multiple columns.



ProductID	ProductName	SupplierID
1	Chai	1
3	Aniseed Syrup	1
4	Chef Anton's ...	2
5	Chef Anton's ...	2

FIGURE 39-7

When a column is sorted, either by clicking the header (as shown on the `SupplierId` column) or in code, the `DataGrid` displays an arrow bitmap to indicate which column the sort has been applied to.

To set the sort order on a column programmatically, use the `Sort` property of the `DataView`:

```
dataView.Sort = "ProductName";
dataView.Sort = "ProductName ASC, ProductID DESC";
```

The first line sorts the data based on the `ProductName` column, as shown in Figure 39-7. The second line sorts the data in ascending order, based on the `ProductName` column, then in descending order of `ProductID`.

The `DataView` supports both ascending (default) and descending sort orders on columns. If more than one column is sorted in code in the `DataView`, the `DataGridView` will cease to display any sort arrows.

Each column in the grid can be strongly typed, so its sort order is not based on the string representation of the column but instead is based on the data within that column. The upshot is that if there is a date column in the `DataGrid`, the user can sort numerically on the date rather than on the date string representation.

IListSource and IList Interfaces

The DataGridView also supports any object that exposes one of the interfaces IListSource or IList. IListSource has only one method, GetList(), which returns an IList interface. IList, however, is somewhat more interesting and is implemented by a large number of classes in the runtime. Some of the classes that implement this interface are Array, ArrayList, and StringCollection.

When using IList, the same caveat for the object within the collection holds true as for the Array implementation shown earlier — if a StringCollection is used as the data source for the DataGrid, the length of the strings is displayed within the grid, not within the text of the item as expected.

Displaying Generic Collections

In addition to the types already described, the DataGridView also supports binding to generic collections. The syntax is just as in the other examples already provided in this chapter — simply set the DataSource property to the collection, and the control will generate an appropriate display.

Once again, the columns displayed are based on the properties of the object — all public readable fields are displayed in the DataGridView. The following example shows the display for a list class defined as follows:

```
class PersonList: List < Person >
{
}

class Person
{
    public Person( string name, Sex sex, DateTime dob )
    {
        _name = name;
        _sex = sex;
        _dateOfBirth = dob;
    }

    public string Name
    {
        get { return _name; }
        set { _name = value; }
    }

    public Sex Sex
    {
        get { return _sex; }
        set { _sex = value; }
    }

    public DateTime DateOfBirth
    {
        get { return _dateOfBirth; }
        set { _dateOfBirth = value; }
    }

    private string _name;
    private Sex _sex;
    private DateTime _dateOfBirth;
}

enum Sex
{
    Male,
    Female
}
```

code snippet 03 MainExample/Person.cs

The display shows several instances of the `Person` class that were constructed within the `PersonList` class. See Figure 39-8.

	Name	Sex	DateOfBirth
▸	Fred	Male	14/12/1970
	Bill	Male	29/10/1976
	Jack	Male	17/05/1945
	Jane	Female	03/01/1982

FIGURE 39-8

In some circumstances, it might be necessary to hide certain properties from the grid display — for this you can use the `Browsable` attribute as shown in the following code snippet. Any properties marked as non-browsable are not displayed in the property grid.

```
 [Browsable(false)]
public bool IsEmployed
{
    .
}
```

The `DataGridView` uses this property to determine whether to display the property or hide it. In the absence of the attribute, the default is to display the property. If a property is read-only, the grid control will display the values from the object, but it will be read-only within the grid.

Any changes made in the grid view are reflected in the underlying objects — so, for example, if in the previous code the name of a person was changed within the user interface, the setter method for that property would be called.

DateTimePicker

The `DateTimePicker` allows users to select a date or time value (or both) in a number of different formats. You can display the `DateTime`-based value in any of the standard time and date formats. The Format property takes a `DateTimePickerFormat` enumeration that sets the format to `Long`, `Short`, `Time`, or `Custom`. If the `Format` property is set to `DateTimePickerFormat.Custom`, you can set the `CustomFormat` property to a string that represents the format.

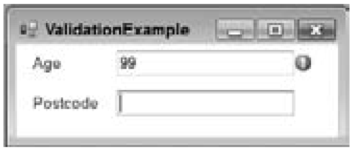
There is both a `Text` property and a `Value` property. The `Text` property returns a text representation of the `DateTime` value, whereas the `Value` property returns the `DateTime` object. You can also set the maximum and minimum allowable date values with the `MinDate` and `MaxDate` properties.

When users click the down arrow, a calendar is displayed allowing the users to select a date in the calendar. Properties are available that allow you to change the appearance of the calendar by setting the title and month background colors as well as the foreground colors.

The `ShowUpDown` property determines whether an `UpDown` arrow is displayed on the control. The currently highlighted value can be changed by clicking the up or down arrow.

ErrorProvider

`ErrorProvider` is actually not a control but a component. When you drag a component to the Designer, it shows in the component tray under the Designer. The `ErrorProvider` flashes an icon next to a control when an error condition or validation failure exists. Suppose that you have a `TextBox` entry for an age and your business rules say that the age value cannot be greater than 65. If users try to enter an age greater than that, you must inform them that the age is greater than the allowable value and that they need to change the entered value. The check for a valid value takes place in the `Validated` event of the text box. If the validation fails, you call the `SetError` method, passing in the control that caused the error and a string that informs the user what the error is. An exclamation point icon starts flashing, indicating that an error has occurred, and when the user hovers over the icon the error text is displayed. Figure 39-9 shows the icon that is displayed when an invalid entry is made in the text box.



Age 99
Postcode

FIGURE 39-9

If the validation of a field fails you would then call the `SetIcon` method of the `ErrorProvider` object and pass through the control that failed validation and an appropriate error message. The error is displayed as a blinking icon next to the control that caused the validation error, and the error message is displayed as a tooltip. You can call `SetError` again with an empty error string to remove the error condition.

ImageList

An `ImageList` component is exactly what the name implies — a list of images. Typically, this component is used for holding a collection of images that are used as toolbar icons or icons in a `TreeView` control. Many controls have an `ImageList` property. The `ImageList` property typically comes with an `ImageIndex` property. The `ImageList` property is set to an instance of the `ImageList` component, and the `ImageIndex` property is set to the index in the `ImageList` that represents the image that should be displayed on the control. You add images to the `ImageList` component by using the `Add` method of the `ImageList.Images` property. The `Images` property returns an `ImageCollection`.

The two most commonly used properties are `ImageSize` and `ColorDepth`. `ImageSize` uses a `Size` structure as its value. The default value is 16 3 16, but it can be any value from 1 to 256. The `ColorDepth` uses a `ColorDepth` enumeration as its value. The color depth values go from 4-bit to 32-bit, with a default of `ColorDepth.Depth8Bit`.

Label

`Labels` are generally used to provide descriptive text to the user. The text might be related to other controls or the current system state. You usually see a label together with a text box. The label provides the user with a description of the type of data to be entered in the text box. The `Label` control is always read-only — the user cannot change the string value of the `Text` property. However, you can change the `Text` property in your code. The `UseMnemonic` property allows you to enable the access key functionality. When you precede a character in the `Text` property with the ampersand (`&`), that letter will appear underlined in the label control. Pressing the Alt key in combination with the underlined letter puts the focus on the next control in the tab order. If you wish to display an ampersand in the text, you need to escape the ampersand with another ampersand. For example, if the label text should be "Nuts & Bolts," set the property to "Nuts && Bolts." Because the `Label` control is read-only, it cannot gain focus; that's why focus is sent to the next control. Because of this, it is important to remember that if you enable mnemonics, you must be certain to set the tab order properly on your form.

The `AutoSize` property is a `Boolean` value that specifies whether the `Label` will resize itself based on the contents of the `Label`. This can be useful for multi-language applications where the length of the `Text` property can change based on the current language.

ListView

The `ListView` control enables you to display items in one of four different ways. You can display text with an optional large icon, text with an optional small icon, or text and small icons in a vertical list or in detail view, which allows you to display the item text plus any subitems in columns. If this sounds familiar, it should, because this is similar to the right-hand side of Windows Explorer. A `ListView` contains a collection of `ListViewItems`. `ListViewItems` allow you to set a `Text` property used for the display. `ListViewItem` has a property called `SubItems` that contains the text that appears in detail view.

The `ListView` control is one of the most flexible in the .NET Framework, and there are a multitude of options you can set to change the appearance of items. For example, you can emulate a checked list box simply by setting the `CheckBoxes` property to `True`. You can add images to items, alter the view, alter the behavior of the column headings to sort, and even group items into different groups.

PictureBox

The `PictureBox` control is used to display an image. The image can be a BMP, JPEG, GIF, PNG, metafile, or icon. The `SizeMode` property uses the `PictureBoxSizeMode` enumeration to determine how the image is sized and positioned in the control. The `SizeMode` property can be `AutoSize`, `CenterImage`, `Normal`, and `StretchImage`.

You can change the size of the display of the `PictureBox` by setting the `ClientSize` property. You load the `PictureBox` by first creating an `Image`-based object. For example, to load a JPEG file into a `PictureBox`, you would do the following:

```
Bitmap myJpeg = Bitmap.FromFile("whatever.png") as Bitmap;
pictureBox1.Image = myJpeg;
```

ProgressBar

The `ProgressBar` control is a visual clue to the status of a lengthy operation. It indicates to users that there is something going on and that they should wait. The `ProgressBar` control works by setting the `Minimum` and `Maximum` properties, which correspond to the progress indicator being all the way to the left (`Minimum`) or all the way to the right (`Maximum`). You set the `Step` property to determine the number that the value is incremented each time the `PerformStep` method is called. You can also use the `Increment` method and increment the value by the value passed in the method call. The `Value` property returns the current value of the `ProgressBar`.

TextBox, RichTextBox, and MaskedTextBox

The `TextBox` control is one of the most used controls in the toolbox. The `TextBox`, `RichTextBox`, and `MaskedTextBox` controls are all derived from `TextBoxBase`. `TextBoxBase` provides properties such as `MultiLine` and `Lines`. `MultiLine` is a `Boolean` value that allows the `TextBox` control to display text in more than one line. Each line in a text box is a part of an array of strings. This array is exposed through the `Lines` property. The `Text` property returns the entire text box contents as a single string. `TextLength` is the total length of the string that text would return. The `MaxLength` property will limit the length of the text to the specified amount.

`SelectedText`, `SelectionLength`, and `SelectionStart` all deal with the currently selected text in the text box. The selected text is highlighted when the control has focus.

The `TextBox` control adds a couple of interesting properties. `AcceptsReturn` is a Boolean value that will allow the `TextBox` to capture the Enter key. If the value is set to `false`, the Enter key clicks the default button on the form. When `AcceptsReturn` is set to `true`, pressing the Enter key creates a new line in the `TextBox`. `CharacterCasing` determines the casing of the text in the text box. The `CharacterCasing` enumeration contains three values, `Lower`, `Normal`, and `Upper`. `Lower` lowercases all text regardless of how it is entered, `Upper` renders all text in uppercase letters, and `Normal` displays the text as it is entered. The `PasswordChar` property takes a `char` that represents what is displayed to the users when they type text in the text box. This is typically used for entering passwords and PINs. The `text` property will return the actual text that was entered; only the display is affected by this property.

The `RichTextBox` is a text-editing control that can handle special formatting features. As the name implies, the `RichTextBox` control uses Rich Text Format (RTF) to handle the special formatting. You can make formatting changes by using the `Selection` properties: `SelectionFont`, `SelectionColor`, and `SelectionBullet`, and paragraph formatting with `SelectionIndent`, `SelectionRightIndent`, and `SelectionHangingIndent`. All of the `Selection` properties work in the same way. If a section of text is highlighted, a change to a `Selection` property affects the selected text. If no text is selected, the change takes effect with any text that is inserted to the right of the current insertion point.

The text of the control can be retrieved by using the `Text` property or the `Rtf` property. The `Text` property returns just the text of the control, whereas the `Rtf` property returns the formatted text.

The `LoadFile` method can load text from a file in a couple of different ways. It can use a string that represents the path and filename or it can use a stream object. You can also specify the `RichTextBoxStreamType`. The following table lists the values of `RichTextBoxStreamType`.

VALUE	DESCRIPTION
`PlainText`	No formatting information. In places that contained OLE objects, spaces are used.
`RichNoOleObjs`	Rich Text formatting, but spaces where the OLE objects would have been.
`RichText`	Formatted RTF with OLE objects in place.
`TextTextOleObjs`	Plain text with text replacing the OLE objects.
`UnicodePlainText`	Same as `PlainText` but Unicode encoded.

The `SaveFile` method works with the same parameters, saving the data from the control to a specified file. If a file by that name already exists, it will be overwritten. In the example, an RTF file is included as a resource in the application, and this text is loaded into the control when the form is loaded.

The `MaskedTextBox` has the ability to limit what the user may input into the control. It also allows for automatic formatting of the data entered. Several properties are used in order to validate or format the user's input. `Mask` is the property that contains the mask string, which is similar to a format string. The number of characters allowed, the data type of allowed characters, and the format of the data are all set using the `Mask` string. A `MaskedTextProvider`-based class can also provide the formatting and validation information needed. The `MaskedTextProvider` can only be set by passing it in on one of the constrictors.

Three different properties will return the text of the `MaskedTextControl`. The `Text` property returns the text of the control at the current moment. This could be different, depending on whether or not the control has focus, which depends on the value of the `HidePromptOnLeave` property. The prompt is a string that users see to guide them on what should be entered. The `InputText` property always returns just the text that the user entered. The `OutputText` property returns the text formatted according to the `IncludeLiterals` and `IncludePrompt` properties. If, for example, the mask is for a phone number, the `Mask` string might include parentheses and a couple of dashes. These would be the literal characters and would be included in the `OutputText` property if the `IncludeLiteral` property were set to `true`.

A couple of extra events also exist for the `MaskedTextBox` control. `OutputTextChanged` and `InputTextChanged` are raised when `InputText` or `OutputText` changes.

Panel

A `Panel` is simply a control that contains other controls. Grouping controls together and placing them in a panel makes it is a little easier to manage them. For example, you can disable all of the controls in the panel by disabling the panel. Because the `Panel` control is derived from `ScrollableControl`, you can also get the advantage of the `AutoScroll` property. If you have too many controls to display in the available area, place them in a `Panel` and set `AutoScroll` to `true` — now you can scroll through all of the controls.

Panels do not show a border by default, but by setting the `BorderStyle` property to something other than `none`, you can use the `Panel` to visually group related controls using borders. This makes the user interface more user-friendly.

`Panel` is the base class for the `FlowLayoutPanel`, `TableLayoutPanel`, `TabPage`, and `SplitterPanel`. Using these controls, you can create a very sophisticated and professional-looking form or window. The `FlowLayoutPanel` and `TableLayoutPanel` are especially useful for creating forms that resize properly.

FlowLayoutPanel and TableLayoutPanel

`FlowLayoutPanel` and `TableLayoutPanel` are recent additions to the .NET Framework. As the names suggest, the panels offer the capability to lay out a form using the same paradigm as a Web Form. `FlowLayoutPanel` is a container that allows the contained controls to flow in either the horizontal or vertical direction. Instead of flowing, it allows for the clipping of the controls. Flow direction is set using the `FlowDirection` property and the `FlowDirection` enumeration. The `WrapContents` property determines if controls flow to the next row or column when the form is resized or if the control is clipped.

TableLayoutPanel uses a grid structure to control the layout of controls. Any Windows Forms control can be a child of the TableLayoutPanel, including another TableLayoutPanel. This allows for a very flexible and dynamic window design. When a control is added to a TableLayoutPanel, four additional properties are added to the Layout category of the property page. They are Column, ColumnSpan, Row, and RowSpan. Much like an HTML table on a Web page, column and row spans can be set for each control. By default, the control will be centered in the cell of the table, but this can be changed by using the Anchor and Dock properties.

The default style of the rows and columns can be changed using RowStyles and ColumnsStyles collections. These collections contain RowStyle and ColumnsStyle objects, respectively. The Style objects have a common property, SizeType. SizeType uses the SizeType enumeration to determine how the column width or row height should be sized. Values include AutoSize, Absolute, and Percent. AutoSize shares the space with other peer controls. Absolute allows a set number of pixels for the size and Percent tells the control to size the column or width as a percentage of the parent control.

Rows, columns, and child controls can be added or removed at runtime. The GrowStyle property takes a TableLayoutPanelGrowStyle enumeration value that sets the table to add a column or a row, or stay a fixed size when a new control is added to a full table. If the value is FixedSized, an ArgumentException is thrown when there is an attempt to add another control. If a cell in the table is empty, the control will be placed in the empty cell. This property has an effect only when the table is full and a control is added.

The sample code includes a form containing both a flow layout panel and a table layout panel to show the effect of resizing the form on the controls within the panels.

SplitContainer

The SplitContainer control is really three controls in one. It has two panel controls with a bar or splitter between them. The user is able to move the bar and resize the panels. As the panels resize, the controls in the panels also can be resized. The best example of a SplitContainer is File Explorer. The left panel contains a TreeView of folders, and the right side contains a ListView of folder contents. When the user moves the mouse over the splitter bar, the cursor changes, showing that the bar can be moved. The SplitContainer can contain any control, including layout panels and other SplitContainers. This allows the creation of very complex and sophisticated forms.

The movement and position of the splitter bar can be controlled with the SplitterDistance and SplitterIncrement properties. The SplitterDistance property determines where the splitter starts in relation to the left or top of the control. The SplitterIncrement determines the number of pixels the splitter moves when being dragged. The panels can have their minimum size set with the Panel1MinSize and Panel2MinSize properties. These properties are also in pixels.

The Splitter control raises two events that relate to moving: the SplitterMoving event and the SplitterMoved event. One takes place during the move, and the other takes place after the move has happened. They both receive SplitterEventArgs. SplitterEventArgs contains properties for the X and Y coordinates of the upper-left corner of the Splitter (SplitX and SplitY) and the X and Y coordinates of the mouse pointer (X and Y).

The sample code includes a poor man's Windows Explorer, which uses a split container along with a tree view and list view to show directories and files.

TabControl and TabPages

TabControl allows you to group related controls onto a series of tab pages. TabControl manages the collection of TabPages. Several properties control the appearance of TabControl. The Appearance property uses the TabAppearance enumeration to determine what the tabs look like. The values are FlatButtons, Buttons, or Normal. The Multiline property is a Boolean that determines if more than one row of tabs is shown. If the Multiline property is set to false and there are more tabs than can fit in the display, arrows appear that allow the user to scroll and see the rest of the tabs.

The `TabPage Text` property is what is displayed on the tab. The `Text` property is a parameter in a constructor override as well.

Once you create a `TabPage` control, it is basically a container control in which you can place other controls. The Designer in Visual Studio .NET makes it easy to add `TabPage` controls to a `TabControl` control by using the collection editor. You can set the various properties as you add each page. Then you can drag the other child controls to each `TabPage` control.

You can determine the current tab by looking at the `SelectedTab` property. The `SelectedIndex` event is raised each time a new tab is selected. By listening to the `SelectedIndex` property and then confirming the current tab with `SelectedTab`, you can do special processing based on each tab. You could, for example, manage the data displayed for each tab.

ToolStrip

The `ToolStrip` control is a container control used to create toolbars, menu structures, and status bars. The `ToolStrip` is used directly for toolbars, and serves as the base class for the `MenuStrip` and `StatusStrip` controls.

When used as a toolbar, the `ToolStrip` control uses a set of controls based on the abstract `ToolStripItem` class. `ToolStripItem` adds the common display and layout functionality as well as managing most of the events used by the controls. `ToolStripItem` is derived from the `System.ComponentModel.Component` class and not from the `Control` class. `ToolStripItem`-based classes must be contained in a `ToolStrip`-based container.

`Image` and `Text` are probably the most common properties that will be set. Images can be set with either the `Image` property or by using the `ImageList` control and setting it to the `ImageList` property of the `ToolStrip` control. The `ImageIndex` property of the individual controls can then be set.

Formatting of the text on a `ToolStripItem` is handled with the `Font`, `TextAlign`, and `TextDirection` properties. `TextAlign` sets the alignment of the text in relation to the control. This can be any of the `ControlAlignment` enumeration values. The default is `MiddleRight`. The `TextDirection` property sets the orientation of the text. Values can be any of the `ToolStripTextDirection` enumeration values, which include `Horizontal`, `Inherit`, `Vertical270`, and `Vertical90`. `Vertical270` rotates the text 270 degrees, and `Vertical90` rotates the text 90 degrees.

The `DisplayStyle` property controls whether text, image, text and image, or nothing is displayed on the control. When `AutoSize` is set to `true`, the `ToolStripItem` will resize itself so that only the minimum amount of space is used.

The controls that are derived directly from `ToolStripItem` are listed in the following table.

TOOL STRIP ITEMS	DESCRIPTION
`ToolStripButton`	Represents a button that the user can select.
`ToolStripLabel`	Displays nonselectable text or images on the `ToolStrip`. The `ToolStripLabel` can also display one or more hyperlinks.
`ToolStripSeparator`	Used to separate and group other `ToolStripItems`. Items can be grouped according to functionality.
`ToolStripDropDownItem`	Displays drop-down items. Base class for `ToolStripDropDownButton`, `ToolStripMenuItem`, and `ToolStripSplitButton`.
`ToolStripControlHost`	Hosts other non–`ToolStripItem`-derived controls on a `ToolStrip`. Base class for `ToolStripComboBox`, `ToolStripProgressBar`, and `ToolStripTextBox`.

The last two items in the list, ToolStripDropDownItem and ToolStripControlHost, deserve a little more discussion. ToolStripDropDownItem is the base class for ToolStripMenuItems, which are used to build the menu structure. ToolStripMenuItems are added to MenuStrip controls. As mentioned earlier, MenuStrips are derived from ToolStrip controls. This is important when it comes time to manipulate or extend menu items. Because toolbars and menus are derived from the same classes, creating a framework for managing and executing commands is much easier.

ToolStripControlHost can be used to host other controls that do not derive from ToolStripItem. Remember that the only controls that can be directly hosted by a ToolStrip are those that are derived from ToolStripItem.

MenuStrip

The MenuStrip control is the container for the menu structure of an application. As mentioned earlier, MenuStrip is derived from the ToolStrip class. The menu system is built by adding ToolStripMenu objects to the MenuStrip. You can do this in code or in the Designer of Visual Studio. Drag a MenuStrip control onto a form in the Designer and the MenuStrip will allow the entry of the menu text directly on the menu items.

The MenuStrip control has only a couple of additional properties. GripStyle uses the ToolStripGripStyle enumeration to set the grip as visible or hidden. The MdiWindowListItem property takes or returns a ToolStripMenuItem. This ToolStripMenuItem is the menu that shows all open windows in an MDI application.

ContextMenuStrip

To show a context menu, or a menu displayed when the user right-clicks the mouse, the ContextMenu Strip class is used. Like MenuStrip, ContextMenuStrip is a container for ToolStripMenuItems objects. However, it is derived from ToolStripDropDownMenu. A ContextMenu is created the same way as a MenuStrip. ToolStripMenuItems are added, and the Click event of each item is defined to perform a specific task. Context menus are assigned to specific controls. This is done by setting the ContextMenuStrip property of the control. When the user right-clicks the control, the menu is displayed.

ToolStripMenuItem

ToolStripMenuItem is the class that builds the menu structures. Each ToolStripMenuItem object represents a single menu choice on the menu system. Each ToolStripMenuItem has a ToolStripItemCollection that maintains the child menus. This functionality is inherited from ToolStripDropDownItem.

Because ToolStripMenuItem is derived from ToolStripItem, all of the same formatting properties apply. Images appear as small icons to the right of the menu text. Menu items can have check marks show up next to them with the Checked and CheckState properties.

Shortcut keys can be assigned to each menu item. They are generally two key chords such as Ctrl+C (common shortcut for Copy). When a shortcut key is assigned, it can optionally be displayed on the menu by setting the ShowShortCutKey property to true.

To be useful, the menu item has to do something when the user clicks it or uses the defined shortcut keys. The most common way is to handle the Click event. If the Checked property is being used, the CheckStateChanged and CheckedChanged events can be used to determine a change in the checked state.

ToolStripManager

Menu and toolbar structures can become large and cumbersome to manage. The ToolStripManager class provides the ability to create smaller, more manageable pieces of a menu or toolbar structure and then combine them when needed. An example of this is a form that has several different controls on it.

Each control must display a context menu. Several menu choices will be available for all of the controls, but each control will also have a couple of unique menu choices. The common choices can be defined on one `ContextMenuStrip`. Each of the unique menu items can be predefined or created at runtime. For each control that needs a context menu assigned to it, the common menu is cloned and the unique choices are merged with the common menu using the `ToolStripManager.Merge` method. The resulting menu is assigned to the `ContextMenuStrip` property of the control.

ToolStripContainer

The `ToolStripContainer` control is used for docking of `ToolStrip`-based controls. When you add a `ToolStripContainer` and set the `Docked` property to `Fill`, a `ToolStripPanel` is added to each side of the form, and a `ToolStripContainerPanel` is added to middle of the form. Any `ToolStrip` (`ToolStrip`, `MenuStrip`, or `StatusStrip)` can be added to any of the `ToolStripPanels`. The user can move a `ToolStrip` by grabbing it and dragging it to either side or bottom of the form. If you set the `Visible` property to false on any of the `ToolStripPanels`, a `ToolStrip` can no longer be placed in the panel. The `ToolStripContainerPanel` in the center of the form can be used to place the other controls the form may need.

FORMS

Earlier in this chapter, you learned how to create a simple Windows application. The example contained one class derived from the `System.Windows.Forms.Form` class. According to the .NET Framework documentation, "a Form is a representation of any window in your application." If you come from a Visual Basic background, the term "form" will seem familiar. If your background is C++ using MFC, you're probably used to calling a form a window, dialog box, or maybe a frame. Regardless, the form is the basic means of interacting with the user. Earlier, the chapter covered some of the more common and useful properties, methods, and events of the `Control` class, and because the `Form` class is a descendant of the `Control class`, all of the same properties, methods, and events exist in the `Form` class. The `Form` class adds considerable functionality to what the `Control` class provides, and that's what this section discusses.

Form Class

A Windows client application can contain one form or hundreds of forms. The forms can be an SDI-based (Single Document Interface) or MDI-based (Multiple Document Interface) application. Regardless, the `System.Windows.Forms.Form` class is the heart of the Windows client. The `Form` class is derived from `ContainerControl`, which is derived from `ScrollableControl`, which is derived from `Control`. Because of this, you can assume that a form is capable of being a container for other controls, is capable of scrolling when the contained controls do not fit the client area, and has many of the same properties, methods, and events that other controls have. This also makes the `Form` class rather complex. This section looks at much of that functionality.

Form Instantiation and Destruction

The process of form creation is important to understand. What you want to do depends on where you write the initialization code. For instantiation, the events occur in the following order:

- `Constructor`
- `Load`
- `Activated`
- `Closing`
- `Closed`
- `Deactivate`

The first three events are of concern during initialization. The type of initialization you want to do could determine which event you hook into. The constructor of a class occurs during the object instantiation. The `Load` event occurs after object instantiation, but just before the form becomes visible. The difference between this and the constructor is the viability of the form. When the `Load` event is raised, the form exists but isn't visible. During constructor execution, the form is in the process of coming into existence. The `Activated` event occurs when the form becomes visible and current.

This order can be altered slightly in one particular situation. If during the constructor execution of the form, the `Visible` property is set to `true` or the `Show` method is called (which sets the `Visible` property to `true`), the `Load` event fires immediately. Because this also makes the form visible and current, the `Activate` event is also raised. If there is code after the `Visible` property has been set, it will execute. So, the startup event might look something like this:

- `Constructor`, up to `Visible = true`
- `Load`
- `Activate`
- `Constructor`, after `Visible = true`

This could potentially lead to some unexpected results. From a best practices standpoint, it would seem that doing as much initialization as possible in the constructor might be a good idea.

Now what happens when the form is closed? The `Closing` event gives you the opportunity to cancel the process. The `Closing` event receives `CancelEventArgs` as a parameter. This has a `Cancel` property that, if set to `true`, cancels the event and the form remains open. The `Closing` event happens as the form is being closed, whereas the `Closed` event happens after the form has been closed. Both allow you to do any cleanup that might have to be done. Notice that the `Deactivate` event occurs after the form has been closed. This is another potential source of difficult-to-find bugs. Be sure that you don't have anything in `Deactivate` that could keep the form from being properly garbage collected. For example, setting a reference to another object would cause the form to remain alive.

If you call the `Application.Exit()` method and you have one or more forms currently open, the `Closing` and `Closed` events will not be raised. This is an important consideration if you have open files or database connections that you were going to clean up. The `Dispose` method is called, so perhaps another best practice would be to put most of your cleanup code in the `Dispose` method.

Some properties that relate to the startup of a form are `StartPosition`, `ShowInTaskbar`, and `TopMost`. `StartPosition` can be any of the `FormStartPosition` enumeration values. They are:

- `CenterParent` — The form is centered in the client area of the parent form.
- `CenterScreen` — The form is centered in the current display.
- `Manual` — The form's location is based on the values in the `Location` property.
- `WindowsDefaultBounds` — The form is located at the default Windows position and uses the default size.
- `WindowsDefaultLocation` — The Windows default location is used, but the size is based on the `Size` property.

The `ShowInTaskbar` property determines if the form should be available in the taskbar. This is relevant only if the form is a child form and you only want the parent form to show in the taskbar. The `TopMost` property tells the form to start in the topmost position in the Z-order of the application. This is true even if the form does not immediately have focus.

In order for users to interact with the application, they must be able to see the form. The `Show` and `ShowDialog` methods accomplish this. The `Show` method just makes the form visible to the user. The following code segment demonstrates how to create a form and show it to the user. Assume that the form you want to display is called `MyFormClass`.

```
MyFormClass myForm = new MyFormClass();
myForm.Show();
```

That's the simple way. The one drawback to this is that there isn't any notification back to the calling code that myForm is finished and has been exited (unless you hook up the Closing or Closed events on the form). Sometimes this isn't a big deal, and the Show method will work fine. If you do need some type of notification, ShowDialog is a better option.

When the Show method is called, the code that follows the Show method is executed immediately. When ShowDialog is called, the calling code is blocked and will wait until the form that ShowDialog called is closed. Not only will the calling code be blocked, but the form will optionally return a DialogResult value. The DialogResult enumeration is a list of identifiers that describe the reason the dialog is closed. These include OK, Cancel, Yes, No, and several others. In order for the form to return a DialogResult, the form's DialogResult property must be set or the DialogResult property on one of the form's buttons must be set.

For example, suppose that part of application asks for the phone number of a client. The form has a text box for the phone number and two buttons; one is labeled OK and the other is labeled Cancel. If you set the DialogResult of the OK button to DialogResult.OK and the DialogResult property on the Cancel button to DialogResult.Cancel, then when either of these buttons is selected, the form becomes invisible and returns to the calling form the appropriate DialogResult value. Now notice that the form is not destroyed; the Visible property is just set to false. That's because you still must get values from the form. For this example, you need to get a phone number. By creating a property on the form for the phone number, the parent form can now get the value and call the Close method on the form. This is what the code for the child form looks like:

```
namespace FormsSample.DialogSample
{
  partial class Phone: Form
  {
    public Phone()
    {
      InitializeComponent();
      btnOK.DialogResult = DialogResult.OK;
      btnCancel.DialogResult = DialogResult.Cancel;
    }

    public string PhoneNumber
    {
      get { return textBox1.Text; }
      set { textBox1.Text = value; }
    }
  }
}
```

The first thing to notice is that there is no code to handle the click events of the buttons. Because the DialogResult property is set for each of the buttons, the form disappears after either the OK or Cancel button is clicked. The only property added is the PhoneNumber property. The following code shows the method in the parent form that calls the Phone dialog:

```
Phone frm = new Phone();
frm.ShowDialog();
if (frm.DialogResult == DialogResult.OK)
{
  label1.Text = "Phone number is " + frm.PhoneNumber;
}
else if (frm.DialogResult == DialogResult.Cancel)
{
  label1.Text = "Form was canceled. ";
}
frm.Close();
```

This looks simple enough. Create the new Phone object (frm). When the frm.ShowDialog() method is called, the code in this method will stop and wait for the Phone form to return. You can then check the

DialogResult property of the Phone form. Because it has not been destroyed yet, just made invisible, you can still access the public properties, one of them being the PhoneNumber property. Once you get the data you need, you can call the Close method on the form.

Within the dialog you can validate the controls before the form closes, so in this example you might want to validate the format of the phone number (and update the Enabled state of the OK button accordingly).

Appearance

The first thing that the user sees is the form for the application. It should be first and foremost functional. If the application doesn't solve a business problem, it really doesn't matter how it looks. This is not to say that the form and application's overall GUI design should not be pleasing to the eye. Simple things like color combinations, font sizing, and window sizing can make an application much more attractive for the user.

Sometimes you don't want the user to have access to the system menu. This is the menu that appears when you click the icon on the top-left corner of a window. Generally, it has such items as Restore, Minimize, Maximize, and Close. The ControlBox property allows you to set the visibility of the system menu. You can also set the visibility of the Maximize and Minimize buttons with the MaximizeBox and MinimizeBox properties. If you remove all of the buttons and then set the Text property to an empty string (""), the title bar disappears completely.

If you set the Icon property of a form and you don't set the ControlBox property to false, the icon will appear in the top-left corner of the form. It's common to set this to the app.ico. This makes each form's icon the same as the application icon.

The FormBorderStyle property sets the type of border that appears around the form. This uses the FormBorderStyle enumeration. The values can be as follows:

- Fixed3D
- FixedDialog
- FixedSingle
- FixedToolWindow
- None
- Sizable
- SizableToolWindow

Most of these are self-explanatory, with the exception of the two tool window borders. A Tool window will not appear in the taskbar, regardless of how ShowInTaskBar is set. Also a Tool window will not show in the list of windows when the user presses Alt+Tab. The default setting is Sizable.

Unless a requirement dictates otherwise, colors for most GUI elements should be set to system colors, not to specific colors. This way, if some users like to have all of their buttons green with purple text, the application will follow along with the same colors. To set a control to use a specific system color, you must call the FromKnownColor method of the System.Drawing.Color class. The FromKnownColor method takes a KnownColor enumeration value. Many colors are defined in the enumeration, as well as the various GUI element colors, such as Control, ActiveBorder, and Desktop. So, for example, if the Background color of the form should always match the Desktop color, the code would look like this:

```
myForm.BackColor = Color.FromKnownColor(KnownColor.Desktop);
```

Now if users change the color of their desktops, the background of the form changes as well. This is a nice, friendly touch to add to an application. Users might pick out some strange color combinations for their desktops, but it is their choice.

Windows XP introduced a feature called visual styles. Visual styles change the way buttons, text boxes, menus, and other controls look and react when either the mouse pointer is hovering or the mouse button is clicked. You can enable visual styles for your application by calling the Application.EnableVisualStyles method.

This method has to be called before any type of GUI is instantiated. Because of this, it is generally called in the `Main` method, as demonstrated in this example:

```
 [STAThread]
static void Main()
{
  Application.EnableVisualStyles();
  Application.Run(new Form1());
}
```

This code allows the various controls that support visual styles to take advantage of them. Because of an issue with the `EnableVisualStyles` method, you might have to add an `Application.DoEvents()` method right after the call to `EnableVisualStyles`. This should resolve the problem if icons on toolbars begin to disappear at runtime. Also, `EnableVisualStyles` is available in .NET Framework 1.1 only.

You have to accomplish one more task pertaining to the controls. Most controls expose the `FlatStyle` property, which takes a `FlatStyle` enumeration as its value. This property can take one of four different values:

- `Flat` — The control has a flat appearance with no 3D outline.
- `Popup` — Similar to `flat`, except that when the mouse pointer hovers over the control, it appears in 3D.
- `Standard` — The control appears in 3D.
- `System` — The look of the control is controlled by the operating system.

To enable visual styles, the control's `FlatStyle` property should be set to `FlatStyle.System`. The application will now take on the XP look and feel and will support XP themes.

Multiple Document Interface

MDI-type applications are used when you have an application that can show either multiple instances of the same type of form, such as a text editor that can show multiple editor windows at the same time, or one in which different forms are contained in some way, such as Microsoft Access. With Access, you can have query windows, design windows, and table windows all open at the same time. The windows never leave the boundaries of the main Access application.

The project that contains the examples for this chapter is an MDI application. The form `MainForm` in the project is the MDI parent form. Setting the `IsMdiContainer` to `true` will make any form an MDI parent form. If you have the form in the Designer, you'll notice that the background turns a dark gray color. This is to let you know that this is an MDI parent form. You can still add controls to the form, but it is generally not recommended.

For a child form to behave like an MDI child, it needs to have a link to the parent form. This is done by setting the `MdiParent` property of the child form to the parent form. In the example, all children forms are created using the `ShowMdiChild` method. This method takes a reference to the child form that is to be shown. After setting the `MdiParent` property to this, which is referencing the `MainForm` form, the form is displayed.

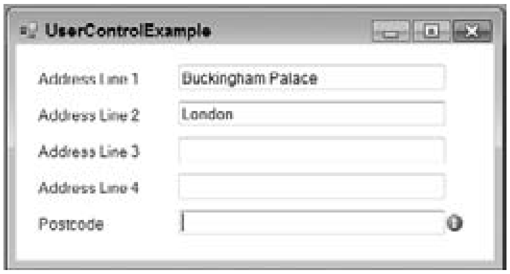
One of the issues with MDI applications is that there may be several child forms open at any given time. A reference to the current active child can be retrieved by using the `ActiveMdiChild` property on the parent form. This is demonstrated on the `Current Active` menu choice on the Window menu. This choice will show a message box with the form's name and text value.

The child forms can be arranged by calling the `LayoutMdi` method. The `LayoutMdi` method takes an `MdiLayout` enumeration value as a parameter. The possible values include `Cascade`, `TileHorizontal`, and `TileVertical`.

Creating Your Own User Controls

In addition to using the built-in controls, it is also possible to create your own custom controls and then reuse these in your own applications. There are two types of custom controls — those derived from the `UserControl` base class and those derived from `Control`. A `UserControl` is the simplest type to create, as you can compose one from the other controls in the toolbox. Typically, you'll write a custom control only when the built-in controls cannot be used to do what you want. Entire books have been written on the creation of custom controls, so here we'll concentrate on user controls.

In this section, you'll build the user control shown in Figure 39-10, which includes an error provider validator, and exposes its fields for reuse. The code for this example is available in the `02 UserControl` folder of the chapter downloads.



UserControlExample

Address Line 1	Buckingham Palace
Address Line 2	London
Address Line 3	
Address Line 4	
Postcode	

FIGURE 39-10

To begin you need to construct a new user control, which can be done from the Solution Explorer or the project menu. Once it is created, you'll have a class that derives from `UserControl` and can then drag and drop other controls onto the design surface. In this example you use a set of label controls and a set of text boxes to replicate the functionality shown in Figure 39-10.

Once the UI has been laid out, you want to define anchor behavior for the controls. This is important to do as it permits the user control to resize properly when its size is changed. In the example control, each of the text boxes has had its alignment set to Left + Top + Right, and a small space on the right of the list boxes has been provided, which will show any validation errors.

In addition to the text boxes, an `ErrorProvider` object has been added to the control so that validation errors can be shown while the user tabs around the control. The first two address fields and the postcode have validation errors assigned, so they are mandatory.

Once you are happy with the design and implementation of your control, you can simply compile it, and it will be displayed within the tool palette in Visual Studio. You can then reuse that control in any application that needs it.

SUMMARY

This chapter has given you the basics for building Windows-based client applications. It explained many of the basic controls by discussing the hierarchy of the `Windows.Forms` namespace and examining the various properties and methods of the controls.

The chapter also showed you how to create a basic user control. The power and flexibility of creating your own controls cannot be emphasized enough. By creating your own toolbox of custom controls, Windows-based client applications will become easier to develop and to test because you will be reusing the same tested components over and over again.

40 Core ASP.NET

WHAT'S IN THIS CHAPTER?

- ➤ Introduction to ASP.NET
- ➤ Creating ASP.NET Web Forms
- ➤ Binding data with ADO.NET
- ➤ Configuring applications

If you are new to the world of C# and .NET, you might wonder why a chapter on ASP.NET has been included in this book. It's a whole new language, right? Well, not really. In fact, as you will see, you can use C# to create ASP.NET pages.

ASP.NET is part of the .NET Framework and is a technology that allows for the dynamic creation of documents on a web server when they are requested via HTTP. This mostly means HTML and XHTML documents, although it is equally possible to create XML documents, cascading style sheet (CSS) files, images, PDF documents, or anything else that supports MIME types.

In some ways, ASP.NET is similar to many other technologies — such as PHP, ASP, or ColdFusion. There is, however, one key difference: ASP.NET, as its name suggests, has been designed to be fully integrated with the .NET Framework, part of which includes support for C#.

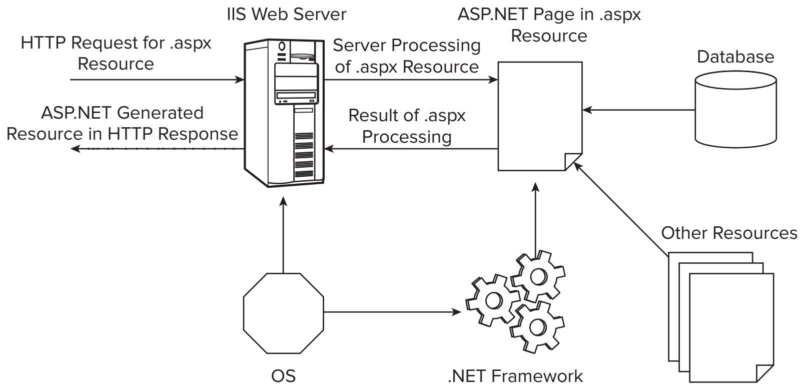
Perhaps you are familiar with Active Server Pages (ASP) technology, which enables you to create dynamic content. If you are, you will probably know that programming in this technology used scripting languages such as VBScript or JScript. The result was not always perfect, at least not for those of us used to "proper," compiled programming languages, and it certainly resulted in a loss of performance.

One major difference related to the use of more advanced programming languages is the provision of a complete server-side object model for use at runtime. ASP.NET provides access to all the controls on a page as objects, in a rich environment. On the server side, you also have access to other .NET classes, allowing for the integration of many useful services. Controls used on a page expose a lot of functionality; in fact, you can do almost as much as with Windows Forms classes, which provide plenty of flexibility. For this reason, ASP.NET pages that generate HTML content are often called *Web Forms*.

This chapter takes a more detailed look at ASP.NET, including how it works, what you can do with it, and how C# fits in.

ASP.NET INTRODUCTION

ASP.NET works with Internet Information Services (IIS) to deliver content in response to HTTP requests. ASP.NET pages are found in `.aspx` files. Figure 40-1 illustrates the technology's basic architecture.



IIS Web Server
HTTP Request for .aspx Resource
ASP.NET Generated Resource in HTTP Response
Server Processing of .aspx Resource
Result of .aspx Processing

.NET Framework

FIGURE 40-1

How ASP.NET Files are Processed

During ASP.NET processing, you have access to all .NET classes, custom components created in C# or other languages, databases, and so on. In fact, you have as much power as you would have running a C# application; using C# in ASP.NET is, in effect, running a C# application.

An ASP.NET file can contain any of the following:

- Processing instructions for the server
- Code in C#, Visual Basic .NET, JScript .NET, or any other language that the .NET Framework supports
- Content in whatever form is appropriate for the generated resource, such as HTML
- Client-side script code, such as JavaScript
- Embedded ASP.NET server controls

So, in fact, you could have an ASP.NET file as simple as this:

```
Hello!
```

This would simply result in an HTML page being returned (as HTML is the default output of ASP.NET pages) containing just this text.

As you will see later in this chapter, it is also possible to split certain portions of the code into other files, which can provide a more logical structure.

Web Sites and Web Applications

In ASP.NET it is possible to create both "web sites" and "web applications". These two terms both mean that you supply a collection of ASP.NET, C#, and other files, but the way that they are processed is subtly different.

In a *web site*, any code that you supply is dynamically compiled as and when it is required. This generally means that code is compiled the first time that the site is accessed. The `.cs` files for a web site are stored on the web server, which means that you can make changes by uploading new versions of these files, which will trigger a recompile the next time the site is accessed.

Conversely, *web applications* are compiled before being deployed to a web server, and don't include `.cs` files. Instead, a pre-compiled assembly is deployed to the server along with ASP.NET pages.

In general, most ASP.NET programmers tend to prefer the web application model, and there are some technologies (such as MVC) that will only work with web applications. Web sites are mainly useful in the development stage, where quick changes to code may be required and a full deployment may not be desirable.

State Management in ASP.NET

One of the key properties of ASP.NET pages is that they are effectively stateless. By default, no information is stored on the server between user requests (although there are methods for doing this, as you will see later in this chapter). At first glance, this seems a little strange because state management is something that seems essential for user-friendly interactive sessions. However, ASP.NET provides a workaround to this problem, such that session management becomes almost transparent.

In short, information such as the state of controls on a Web Form (including data entered in text boxes or selections from drop-down lists) is stored in a hidden *viewstate* field that is part of the page generated by the server and passed to the user. Subsequent actions, such as triggering events that require server-side processing, such as submitting form data, result in this information being sent back to the server; this is known as a *postback* operation. On the server, this information is used to repopulate the page object model allowing you to operate on it as if the changes had been made locally.

You will see this in action shortly and examine the details.

ASP.NET WEB FORMS

As mentioned earlier, much of the functionality in ASP.NET is achieved using Web Forms. Before long, you will dive in and create a simple Web Form to give you a starting point to explore this technology. First, however, this section reviews some key points pertinent to Web Form design.

Note that some ASP.NET developers simply use a text editor such as Notepad to create files. We wouldn't advocate this ourselves because the benefits you get via an IDE, such as Visual Studio or Web Developer Express are substantial, but it's worth mentioning because it is a possibility. If you do take this route, you have a great deal of flexibility as to which parts of a web application you put where. This enables you, for example, to combine all your code in one file. You can achieve this by enclosing code in `<script>` elements, using two attributes on the opening `<script>` tag:

```
<script language="c#" runat="server">
   // Server-side code goes here.
</script>
```

The `runat="server"` attribute here is crucial because it instructs the ASP.NET engine to execute this code on the server rather than sending it to the client, thus giving you access to the rich environment hinted at earlier. You can place your functions, event handlers, and so on in server-side script blocks.

If you omit the `runat="server"` attribute, you are effectively providing client-side code, which will fail if it uses any of the server-side style coding that is discussed in this chapter. You can, however, use `<script>` elements to supply client-side script in languages such as JavaScript. For example:

```
<script language="JavaScript" type="text/JavaScript">
   // Client-side code goes here; you can also use "vbscript".
</script>
```

Note that the `type` *attribute here is optional, but necessary if you want to comply with HTML and XHTML standards.*

It may seem strange that the facility to add JavaScript code to your pages is included with ASP.NET. However, JavaScript allows you to add dynamic client-side behavior to your web pages and can be very useful. This is especially true for Ajax programming, as you will see in Chapter 41, "ASP.NET Features."

It is possible to create ASP.NET files in Visual Studio, which is great for you, as you are already familiar with this environment for C# programming. However, the default project setup for web applications in this environment has a slightly more complex structure than a single `.aspx` file. This isn't a problem for you, however, and does make things a bit more logical (more programmer-like and less web developer–like). For this reason, you will use Visual Studio throughout this chapter for your ASP.NET programming (instead of Notepad).

The `.aspx` files can also include code in blocks enclosed by `<%` and `%>` tags. However, function definitions and variable declarations cannot go here. Instead, you can insert code that is executed as soon as the block is reached, which is useful when outputting simple HTML content. This behavior is similar to that of old-style ASP pages, with one important difference — the code is compiled, not interpreted. This results in far better performance.

Now it's time for an example. In Visual Studio, you create a new web site by using the File ➪ New ➪ Web Site . . . menu option or a web application through the File ➪ New ➪ Project . . . menu option by selecting a web application template. In either case, from the dialog box that appears, select the Visual C# language type and the specific template you want. For web sites, you have an additional choice to make. Visual Studio can create web sites in a number of different locations:

➤ On your local IIS web server
➤ On your local disk, configured to use the built-in Visual Web Developer web server
➤ At any location accessible via FTP
➤ On a remote web server that supports Front Page Server Extensions

The latter two choices use remote servers so you are left with the first two choices. In general, IIS is the best place to install ASP.NET web sites because it is likely to be closest to the configuration required when you deploy a web site. The alternative, using the built-in web server, is fine for testing but has certain limitations:

➤ Only the local computer can see the web site.
➤ Access to services such as SMTP is restricted.
➤ The security model is different from IIS — the application runs in the context of the current user rather than in an ASP.NET-specific account.

This last point requires clarification because security is very important when it comes to accessing databases or anything else that requires authentication. By default, web applications running on IIS do so in an account called ASPNET on IIS5 web servers, or in an account called NT AUTHORITY\NETWORK SERVICE on IIS6 and above. This is configurable if you are using IIS, but not if you use the built-in web server.

For the purposes of illustration, however, and because you may not have IIS installed on your computer, you can use the built-in web server. You aren't worried about security at this stage, so you can go with simplicity.

Web applications don't prompt you to choose a location like web sites do. Instead, web sites must be deployed to web servers in a separate step — although for testing they will use the VWD web server.

Create a new ASP.NET web site called `PCSWebSite1` using the File System option and the Empty Web Site template, at `C:\ProCSharp\Chapter40`, as shown in Figure 40-2.

FIGURE 40-2

Note that the ASP.NET Web Site template is not used here in order to keep things simple for the first example. The ASP.NET Web Site template includes techniques such as Master Pages, which you won't examine until the next chapter.

After a few moments, Visual Studio .NET should have set up the following:

- `PCSWebSite1`, a new solution containing the C# web site PCSWebSite1
- `Web.config`, a configuration file for the web application

Next you need to add a web page. You can do this through the Website ➪ Add New Item . . . menu option. Select the Web Form template and leave the rest of the settings unchanged (with a file name of `Default.aspx` and the "Place code in separate file" option selected), and then click Add. This adds the following:

- `Default.aspx`, the first ASP.NET page in the web application
- `Default.aspx.cs`, a "code-behind" class file for `Default.aspx`

You can see all this in the Solution Explorer, as shown in Figure 40-3.

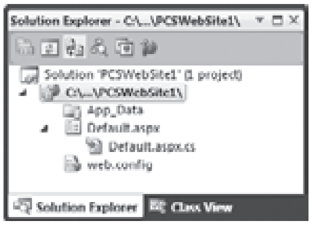

FIGURE 40-3

You can view `.aspx` files in design or source (HTML) view. This is the same as for Windows Forms (as discussed in Chapter 39, "Windows Forms"). The initial view in Visual Studio is either the design or source view for `Default.aspx` (you can toggle between the views or view them together in a split view using the buttons in the bottom left). The design view is shown in Figure 40-4.

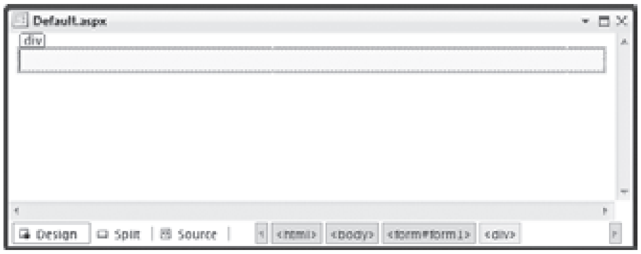

FIGURE 40-4

Underneath the (currently empty) form, you can see where in the HTML for the form the cursor is currently positioned. Here the cursor is in a `<div>` element inside a `<form>` element inside the `<body>` element of the page. The `<form>` element is displayed as `<form#form1>` to identify the element by its `id` attribute, which you will see shortly. The `<div>` element is also labeled in the design view.

The source view for the page shows you the code generated inside the `.aspx` file:

```
<%@ Page Language="C#" AutoEventWireup="true" CodeFile="Default.aspx.cs"
  Inherits="_Default" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
  "http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml">
<head runat="server">
  <title></title>
</head>
<body>
  <form id="form1" runat="server">
    <div>
    </div>
  </form>
</body>
</html>
```

code snippet PCSWebSite1/Default.aspx

If you know any HTML syntax, then this will look familiar to you. You are presented with the basic code required for an HTML page following the XHTML schema, with a few extra bits of code. The most important extra is the `<form>` element, which has an `id` attribute of `form1`. This element will contain your ASP.NET code. The most important thing to note here is the `runat` attribute. Just as with the server-side code blocks you saw at the start of this section, this is set to `server`, meaning that the processing of the form will take place on the server. If you don't include this reference, then no server-side processing will be performed, and the form won't do anything. There can be only one server-side `<form>` element in an ASP.NET page.

The other interesting thing about this code is the `<%@ Page %>` tag at the top. This tag defines page characteristics that are important to you as a C# web developer. There is a `Language` attribute that specifies that you will use C# throughout your page, as you saw earlier with `<script>` blocks. (The default for ASP.NET pages is Visual Basic .NET, although this can be changed using a `Web.config` file, which you will see later in this chapter.) The other three attributes — `AutoEventWireup`, `CodeFile`, and `Inherits` — are used to associate the Web Form with a class in a code-behind code file, in this case the partial class `_Default` in the file `Default.aspx.cs`. This leads straight into a necessary discussion about the ASP.NET code model.

The ASP.NET Code Model

In ASP.NET, a combination of layout (HTML) code, ASP.NET controls, and C# code is used to generate the HTML that users see. The layout and ASP.NET code are stored in an `.aspx` file, such as the one you looked at in the preceding section. The C# code that you add to customize the behavior of the form is contained either in the `.aspx` file or, as in the preceding example, in a separate `.aspx.cs` file, which is usually referred to as the "code-behind" file.

In a web site project, when an ASP.NET Web Form is processed — typically when a user requests the page, although sites can be precompiled — several things happen:

- The ASP.NET process examines the page and determines what objects must be created to instantiate the page object model.
- A base class for the page is dynamically created, including members for the controls on the page as well as event handlers for these controls (such as button click events).
- Additional code contained in the `.aspx` page is combined with this base class to complete the object model.

- The complete code is compiled and cached ready to process subsequent requests.
- HTML is generated and returned to the user.

In web applications the process is similar, although no dynamic compilation is required as web applications are precompiled by definition.

The code-behind file generated for you in the PCSWebSite1 web site for `Default.aspx` is initially very sparse. First, you see the default set of namespace references that you are likely to use in ASP.NET web pages:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.UI;
using System.Web.UI.WebControls;
```

code snippet PCSWebSite1/Default.aspx.cs

Below these references, you see an almost completely empty partial class definition for `Default_aspx`:

```
public partial class _Default : System.Web.UI.Page
{
   protected void Page_Load(object sender, EventArgs e)
   {
   }
}
```

Here, the `Page_Load()` event handler can be used to add any code that is required when the page is loaded. As you add more event handlers, and so on, this class file will become increasingly full of code. Note that you don't see the code that wires up this event handler to the page — event handlers are inferred by the ASP.NET runtime, as noted earlier. This is due to the `AutoEventWireUp` attribute — setting this to `false` will mean that you will need to associate the event handlers in your code with events on your own.

This class is a partial class definition because the process outlined earlier requires it. When the page is precompiled, a separate partial class definition is created from the ASP.NET code for your page. This includes all the controls you have added to the page. At design time, the compiler infers this partial class definition, which allows you to use IntelliSense in your code-behind to reference controls on your page.

ASP.NET Server Controls

Your generated code doesn't do very much yet, so next you need to add some content. You can do this in Visual Studio using the Web Form designer, which supports drag-and-drop in just the same way as the Windows Forms designer.

You can add three types of server controls to your ASP.NET pages:

- **HTML server controls** — These controls mimic HTML elements, which will be familiar to HTML developers.
- **Web server controls** — This is a new set of controls, some of which have the same functionality as HTML controls. These controls have a common naming scheme for properties and other elements to ease development, and provide consistency with analogous Windows Forms controls. There are also some completely new and very powerful controls, as you will see later. Several types of web server controls exist, including the standard ones such as buttons, validation controls for validating user input, login controls to simplify user management, and more complicated controls for dealing with data sources.
- **Custom and user controls** — These controls are defined by the developer and can be created in a number of ways, as discussed in Chapter 41.

Adding Web Server Controls

You can add a couple of web server controls to the PCSWebSite1 web site that you created in the last section. All web server controls are used in the following XML element-type form:

```
<asp:controlName runat="server" attribute="value">Contents</asp:controlName>
```

In the preceding code, `controlName` is the name of the ASP.NET server control, `attribute="value"` is one or more attribute specifications, and `Contents` specifies the control content, if any. Some controls allow properties to be set using attributes and control element content, such as `Label` (used for simple text display), where `Text` can be specified in either way. Other controls might use an element containment scheme to define their hierarchy — for example `Table` (which defines a table), which can contain `TableRow` elements in order to specify table rows declaratively.

Because the syntax for controls is based on XML (although the controls may be used embedded in non-XML code such as HTML), it is an error to omit the closing tags and `/>` for empty elements, or to overlap controls.

Finally, you once again see the `runat="server"` attribute on the web server controls. It is just as essential here as it is elsewhere, and it is a common mistake to skip this attribute. If you do, your Web Forms won't work.

Adding Web Server Controls In Source View

This first example is simple. Change the HTML source view for `Default.aspx` as follows:

```
<%@ Page Language="C#" AutoEventWireup="true" CodeFile="Default.aspx.cs"
  Inherits="_Default" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.1//EN"
"http://www.w3.org/TR/xhtml11/DTD/xhtml11.dtd">
<html xmlns="http://www.w3.org/1999/xhtml">
<head runat="server">
  <title></title>
</head>
<body>
  <form id="form1" runat="server">
    <div>
      <asp:Label runat="server" ID="resultLabel" /><br />
      <asp:Button runat="server" ID="triggerButton" Text="Click Me" />
    </div>
  </form>
</body>
</html>
```

code snippet PCSWebSite1/Default.aspx

Here you have added two Web Form controls: a label and a button.

Note that as you do this, Visual Studio .NET IntelliSense predicts your code entry, just as in the C# code editor. Also, if you edit your code in split view and synchronize the views, the element that you are editing in the source pane will be highlighted in the design pane.

Going back to the design screen, you can see that your controls have been added and named using their `ID` attributes (the `ID` attribute is often known as the *identifier* of a control). As with Windows Forms, you have full access to properties, events, and so on through the Properties window and get instant feedback in code or design whenever you make changes.

Any server controls you add will automatically become part of the object model for the form that you are building. This is an instant bonus for Windows Forms developers — the similarities are beginning to emerge!

Adding an Event Handler

To make this application do something, you can add an event handler for clicking the button. Here you can either enter a method name in the Properties window for the button or just double-click the button to get the default event handler. If you double-click the button, you will automatically add an event-handling method as follows:

```
protected void triggerButton_Click(object sender, EventArgs e)
{
}
```

code snippet PCSWebSite1/Default.aspx.cs

This is hooked up to the button by some code added to the source of `Default.aspx`:

```
<div>
  <asp:Label Runat="server" ID="resultLabel" /><br />
  <asp:Button Runat="server" ID="triggerButton" Text="Click Me"
    onclick="triggerButton_Click" />
</div>
```

Here, the `onclick` attribute lets the ASP.NET runtime know to wire up the click event of the button to the `triggerButton_Click()` method when it generates the code model for the form.

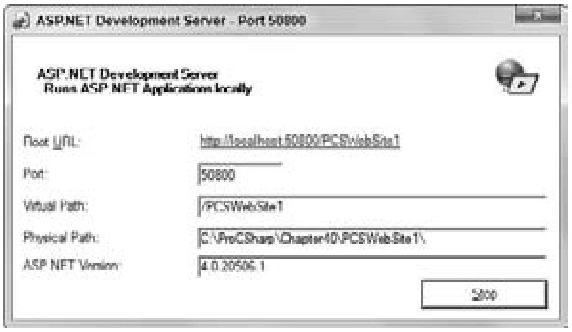
Modify the code in `triggerButton_Click()` as follows (note that the label control type is inferred from the ASP.NET code so that you can use it directly from the code-behind):

```
protected void triggerButton_Click(object sender, EventArgs e)
{
   resultLabel.Text = "Button clicked!";
}
```

Running the Project

Now you're ready to make it go. There is no need to build the project; you simply need to make sure everything is saved and then point a web browser at the location of the web site. If you had used IIS, this would be simple because you would know the URL to point at. However, because you are using the built-in web server for this example, you need to start things running. The quickest way to do this is to press Ctrl+F5, which will start the server and open a browser pointing at the required URL.

When the built-in web server is running, an icon will appear in your system tray. By double-clicking this icon, you can see what the web server is doing, and stop it if required (see Figure 40-5).



ASP.NET Development Server - Port 50800

ASP.NET Development Server
Runs ASP.NET Applications locally

Root URL: http://localhost:50800/PCSWebSite1
Port: 50800
Virtual Path: /PCSWebSite1
Physical Path: C:\ProCSharp\Chapter40\PCSWebSite1\
ASP.NET Version: 4.0.20506.1

FIGURE 40-5

In Figure 40-5, you can see the port that the web server is running on and the URL required to see the web site you have created.

The browser that has opened should display the Click Me button on a web page. Before you press the button, take a quick look at the code received by the browser by selecting Page ➪ View Source (in IE7). The `<form>` section should look something like this:

```
<form method="post" action="Default.aspx" id="form1">
  <div>
    <input type="hidden" name="__VIEWSTATE" id="__VIEWSTATE"
       value="/wEPDwUKLTE2MjY5MTY1NWRkzNjRYstd1OK5KcJ9a8/X3pYTHvM=" />
  </div>
  <div>
    <input type="hidden" name="__EVENTVALIDATION" id="__EVENTVALIDATION"
      value="/wEWAgK39qTFBwLHpP+yC4rCCl22/GGMaFwD0l7nokvyFZ8Q" />
  </div>
  <div>
    <span id="resultLabel"></span><br />
    <input type="submit" name="triggerButton" value="Click Me"
      id="triggerButton" />
  </div>
</form>
```

The web server controls have generated straight HTML: `<span>` and `<input>` for `<asp:Label>` and `<asp:Button>`, respectively. There is also an `<input type="hidden">` field with the name `__VIEWSTATE`. This encapsulates the state of the form, as mentioned earlier. This information is used when the form is posted back to the server to re-create the user interface, so that the server can keep track of changes and so on. Note that the `<form>` element has been configured for this; it will post data back to `Default.aspx` (specified in `action`) via an HTTP POST operation (specified in `method`). It has also been assigned the name `form1`.

Changes to the Source HTML when the Button is Clicked

After clicking the button and seeing the text appear, check out the source HTML again (spacing has been added for clarity):

```
<form method="post" action="Default.aspx" id="form1">
  <div>
    <input type="hidden" name="__VIEWSTATE" id="__VIEWSTATE"
      value="/wEPDwUKLTE2MjY5MTY1NQ9kFgICAw9kFgICAQ8PFgIeBFRleHQFD0J1dHR
             vbiBjbGlja2VkIWRkZExUtMwuSlVTrzMtG7wrmj98tVn7" />
  </div>
  <div>
    <input type="hidden" name="__EVENTVALIDATION" id="__EVENTVALIDATION"
      value="/wEWAgKTpL7LBALHpP+yC0Ymqe9SgScfB2yHTGjnlQKtbudV" />
  </div>
  <div>
    <span id="resultLabel">Button clicked!</span><br />
    <input type="submit" name="triggerButton" value="Click Me"
      id="triggerButton" />
  </div>
</form>
```

This time, the value of the view state contains more information because the HTML result relies on more than the default output from the ASP.NET page. In complex forms this can be a very long string indeed, but you shouldn't complain because so much is done for you behind the scenes. You can almost forget about state management, keeping field values between posts, and so on. Where the length of the view state string becomes a problem, you can disable the view state for controls that do not need to retain state information. You can also do this for entire pages if you want, which can be useful if the page does not ever need to retain state between postbacks to improve performance.

To convince yourself that you don't need to perform any compilation for web sites manually, try changing the text "Button clicked!" in `Default.aspx.cs` to something else, saving the file, and clicking the button again. The text on the web page should change appropriately.

The Control Palette

This section takes a quick look at some of the available controls before you put more of them together into a full, and more interesting, application. Figure 40-6 shows the toolbox that you see when editing ASP.NET pages.

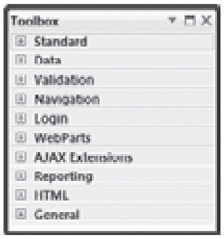


FIGURE 40-6

Note that the following control descriptions discuss properties; in all cases, the corresponding attribute for use in ASP.NET code is identically named. This section isn't an attempt to provide a complete reference, so instead, we focus on only the most frequently used controls and properties. The controls you see in this chapter are in the Standard, Data, and Validation categories. The Navigation, Login, Web Parts, and AJAX Extensions categories are covered in Chapter 41. The Reporting controls to be presented on web pages, which enable reporting information, including Crystal Reports, are not covered in this book.

Standard Web Server Controls

Almost all the web server controls (in this and other categories) inherit from `System.Web.UI.WebControls.WebControl`, which in turn inherits from `System.Web.UI.Control`. Those that don't use this inheritance instead derive either directly from `Control` or from a more specialized base class that derives (eventually) from `Control`. As a result, the web server controls have many common properties and events that you can use as required. There are quite a few of these, so we won't attempt to cover them all, just as with the properties and events of the web server controls themselves.

Many of the frequently used inherited properties are those that deal with display style. This can be controlled simply, using properties such as `ForeColor`, `BackColor`, `Font`, and so on, but can also be controlled using CSS classes. To use CSS styling, you set the string property `CssClass` to the name of a CSS class in a separate file. You can use the CSS Properties window along with the style management windows to assist you with CSS control styling. Other notable properties include `Width` and `Height` to size a control, `AccessKey` and `TabIndex` to ease user interaction, and `Enabled` to set whether the control's functionality is activated in the Web Form.

Some controls can contain other controls, building up a control hierarchy on a page. You can get access to the controls contained by a given control using its `Controls` property, or to the container of a control via the `Parent` property.

You are likely to use the inherited `Load` event most often, to perform initialization on a control, and `PreRender` to perform last-minute modifications before HTML is output by the control.

Plenty more events and properties exist, and you see many of these in more detail in the next chapter. In particular, Chapter 41 deals with more advanced styling and skinning techniques. The following table describes the standard web server controls in more detail.

CONTROL	DESCRIPTION
`Label`	Simple text display; use the `Text` property to set and programmatically modify displayed text.
`TextBox`	Provides a text box that users can edit. Use the `Text` property to access the entered data, and the `TextChanged` event to act on selection changes on post-back. If automatic postback is required (as opposed to using a button), then set the `AutoPostBack` property to `true`.
`Button`	Adds a standard button for the user to click. Use the `Text` property for text on the button, and the `Click` event to respond to clicks (server postback is automatic). You can also use the `Command` event to respond to clicks, which gives access to additional `CommandName` and `CommandArgument` properties on receipt.
`LinkButton`	Identical to `Button`, but displays the button as a hyperlink.
`ImageButton`	Displays an image that doubles as a clickable button. Properties and events are inher-ited from `Button` and `Image`.
`HyperLink`	Adds an HTML hyperlink. Set the destination with `NavigateUrl` and the text to display with `Text`. You can also use `ImageUrl` to specify an image for the link and `Target` to specify the browser window to use. This control has no nonstandard events, so use a `LinkButton` instead if additional processing is required when the link is followed.
`DynamicHyperLink`	Used to render an HTML hyperlink to a predefined location in a dynamic data web site. Dynamic data web sites are covered in Chapter 42, "ASP.NET MVC."
`DropDownList`	Allows the user to select one of a list of choices, either by choosing it directly from a list or by typing the first letter or two. Use the `Items` property to set the item list (this is a `ListItemCollection` class containing `ListItem` objects) and the `SelectedItem` and `SelectedIndex` properties to determine what is selected. The `SelectedIndexChanged` event can be used to determine whether the selection has changed, and this control also has an `AutoPostBack` property so that this selection change will trigger a postback operation.
`ListBox`	Allows the user to make one or more selections from a list. Set `SelectionMode` to `Multiple` or `Single` to specify if only one or multiple items can be selected at the same time, and `Rows` to determine how many items to display. Other properties and events are the same as for `DropDownList`.
`CheckBox`	Displays a box that can be checked or unchecked. The state is stored in the Boolean property `Checked`, and the text associated with the check box in `Text`. The `AutoPostBack` property can be used to initiate automatic postback and the `CheckedChanged` event to act on changes.
`CheckBoxList`	Creates a group of check boxes. Properties and events are identical to other list con-trols, such as `DropDownList`.
`RadioButton`	Displays a button that can be turned on or off. Generally, these are grouped such that only one in the group is active at any time. Use the `GroupName` property to link `RadioButton` controls into a group. Other properties and events are as per `CheckBox`.
`RadioButtonList`	Creates a group of radio buttons where only one button in the group can be selected at a time. Properties and events are the same for other list controls, such as `DropDownList`.
`Image`	Displays an image. Use `ImageUrl` for the image reference, and `AlternateText` to provide text if the image fails to load.
`ImageMap`	Like `Image`, but it allows you to specify specific actions to trigger if users click one or more hotspots in the image. The action to take can either be a postback or a redirec-tion to another URL. Hotspots are supplied by embedded controls that derive from `HotSpot`, such as `RectangleHotSpot` and `CircleHotSpot`.

CONTROL	DESCRIPTION
`Table`	Specifies a table. Use this in conjunction with `TableRow` and `TableCell` at design time, or programmatically assign rows using the `Rows` property of type `TableRowCollection`. You can also use this property for runtime modifications. This control has several styling properties unique to tables, as do `TableRow` and `TableCell`.
`BulletedList`	Formats a list of items as a bulleted list. Unlike the other list controls, this one has a `Click` event that you can use to determine what item a user has clicked during a post-back. Other properties and events are the same as for `DropDownList`.
`HiddenField`	Used to provide a hidden field, to store nondisplayed values for any reason. These can be very useful to store settings that would otherwise need an alternative storage mechanism to function. Use the `Value` property to access the stored value.
`Literal`	Performs the same function as `Label`, but has no styling properties because it derives from `Control`, not `WebControl`. You set the text to display for this control with the `Text` property.
`Calendar`	Allows the user to select a date from a graphical calendar display. This control has many style-related properties, but essential functionality can be achieved using the `SelectedDate` and `VisibleDate` properties (of type `System.DateTime`) to get access to the date selected by the user and the month to display (which will always contain `VisibleDate`). The key event to hook up to is `SelectionChanged`. Postback from this control is automatic.
`AdRotator`	Displays several images in succession, with a different one displayed after each server round trip. Use the `AdvertisementFile` property to specify the XML file describing the possible images, and the `AdCreated` event to perform processing before each image is sent back. You can also use the `Target` property to name a window to open when an image is clicked.
`FileUpload`	This control presents the user with a text box and a Browse button, such that a file to be uploaded can be selected. After the user has done this, you can look at the `HasFile` property to determine if a file has been selected, and then use the `SaveAs()` method from code-behind to perform the file upload.
`Wizard`	An advanced control used to simplify the common task of getting several pages of user input in one go. You can add multiple steps to a wizard, which can be presented to a user sequentially or nonsequentially, and rely on this control to maintain state and so on.
`Xml`	A more complicated text display control, used for displaying XML content, which may be transformed using an XSLT style sheet. The XML content is set using one of the `Document`, `DocumentContent`, or `DocumentSource` properties (depending on the format of the original XML), and the XSLT style sheet (optional) using either `Transform` or `TransformSource`.
`MultiView`	A control that contains one or more `View` controls, where only one `View` is rendered at a time. The currently displayed view is specified using `ActiveViewIndex`, and you can detect if the view changes (perhaps because a Next link on the currently dis-played view is clicked) with the `ActiveViewChanged` event.
`Panel`	Adds a container for other controls. You can use `HorizontalAlign` and `Wrap` to specify how the contents are arranged.
`PlaceHolder`	This control doesn't render any output but can be handy for grouping other controls together, or for adding controls programmatically to a given location. Contained con-trols can be accessed using the `Controls` property.
`View`	A container for controls, much like `PlaceHolder`, but designed for use as a child of `MultiView`. You can tell if a given `View` is being displayed using `Visible`, or use the `Activate` and `Deactivate` events to detect changes in activation state.

continues

(continued)

CONTROL	DESCRIPTION
`Substitution`	Specifies a section of a web page that isn't cached along with other output. This is an advanced topic related to ASP.NET caching behavior, which you won't be looking at in this book.
`Localize`	Exactly like `Literal`, but enables text to be localized by using project resources to specify the text to display for various locales.

Data Web Server Controls

The data web server controls are divided into three types:

- **Data source controls** (`SqlDataSource`, `AccessDataSource`, `LinqDataSource`, `EntityDataSource`, `ObjectDataSource`, `XmlDataSource`, and `SiteMapDataSource`)
- **Data display controls** (`GridView`, `DataList`, `DetailsView`, `FormView`, `ListView`, `Repeater`, and `DataPager`)
- **Dynamic data controls** (`DynamicControl` and `DynamicDataManager`)

In general, you will place one of the (nonvisual) data source controls on a page to link to a data source; and then you will add a data display control that binds to a data source control to display that data. Some of the more advanced data display controls, such as `GridView`, also allow you to edit data.

All the data source controls derive from either `System.Web.UI.DataSource` or `System.Web.UI.HierarchicalDataSource`. These classes expose methods such as `GetView()` or `GetHierarchicalView()` to give access to internal data views and skinning capabilities.

The following table describes the various data source controls. Note that there is less detail about properties in this section than in others — mainly because configuration of these controls is best done graphically or through wizards. Later in this chapter, you will see some of these controls in action.

CONTROL	DESCRIPTION
`SqlDataSource`	Acts as a conduit for data stored in a SQL Server database. By placing this control on a page, you can manipulate SQL Server data using a data display control. You will see this control in action later in this chapter.
`AccessDataSource`	Like `SqlDataSource`, but it works with data stored in a Microsoft Access database.
`LinqDataSource`	This control allows you to manipulate objects in a LINQ-enabled data model.
`EntityDataSource`	This control allows you to manipulate ADO.NET Entity Data Model objects.
`ObjectDataSource`	This control allows you to manipulate data stored in objects that you have created, which may be grouped in a collection class. This can be a very quick way to expose custom object models to an ASP.NET page.
`XmlDataSource`	Enables you to bind to XML data. This works well in binding to, for example, a `TreeView` control (one of the Navigation controls). You can also transform XML data using an XSL style sheet using this control if desired.
`SiteMapDataSource`	Allows binding to hierarchical site map data. See the section on navigation web server controls in Chapter 41 for more information.

The following table displays the data display controls. Several of these are available to suit various needs. Some are more fully functional than others, but often you can go with simplicity (for example, when you don't need to be able to edit data items).

CONTROL	DESCRIPTION
`GridView`	Displays multiple data items (such as rows in a database) in the form of rows, where each row has columns reflecting data fields. By manipulating the properties of this control, you can select, sort, and edit data items.
`DataList`	Displays multiple data items where you can supply templates for each item to display data fields in any way you choose. As with `GridView`, you can select, sort, and edit data items.
`DetailsView`	Displays a single data item in tabular form, with each row of the table relating to a data field. This control enables you to add, edit, and delete data items.
`FormView`	Displays a single data item using a template. As with `DetailsView`, this control enables you to add, edit, and delete data items.
`ListView`	Like `DataList`, but with support for pagination using `DataPager` and more template capabilities.
`Repeater`	Like `DataList`, but without selecting or editing capabilities.
`DataPager`	Allows pagination of `ListView` controls.
`Chart`	Displays data in a chart, such as a bar chart or pie chart. This control is examined in the next chapter.

The dynamic data controls are covered in Chapter 42.

Validation Web Server Controls

Validation controls provide a method of validating user input without (in most cases) your having to write any code at all. Whenever postback is initiated, each validation control checks the control it is validating and changes its `IsValid` property accordingly. If this property is `false`, then the user input for the validated control has failed validation. The page containing all the controls also has an `IsValid` property — if any of the validation controls has its version of this property set to `false`, then this will be `false` also. You can check this property from your server-side code and act on it.

Validation controls also have another function. Not only do they validate controls at runtime; they can also output helpful hints to users. Simply setting the `ErrorMessage` property to the text you want means users will see it when they attempt to postback invalid data.

The text stored in `ErrorMessage` may be output at the point where the validation control is located, or at a separate point, along with the messages from all other validation controls on a page. This latter behavior is achieved using the `ValidationSummary` control, which displays all error messages along with additional text as required.

On browsers that support it, these controls even generate client-side JavaScript functions to streamline their validation behavior. This means that in some cases postback won't even occur, because the validation controls can prevent this under certain circumstances and output error messages without involving the server.

All validation controls inherit from `BaseValidator` and thus share several important properties. Perhaps the most important is the `ErrorMessage` property discussed earlier in this section, with the `ControlToValidate` property coming in a close second. This property specifies the programmatic `ID` of the control that is being validated. Another important property is `Display`, which determines whether to place text at the validation summary position (if set to `none`), or at the validator position. You also have the choice to make space for the error message even when it is not being displayed (set `Display` to `Static`) or to dynamically allocate space when required, which might shift page contents around slightly (set `Display` to `Dynamic`). The following table describes the validation controls.

CONTROL	DESCRIPTION
`RequiredFieldValidator`	Used to check if the user has entered data in a control such as `TextBox`.
`CompareValidator`	Used to check that data entered fulfills simple requirements, by use of an operator set using the `Operator` property and a `ValueToCompare` property to validate against. `Operator` can be `Equal`, `GreaterThan`, `GreaterThanEqual`, `LessThan`, `LessThanEqual`, `NotEqual`, and `DataTypeCheck`. `DataTypeCheck` simply compares the data type of `ValueToCompare` with the data in the control to be validated. `ValueToCompare` is a string property but is interpreted as different data types based on its contents. To further control the comparison, you can set the `Type` property to `Currency`, `Date`, `Double`, `Integer`, or `String`.
`RangeValidator`	Validates that data in the control falls between `MaximumValue` and `MinimumValue` property values. Has a `Type` property similar to `CompareValidator`.
`RegularExpressionValidator`	Validates the contents of a field based on a regular expression stored in `ValidationExpression`. This can be useful for known sequences such as ZIP codes, phone numbers, IP numbers, and so on.
`CustomValidator`	Used to validate data in a control using a custom function. `ClientValidationFunction` is used to specify a client-side function used to validate a control (which means, unfortunately, that you can't use C#). This function should return a Boolean value indicating whether validation was successful. Alternatively, you can use the `ServerValidate` event to specify a server-side function to use for validation. This function is a `bool` type event handler that receives a string containing the data to validate, instead of an `EventArgs` parameter. Returns `true` if validation succeeds, otherwise `false`.
`DynamicValidator`	This validation control is used to provide business logic validation for dynamic data sites, and is covered in Chapter 42.
`ValidationSummary`	Displays validation errors for all validation controls that have an `ErrorMessage` set. The display can be formatted by setting the `DisplayMode` (`BulletList`, `List`, or `SingleParagraph`) and `HeaderText` properties. The display can be disabled by setting `ShowSummary` to `false`, and displayed in a pop-up message box by setting `ShowMessageBox` to `true`.

Server Control Event-Booking Example

In this example, you create the framework for a web application, a meeting room booking tool. (As with the other examples in this book, you can download the sample application and code from the Wrox web site at `www.wrox.com`.) At first, you will include only the front end and simple event processing; later, you will extend this example with ADO.NET and data binding to include server-side business logic.

The Web Form you are going to create contains fields for username, event name, meeting room, and attendees, along with a calendar to select a date (you are assuming for the purposes of this example that you are dealing with all-day events). You will include validation controls for all fields except the calendar, which you will validate on the server side, and provide a default date in case none has been entered.

For user interface (UI) testing, you will also have a `Label` control on the form that you can use to display submission results.

For starters, create a new empty web site in Visual Studio .NET in the `C:\ProCSharp\Chapter40\` directory, and call it PCSWebSite2. Next, add a new Web Form using the default settings and modify the code in the generated `Default.aspx` file as follows:

```
<%@ Page Language="C#" AutoEventWireup="true" CodeFile="Default.aspx.cs"
  Inherits="_Default" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.1//EN"

    </div>
```

code snippet PCSWebSite2/Default.aspx

After the title of the page (which is enclosed in HTML `<h1>` tags to get large, title-style text), the main body of the form is enclosed in an HTML `<table>`. You could use a web server control table, but this introduces unnecessary complexity because you are using a table purely for formatting the display, not to be a dynamic UI element. This is an important point to bear in mind when designing Web Forms — don't add web server controls unnecessarily. The table is divided into three columns: the first column holds simple text labels; the second column holds UI fields corresponding to the text labels (along with validation controls for these); and the third column contains a calendar control for date selection, which spans four rows. The fifth row contains a submission button spanning all columns, and the sixth row contains a `ValidationSummary` control to display error messages, when required (all the other validation controls have `Display="None"`, because they will use this summary for display). Beneath the table is a simple label that you can use to display results for now, before you add database access later:

```
    <div style="text-align: center;">
      <table style="text-align: left; border-color: #000000;
        border-width: 2px; background-color: #fff99e;" cellspacing="0"
        cellpadding="8" rules="none" width="540">
        <tr>
          <td valign="top">
            Your Name:</td>
          <td valign="top">
            <asp:TextBox ID="nameBox" Runat="server" Width="160px" />
            <asp:RequiredFieldValidator ID="validateName" Runat="server"
              ErrorMessage="You must enter a name."
              ControlToValidate="nameBox" Display="None" />
          </td>
          <td valign="middle" rowspan="4">
            <asp:Calendar ID="calendar" Runat="server" BackColor="White" />
          </td>
        </tr>
        <tr>
          <td valign="top">
            Event Name:</td>
          <td valign="top">
            <asp:TextBox ID="eventBox" Runat="server" Width="160px" />
            <asp:RequiredFieldValidator ID="validateEvent" Runat="server"
          ErrorMessage="You must enter an event name."
          ControlToValidate="eventBox" Display="None" />
      </td>
    </tr>
```

Most of the ASP.NET code in this file is remarkably simple, and much can be learned simply by reading through it. Of particular note in this code is the way in which list items are attached to the controls for selecting a meeting room and multiple attendees for the event:

```
    <tr>
      <td valign="top">
        Meeting Room:</td>
      <td valign="top">
        <asp:DropDownList ID="roomList" Runat="server" Width="160px">
          <asp:ListItem Value="1">The Happy Room</asp:ListItem>
          <asp:ListItem Value="2">The Angry Room</asp:ListItem>
          <asp:ListItem Value="3">The Depressing
           Room</asp:ListItem>
          <asp:ListItem Value="4">The Funked Out
           Room</asp:ListItem>
        </asp:DropDownList>
        <asp:RequiredFieldValidator ID="validateRoom" Runat="server"
          ErrorMessage="You must select a room."
          ControlToValidate="roomList" Display="None" />
      </td>
    </tr>
    <tr>
      <td valign="top">
        Attendees:</td>
      <td valign="top">
        <asp:ListBox ID="attendeeList" Runat="server" Width="160px"
          SelectionMode="Multiple" Rows="6">
          <asp:ListItem Value="1">Bill Gates</asp:ListItem>
          <asp:ListItem Value="2">Monica Lewinsky</asp:ListItem>
          <asp:ListItem Value="3">Vincent Price</asp:ListItem>
          <asp:ListItem Value="4">Vlad the Impaler</asp:ListItem>
          <asp:ListItem Value="5">Iggy Pop</asp:ListItem>
          <asp:ListItem Value="6">William
           Shakespeare</asp:ListItem>
        </asp:ListBox>
```

Here you are associating `ListItem` objects with the two web server controls. These objects are not web server controls in their own right (they simply inherit from `System.Object`), which is why you don't need to use `Runat="server"` on them. When the page is processed, the `<asp:ListItem>` entries are used to create `ListItem` objects, which are added to the `Items` collection of their parent list control. This makes it easier for you to initialize lists than to write code for this yourself (you would need to create a `ListItemCollection` object, add `ListItem` objects, and then pass the collection to the list control). Of course, you can still do all this programmatically if you want.

```
        <asp:RequiredFieldValidator ID="validateAttendees" Runat="server"
          ErrorMessage="You must have at least one attendee."
          ControlToValidate="attendeeList" Display="None" />
      </td>
    </tr>
    <tr>
      <td align="center" colspan="3">
        <asp:Button ID="submitButton" Runat="server" Width="100%"
          Text="Submit meeting room request" />
      </td>
    </tr>
    <tr>
```

```
            <td align="center" colspan="3">
              <asp:ValidationSummary ID="validationSummary" Runat="server"
                HeaderText="Before submitting your request:" />
            </td>
          </tr>
        </table>
      </div>
      <div>
        <p>
          Results:
          <asp:Label Runat="server" ID="resultLabel" Text="None." />
        </p>
      </div>
    </form>
  </body>
</html>
```

In design view, the form you have created looks like Figure 40-7. This is a fully functioning UI, which maintains its own state between server requests, and validates user input. Considering the brevity of the preceding code, this is quite something. In fact, it leaves you with very little to do, at least for this example; you just need to specify the button click event for the submission button.

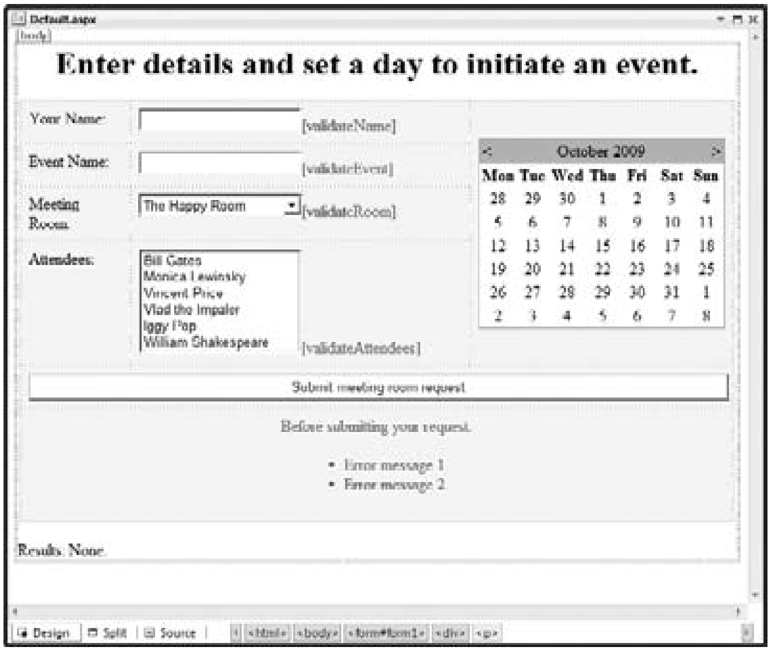

FIGURE 40-7

Actually, that's not quite true. So far, you have no validation for the calendar control. All you need to do is give it an initial value. You can do this in the `Page_Load()` event handler for your page in the code-behind file:

```
protected void Page_Load(object sender, EventArgs e)
{
   if (!this.IsPostBack)
   {
```

```
            calendar.SelectedDate = DateTime.Now;
         }
      }
```

code snippet PCSWebSite2/Default.aspx.cs

Here you just select today's date as a starting point. Note that you first check to see if `Page_Load()` is being called as the result of a postback operation, by checking the `IsPostBack` property of the page. If a postback is in progress, this property will be `true` and you leave the selected date alone (you don't want to lose the user's selection, after all).

To add the button click handler, simply double-click the button and add the following code:

```
      protected void submitButton_Click(object sender, EventArgs e)
      {
         if (this.IsValid)
         {
            resultLabel.Text = roomList.SelectedItem.Text +
               " has been booked on " +
               calendar.SelectedDate.ToLongDateString() +
               " by " + nameBox.Text + " for " +
               eventBox.Text + " event. ";
            foreach (ListItem attendee in attendeeList.Items)
            {
               if (attendee.Selected)
               {
                  resultLabel.Text += attendee.Text + ", ";
               }
            }
            resultLabel.Text += " and " + nameBox.Text +
               " will be attending.";
         }
      }
```

Here you just set the `resultLabel` control `Text` property to a result string, which will then appear below the main table. In IE, the result of such a submission might look something like Figure 40-8, unless there are errors, in which case the `ValidationSummary` will activate instead, as shown in Figure 40-9.

FIGURE 40-9

ADO.NET AND DATA BINDING

The web site you created in the previous section is perfectly functional, but it contains only static data. In addition, the event-booking process does not include persisting event data. To solve both of these problems, you can make use of ADO.NET to access data stored in a database, so that you can store and retrieve event data along with the lists of rooms and attendees.

Data binding makes the process of retrieving data even easier. Controls such as list boxes (and some of the more specialized controls you'll look at a bit later) come enabled for this technique. They can be bound to any object that exposes an `IEnumerable`, `ICollection`, or `IListSource` interface, as well as any of the data source web server controls.

In this section, you start by updating your event-booking application to be data-aware, and then move on to take a look at some of the other results you can achieve with data binding, using some of the other data-aware web controls.

Updating the Event-Booking Application

To keep things separate from the last example, create a new empty web site called `PCSWebSite3` in the directory `C:\ProCSharp\Chapter40\` and copy the code from the `PCSWebSite2` application created earlier into the new application. Before you start on your new code, take a look at the database you will be accessing.

The Database

For the purposes of this example, you will use a Microsoft SQL Server Express database called `MeetingRoomBooker.mdf`, which is part of the downloadable code for this book. For an enterprise-scale application, it makes more sense to use a full SQL Server database, but the techniques involved are practically identical, and SQL Server Express makes life a bit easier for testing. The code will also be identical.

If you are adding your own version of this database, you will need to add a new database to a folder called App_Data in the web site. This is one of several "special" folders that can exist in an ASP.NET web site; you can add by selecting Website ➪ Add ASP.NET Folder ➪ App_Data. To add a new database to this folder, right-click the new App_Data folder, select Add New Item, then select the SQL Server Database option. Name the new database MeetingRoomBooker and click Add. This will also configure a data connection in the Server Explorer window ready for you to use. Next, you can add the tables required as shown in the next sections and supply your own data. Alternatively, to use the downloadable database with your own code, simply copy it to the `App_Data` *directory for your web site.*

The database provided contains three tables:

- `Attendees`, which contains a list of possible event attendees
- `Rooms`, which contains a list of possible rooms for events
- `Events`, which contains a list of booked events

Attendees

The `Attendees` table contains the columns shown in the following table.

COLUMN	TYPE	NOTES
`ID`	Identity, primary key	Attendee identification number
`Name`	varchar, required, 50 chars	Name of attendee
`Email`	varchar, optional, 50 chars	E-mail address of attendee

The supplied database includes entries for 20 attendees, all with their own (fictional) e-mail addresses. You can envision that in a more developed application, e-mails could automatically be sent to attendees when a booking is made, but this is left to you as an optional exercise using techniques found elsewhere in this book.

Rooms

The `Rooms` table contains the columns shown in the following table.

COLUMN	TYPE	NOTES
`ID`	Identity, primary key	Room identification number
`Room`	varchar, required, 50 chars	Name of room

Twenty records are supplied in the database.

Events

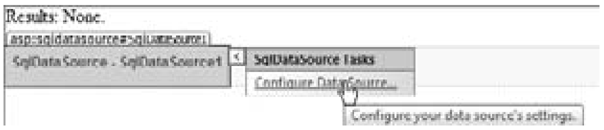
The `Events` table contains the columns shown in the following table.

COLUMN	TYPE	NOTES
`ID`	Identity, primary key	Event identification number
`Name`	varchar, required, 255 chars	Name of event
`Room`	int, required	ID of room for event
`AttendeeList`	text, required	List of attendee names
`EventDate`	datetime, required	Date of event

A few events are supplied in the downloadable database.

Binding to the Database

The two controls you are going to bind to data are `attendeeList` and `roomList`. Before you do this, you need to add `SqlDataSource` web server controls that map to the tables you want to access in the `MeetingRoomBooker.mdf` database. The quickest way to do this is to drag them from the toolbox onto the `Default.aspx` Web Form and configure them via the Configuration Wizard. Figure 40-10 shows how to access this wizard for a `SqlDataSource` control.



Results: None.
asp:sqldatasource#sqldatasource1
SqlDataSource - SqlDataSource1
SqlDataSource Tasks
Configure Data Source...
Configure your data source's settings.

FIGURE 40-10

From the first page of the data source Configuration Wizard, you need to select the connection to the database created earlier. Next, choose to save the connection string as `MRBConnectionString`; then choose to select `*` (all fields) from the `Attendees` table in the database.

After completing the wizard, change the `ID` of the `SqlDataSource` control to `MRBAttendeeData`. You also need to add and configure two more `SqlDataSource` controls to obtain data from the `Rooms` and `Events` tables, with `ID` values of `MRBRoomData` and `MRBEventData` respectively. For these subsequent controls, you can use the saved `MRBConnectionString` for your connection.

After you've added these data sources, you will see in the code for the form that the syntax is very simple:

```
<asp:SqlDataSource ID="MRBAttendeeData" runat="server"
  ConnectionString="<%$ ConnectionStrings:MRBConnectionString %>"
  SelectCommand="SELECT * FROM [Attendees]"></asp:SqlDataSource>
<asp:SqlDataSource ID="MRBRoomData" runat="server"
  ConnectionString="<%$ ConnectionStrings:MRBConnectionString %>"
  SelectCommand="SELECT * FROM [Rooms]"></asp:SqlDataSource>
<asp:SqlDataSource ID="MRBEventData" runat="server"
  ConnectionString="<%$ ConnectionStrings:MRBConnectionString %>"
  SelectCommand="SELECT * FROM [Events]"></asp:SqlDataSource>
```

code snippet PCSWebSite3/Default.aspx

The definition of the connection string in use is found in the `web.config` file, which we look at in more detail later in this chapter.

Next, you need to set the data-binding properties of the `roomList` and `attendeeList` controls. For `roomList` the settings required are as follows:

- `DataSourceID` — `MRBRoomData`
- `DataTextField` — `Room`
- `DataValueField` — `ID`

And, similarly, for `attendeeList`:

- `DataSourceID` — `MRBAttendeeData`
- `DataTextField` — `Name`
- `DataValueField` — `ID`

You can also remove the existing hard-coded list items from the code for these controls.

Running the application now will result in the full attendee and room data being available from your data-bound controls. You will use the `MRBEventData` control shortly.

Customizing the Calendar Control

Before adding events to the database, you need to modify your calendar display. It would be nice to display all days where a booking has previously been made in a different color, and prevent such days from being selectable. This requires that you modify the way you set dates in the calendar and the way day cells are displayed.

You will start with date selection. You need to check for dates where events are booked in three places, and modify the selection accordingly: 1) when you set the initial date in `Page_Load()`, 2) when the user attempts to select a date from the calendar, and 3) when an event is booked and you want to set a new date to prevent the user from booking two events on the same day before selecting a new date. Because this is going to be a common feature, you might as well create a private method to perform this calculation. This method should accept a trial date as a parameter and return the date to use, which will either be the same date as the trial date, or the next available day after the trial date.

Before adding this method, you need to give your code access to data in the `Events` table. You can use the `MRBEventData` control to do this because this control is capable of populating a `DataView`. To facilitate this, add the following private member and property (you may also require a namespace import for `System.Data` for this code to work):

```
private DataView eventData;
private DataView EventData
{
   get
   {
      if (eventData == null)
      {
         eventData =
           MRBEventData.Select(new DataSourceSelectArguments())
           as DataView;
      }
      return eventData;
   }
   set
   {
      eventData = value;
   }
}
```

code snippet PCSWebSite3/Default.aspx.cs

The `EventData` property populates the `eventData` member with data as it is required, with the results cached for subsequent use. Here you use the `SqlDataSource.Select()` method to obtain a `DataView`.

Next, add this method, `GetFreeDate()`, to the code-behind file:

```
private DateTime GetFreeDate(DateTime trialDate)
{
   if (EventData.Count > 0)
   {
      DateTime testDate;
      bool trialDateOK = false;
      while (!trialDateOK)
      {
         trialDateOK = true;
         foreach (DataRowView testRow in EventData)
         {
            testDate = (DateTime)testRow["EventDate"];
            if (testDate.Date == trialDate.Date)
            {
               trialDateOK = false;
```

```
                    trialDate = trialDate.AddDays(1);
                }
            }
        }
    }
    return trialDate;
}
```

This simple code uses the EventData DataView to extract event data. First, you check for the trivial case where no events have been booked, in which case you can just confirm the trial date by returning it. Next, you iterate through the dates in the Event table, comparing them with the trial date. If you find a match, add one day to the trial date and perform another search.

Extracting the date from the DataTable is remarkably simple:

```
testDate = (System.DateTime)testRow["EventDate"];
```

Casting the column data into System.DateTime works fine.

The first place you will use GetFreeDate(), then, is back in Page_Load(). This simply means making a minor modification to the code that sets the calendar SelectedDate property:

```
if (!this.IsPostBack)
{
    DateTime trialDate = DateTime.Now;
    calendar.SelectedDate = GetFreeDate(trialDate);
}
```

Next, you need to respond to date selection on the calendar. To do this, simply add an event handler for the SelectionChanged event of the calendar, and force the date to be checked against existing events. Double-click the calendar in the Designer and add this code:

```
protected void calendar_SelectionChanged(object sender, EventArgs e)
{
   DateTime trialDate = calendar.SelectedDate;
     calendar.SelectedDate = GetFreeDate(trialDate);
}
```

The code here is practically identical to that in Page_Load().

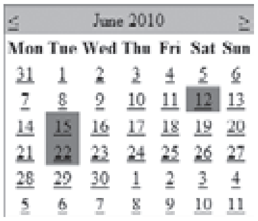
The third place that you must perform this check is in response to the pressed booking button. We will come back to this shortly, as you have several changes to make here.

Next, you need to color the day cells of the calendar to signify existing events. To do this, you add an event handler for the DayRender event of the calendar object. This event is raised each time an individual day is rendered, and gives you access to the cell object being displayed and the date of this cell through the Cell and Date properties of the DayRenderEventArgs parameter you receive in the handler function. You simply compare the date of the cell being rendered to the dates in the eventTable object and color the cell using the Cell.BackColor property if there is a match:

```
protected void calendar_DayRender(object sender, DayRenderEventArgs e)
{
   if (EventData.Count > 0)
   {
      DateTime testDate;
      foreach (DataRowView testRow in EventData)
      {
         testDate = (DateTime)testRow["EventDate"];
         if (testDate.Date == e.Day.Date)
         {
            e.Cell.BackColor = System.Drawing.Color.Red;
         }
      }
   }
}
```

Here you are using red, which will give you a display along the lines of Figure 40-11, in which June 12, 15, and 22 (2010) all contain events.

With the addition of the date-selection logic, it is now impossible to select a day that is shown in red. If you attempt it, a later date is selected instead (for example, selecting June 15 results in the selection of June 16).



<			June 2010			>
Mon	Tue	Wed	Thu	Fri	Sat	Sun
31	1	2	3	4	5	6
7	8	9	10	11	12	13
14	15	16	17	18	19	20
21	22	23	24	25	26	27
28	29	30	1	2	3	4
5	6	7	8	9	10	11

FIGURE 40-11

Adding Events to the Database

The `submitButton_Click()` event handler currently assembles a string from the event characteristics and displays it in the `resultLabel` control. To add an event to the database, you simply reformat the string created in a SQL `INSERT` query and execute it.

Note that in the development environment that you are using, you don't have to worry too much about security. Adding a SQL Server 2008 Express database via a web site solution and configuring `SqlDataSource` *controls to use it will automatically give you a connection string that you can use to write to the database. In more advanced situations, you might want to access resources using other accounts — for example, a domain account used to access a SQL Server instance elsewhere on a network. The capability to do this (via impersonation, COM+ Services, or other means) exists in ASP.NET, but is beyond the scope of this chapter. In most cases, configuring the connection string appropriately is as complicated as things need to get.*

Much of the following code will therefore look familiar:

```
protected void submitButton_Click(object sender, EventArgs e)
{
   if (this.IsValid)
   {
      System.Text.StringBuilder sb = new System.Text.StringBuilder();
      foreach (ListItem attendee in attendeeList.Items)
      {
         if (attendee.Selected)
         {
            sb.AppendFormat("{0} ({1}), ", attendee.Text, attendee.Value);
         }
      }
      sb.AppendFormat(" and {0}", nameBox.Text);
      string attendees = sb.ToString();
      try
      {
         System.Data.SqlClient.SqlConnection conn =
            new System.Data.SqlClient.SqlConnection(
               ConfigurationManager.ConnectionStrings[
               "MRBConnectionString"].ConnectionString);
         System.Data.SqlClient.SqlCommand insertCommand =
            new System.Data.SqlClient.SqlCommand("INSERT INTO [Events] "
               + "(Name, Room, AttendeeList, EventDate) VALUES (@Name, "
               + "@Room, @AttendeeList, @EventDate)", conn);
         insertCommand.Parameters.Add(
            "Name", SqlDbType.VarChar, 255).Value = eventBox.Text;
         insertCommand.Parameters.Add(
            "Room", SqlDbType.Int, 4).Value = roomList.SelectedValue;
         insertCommand.Parameters.Add(
            "AttendeeList", SqlDbType.Text, 16).Value = attendees;
         insertCommand.Parameters.Add(
            "EventDate", SqlDbType.DateTime, 8).Value =
            calendar.SelectedDate;
```

The most interesting thing here is how you access the connection string you created earlier, using the following syntax:

```
ConfigurationManager.ConnectionStrings["MRBConnectionString"].ConnectionString
```

The `ConfigurationManager` class (which requires a namespace import for `System.Configuration`) gives you access to all assorted configuration information, all stored in the `Web.config` configuration file for your web application. You will look at this in more detail later in this chapter.

After you have created your SQL command, you can use it to insert the new event:

```
            conn.Open();
            int queryResult = insertCommand.ExecuteNonQuery();
            conn.Close();
```

`ExecuteNonQuery()` returns an integer representing how many table rows were affected by the query. If this is equal to 1, your insertion was successful. If so, put a success message in `resultLabel`, clear `EventData` because it is now out of date, and change the calendar selection to a new, free date. Because `GetFreeDate()` involves using `EventData`, and the `EventData` property automatically refreshes itself if it has no data, the stored event data will be refreshed:

```
            if (queryResult == 1)
            {
               resultLabel.Text = "Event Added.";
               EventData = null;
               calendar.SelectedDate =
                  GetFreeDate(calendar.SelectedDate.AddDays(1));
            }
```

If `ExecuteNonQuery()` returns a number other than 1, you know that there has been a problem. The code in this example throws an exception if a number other than 1 is returned. This exception is caught by the general catch block for the database access code.

This catch block simply displays a general failure notification in `resultLabel`:

```
            else
            {
               throw new System.Data.DataException("Unknown data error.");
            }
         }
         catch
         {
            resultLabel.Text = "Event not added due to DB access "
                               + "problem.";
         }
      }
   }
```

This completes your data-aware version of the event-booking application.

More on Data Binding

As mentioned earlier in this chapter, the available web server controls include several that deal with data display (`GridView`, `DataList`, `DetailsView`, `FormView`, and `Repeater`). These are all extremely useful when it comes to outputting data to a web page because they perform many tasks automatically that would otherwise require a fair amount of coding.

First, you will look at how easy using these controls can be, by adding an event list display to the bottom of the display of `PCSWebSite3`.

Drag a `GridView` control from the toolbox to the bottom of `Default.aspx`, and select the `MRBEventData` data source you added earlier for it, as shown in Figure 40-12.

Next, click Refresh Schema, and that's all you need to do to display a list of events under the form — try viewing the web site now and you should see the events, as shown in Figure 40-13.

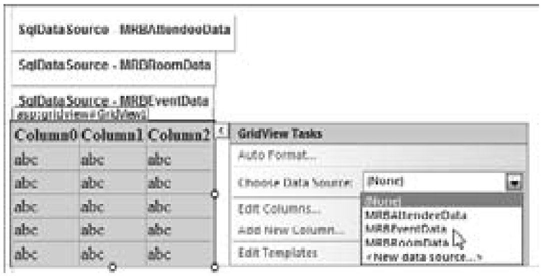


FIGURE 40-12

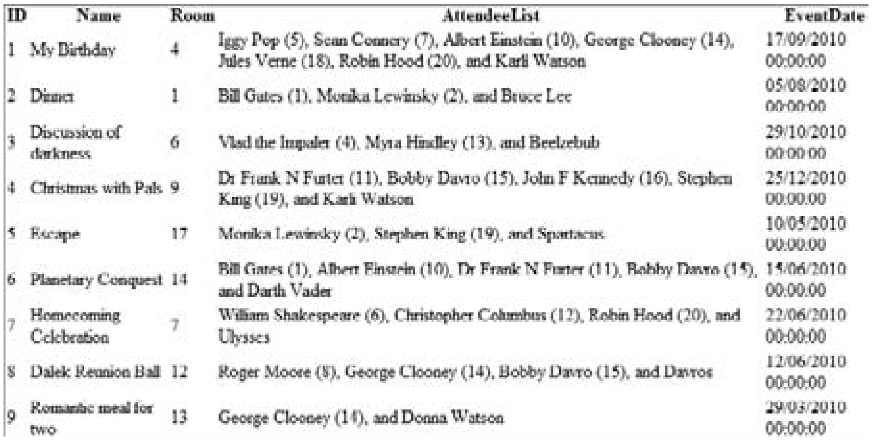

ID	Name	Room	AttendeeList	EventDate
1	My Birthday	4	Iggy Pop (5), Sean Connery (7), Albert Einstein (10), George Clooney (14), Jules Verne (18), Robin Hood (20), and Karli Watson	17/09/2010 00:00:00
2	Dinner	1	Bill Gates (1), Monika Lewinsky (2), and Bruce Lee	05/08/2010 00:00:00
3	Discussion of darkness	6	Vlad the Impaler (4), Myra Hindley (13), and Beelzebub	29/10/2010 00:00:00
4	Christmas with Pals	9	Dr Frank N Furter (11), Bobby Davro (15), John F Kennedy (16), Stephen King (19), and Karli Watson	25/12/2010 00:00:00
5	Escape	17	Monika Lewinsky (2), Stephen King (19), and Spartacus	10/05/2010 00:00:00
6	Planetary Conquest	14	Bill Gates (1), Albert Einstein (10), Dr Frank N Furter (11), Bobby Davro (15), and Darth Vader	15/06/2010 00:00:00
7	Homecoming Celebration	7	William Shakespeare (6), Christopher Columbus (12), Robin Hood (20), and Ulysses	22/06/2010 00:00:00
8	Dalek Reunion Ball	12	Roger Moore (8), George Clooney (14), Bobby Davro (15), and Davros	12/06/2010 00:00:00
9	Romantic meal for two	13	George Clooney (14), and Donna Watson	29/03/2010 00:00:00

FIGURE 40-13

You can also make one further modification in `submitButton_Click()` to ensure that this data is updated when new records are added:

```
if (queryResult == 1)
{
   resultLabel.Text = "Event Added.";
   EventData = null;
   calendar.SelectedDate =
      GetFreeDate(calendar.SelectedDate.AddDays(1));
   GridView1.DataBind();
}
```

All data-bindable controls support this method, which is normally called by the form if you call the top-level (`this`) `DataBind()` method.

You probably noticed in Figure 40-13 that the date/time display for the `EventDate` field is a little messy. Because you are looking at dates only, the time is always 00:00:00 AM — information that isn't really necessary to display. In the next sections, you see how this date information can be displayed in a more user-friendly fashion in the context of a `ListView` control. As you might expect, the `DataGrid` control contains many properties that you can use to format the displayed data, but I'll leave these for you to discover.

Data Display with Templates

Many of the data display controls allow you to use templates to format data for display. Templates, in an ASP.NET sense, are parameterized sections of HTML that are used as elements of output in certain controls. They enable you to customize exactly how data is output to the browser, and can result in professional-looking displays without too much effort.

Several templates are available to customize various aspects of list behavior. One of the most important templates is `<ItemTemplate>`, which is used in the display of each data item in a list for `Repeater`, `DataList`, and `ListView` controls. You declare this template (and all the others) inside the control declaration. For example:

```
<asp:DataList Runat="server" ... >
  <ItemTemplate>
    ...
  </ItemTemplate>
</asp:DataList>
```

Within template declarations, you will normally want to output sections of HTML along with parameters from the data that is bound to the control. You can use a special syntax to output such parameters:

```
<%# expression %>
```

The *expression* placeholder might be simply an expression binding the parameter to a page or control property, but is more likely to consist of an `Eval()` or `Bind()` expression. These functions can be used to output data from a table bound to a control simply by specifying the column. The following syntax is used for `Eval()`:

```
<%# Eval("ColumnName") %>
```

An optional second parameter allows you to format the data returned, which has syntax identical to string formatting expressions used elsewhere. This can be used, for example, to format date strings into a more readable format — something that was lacking in the earlier example.

The `Bind()` expression is identical but allows you to insert data into attributes of server controls. For example:

```
<asp:Label RunAt="server" ID="ColumnDisplay" Text='<%# Bind("ColumnName") %>' />
```

Note that because double quotes are used in the `Bind()` parameter, single quotes are required to enclose the attribute value.

The following table provides a list of available templates and when they are used.

TEMPLATE	APPLIES TO	DESCRIPTION
`<ItemTemplate>`	`DataList, Repeater, ListView`	Used for list items
`<HeaderTemplate>`	`DataList, DetailsView, FormView, Repeater`	Used for output before item(s)
`<FooterTemplate>`	`DataList, DetailsView, FormView, Repeater`	Used for output after item(s)
`<LayoutTemplate>`	`ListView`	Used to specify output surrounding items
`<SeparatorTemplate>`	`DataList, Repeater`	Used between items in list
`<ItemSeparatorTemplate>`	`ListView`	Used between items in list
`<AlternatingItemTemplate>`	`DataList, ListView`	Used for alternate items; can aid visibility
`<SelectedItemTemplate>`	`DataList, ListView`	Used for selected items in the list
`<EditItemTemplate>`	`DataList, FormView, ListView`	Used for items being edited
`<InsertItemTemplate>`	`FormView, ListView`	Used for items being inserted

continues

(continued)

TEMPLATE	APPLIES TO	DESCRIPTION
`<EmptyDataTemplate>`	`GridView, DetailsView, FormView, ListView`	Used to display empty items — for example, when no records are available in a `GridView`
`<PagerTemplate>`	`GridView, DetailsView, FormView`	Used to format pagination
`<GroupTemplate>`	`ListView`	Used to specify the output surrounding groups of items
`<GroupSeparatorTemplate>`	`ListView`	Used between groups of items
`<EmptyItemTemplate>`	`ListView`	When using item groups, used to supply output for empty items in a group. This template is used when there are not enough items in a group to fill the group.

The easiest way to understand how to use these is through an example.

Using Templates

You will extend the table at the top of the `Default.aspx` page of `PCSWebSite3` to contain a `ListView` displaying each of the events stored in the database. You will make these events selectable such that details of any event can be displayed by clicking on its name, in a `FormView` control.

First, you need to create new data sources for the data-bound controls. It is good practice (and strongly recommended) to have a separate data source for each data-bound control.

The `SqlDataSource` control required for the `ListView` control, `MRBEventData2`, is similar to `MRBEventData`, except that it needs to return only `Name` and `ID` data. The required code is as follows:

```
<asp:SqlDataSource ID="MRBEventData2" Runat="server"
  SelectCommand="SELECT [ID], [Name] FROM [Events]"
  ConnectionString="<%$ ConnectionStrings:MRBConnectionString %>">
</asp:SqlDataSource>
```

The data source for the `FormView` control, `MRBEventDetailData`, is more complicated, although you can build it easily enough through the data source Configuration Wizard. This data source uses the selected item of the `ListView` control, which you will call `EventList`, to get only the selected item data. This is achieved using a parameter in the SQL query, as follows:

```
<asp:SqlDataSource ID="MRBEventDetailData" Runat="server"
  SelectCommand="SELECT dbo.Events.Name, dbo.Rooms.Room,
                 dbo.Events.AttendeeList, dbo.Events.EventDate
                 FROM dbo.Events INNER JOIN dbo.Rooms
                 ON dbo.Events.ID = dbo.Rooms.ID WHERE dbo.Events.ID = @ID"
  ConnectionString="<%$ ConnectionStrings:MRBConnectionString %>">
  <SelectParameters>
    <asp:ControlParameter Name="ID" DefaultValue="-1" ControlID="EventList"
      PropertyName="SelectedValue" />
  </SelectParameters>
</asp:SqlDataSource>
```

Here, the `ID` parameter results in a value being inserted in place of `@ID` in the select query. The `ControlParameter` entry takes this value from the `SelectedValue` property of `EventList`, or uses –1 if there is no selected item. At first glance, this syntax seems a little odd, but it is very flexible, and after you've generated a few of these using the wizard, you won't have any trouble assembling your own.

Next, you need to add the `ListView` and `FormView` controls. The changes to the code in `Default.aspx` in the `PCSWebSite3` project are shown in the following code:

```
    <tr>
      <td align="center" colspan="3">
        <asp:ValidationSummary ID="validationSummary" Runat="server"
          HeaderText="Before submitting your request:" />
      </td>
    </tr>
    <tr>
      <td align="left" colspan="3" style="width: 40%;">
        <table cellspacing="4" style="width: 100%;">
          <tr>
            <td colspan="2" style="text-align: center;">
              <h2>Event details</h2>
            </td>
          </tr>
          <tr>
            <td style="width: 40%; background-color: #ccffcc;"
              valign="top">
              <asp:ListView ID="EventList" runat="server"
                DataSourceID="MRBEventData2" DataKeyNames="ID"
                OnSelectedIndexChanged="EventList_SelectedIndexChanged">
                <LayoutTemplate>
                  <ul>
                    <asp:PlaceHolder ID="itemPlaceholder"
                      runat="server" />
                  </ul>
                </LayoutTemplate>
                <ItemTemplate>
                  <li>
                    <asp:LinkButton Text='<%# Bind("Name") %>'
                      runat="server" ID="NameLink" CommandName="Select"
                      CommandArgument='<%# Bind("ID") %>'
                      CausesValidation="false" />
                  </li>
                </ItemTemplate>
                <SelectedItemTemplate>
                  <li>
                    <b><%# Eval("Name") %></b>
                  </li>
                </SelectedItemTemplate>
              </asp:ListView>
            </td>
            <td valign="top">
              <asp:FormView ID="FormView1" Runat="server"
                DataSourceID="MRBEventDetailData">
                <ItemTemplate>
                  <h3><%# Eval("Name") %></h3>
                  <b>Date:</b>
                  <%# Eval("EventDate", "{0:D}") %>
                  <br />
                  <b>Room:</b>
                  <%# Eval("Room") %>
                  <br />
                  <b>Attendees:</b>
                  <%# Eval("AttendeeList") %>
                </ItemTemplate>
              </asp:FormView>
            </td>
          </tr>
        </table>
      </td>
    </tr>
  </table>
```

Here you have added a new table row containing a table with a `ListView` control in one column and a `FormView` control in the other.

The `ListView` uses `<LayoutTemplate>` to output a bulleted list and `<ItemTemplate>` and `<SelectedItemTemplate>` to display event details as list items. In `<LayoutTemplate>`, a container element for items is specified with a `PlaceHolder` control that has the `ID="itemPlaceholder"` attribute. To facilitate selection, you raise a `Select` command from the event name link rendered in `<ItemTemplate>`, which automatically changes the selection. You also use the `OnSelectedIndexChanged` event, triggered when the `Select` command changes the selection, to ensure that the list display updates itself to display the selected item in a different style. The event handler for this is shown in the following code:

```
protected void EventList_SelectedIndexChanged(object sender, EventArgs e)
{
   EventList.DataBind();
}
```

You also need to ensure new events are added to the list:

```
            if (queryResult == 1)
            {
               resultLabel.Text = "Event Added.";
               EventData = null;
               calendar.SelectedDate =
                  GetFreeDate(calendar.SelectedDate.AddDays(1));
               GridView1.DataBind();
               EventList.DataBind();
            }
```

Now selectable event details are available in the table, as shown in Figure 40-14.

There is *much* more that you can do with templates and data-bound controls in general, enough in fact to fill a whole book. However, this should be enough to get you started with your experimentation.

FIGURE 40-14

APPLICATION CONFIGURATION

Throughout this chapter, we have alluded to the existence of a conceptual application containing web pages and configuration settings. This is an important concept to grasp, especially when configuring your web site for multiple concurrent users.

A few notes on terminology and application lifetime are necessary here. An *application* is defined as all files in your project, and is configured by the `web.config` file. An `Application` object is created when an application is started for the first time, which will be when the first HTTP request arrives. Also at this time, the `Application_Start` event is triggered and a pool of `HttpApplication` instances is created. Each incoming request receives one of these instances, which performs request processing. Note that this means `HttpApplication` objects do not need to cope with concurrent access, unlike the global `Application` object. When all `HttpApplication` instances finish their work, the `Application_End` event fires and the application terminates, destroying the `Application` object.

The event handlers for the events mentioned earlier (along with handlers for all other events discussed in this chapter) can be defined in a `global.asax` file, which you can add to any web site project (it is listed as Global Application Class in the templates that you see when you add a new item to a web application). The generated file contains blanks for you to fill in; for example:

```
void Application_Start(Object sender, EventArgs e)
{
   // Code that runs on application startup
}
```

When an individual user accesses the web application, a *session* is started. Similar to the application, this involves the creation of a user-specific `Session` object, along with the triggering of a `Session_Start` event. Within a session, individual *requests* trigger `Application_BeginRequest` and `Application_EndRequest` events. These can occur several times during the scope of a session as different resources within the application are accessed. Individual sessions can be terminated manually, or will time out if no further requests are received. Session termination triggers a `Session_End` event and the destruction of the `Session` object.

Against the background of this process, you can do several things to streamline your application. If all instances of your application use a single, resource-heavy object, for example, then you might consider instantiating it at the application level. This can improve performance and reduce memory usage with multiple users because in most requests no such instantiation will be required.

Another technique you can use is to store session-level information for use by individual users across requests. This might include user-specific information that is extracted from a data store when the user first connects (in the `Session_Start()` event handler), and is made available until the session is terminated (through a timeout or user request).

These techniques are beyond the scope of this book — and you might want to consult *Professional ASP.NET 4: in C# and VB* (Wiley Publishing, Inc., 2010, ISBN 978-0470-502204) for details — but it helps to have a broad understanding of the processes.

Finally, you need to look at `web.config` files. A web site will usually have one of these in its root directory (although it is not created for you by default), and may have additional ones in subdirectories to configure directory-specific settings (such as security). The `PCSWebSite3` web site developed in this chapter received an auto-generated `Web.config` file when you added a stored database connection string, which you can see in the file:

```
<connectionStrings>
  <add name="MRBConnectionString"
     connectionString="Data Source=.\SQLEXPRESS;
     AttachDbFilename=|DataDirectory|\MeetingRoomBooker.mdf;
     Integrated Security=True;User Instance=True"
     providerName="System.Data.SqlClient" />
</connectionStrings>
```

If you ran the project in debug mode, then you will also see some additional settings in the `web.config` file.

You can edit `web.config` files manually, but you can also configure web sites (and their underlying configuration files) using a tool that is accessible on the web site menu in Visual Studio, under ASP.NET Configuration. The display for this tool is shown in Figure 40-15.

As you can see from the figure, this tool lets you configure a number of settings, including security. You will see much more of this tool in the next chapter.

Application:/PCSWebSite3
Current User Name:TOL\KARLI

Security	Enables you to set up and edit users, roles, and access permissions for your site. Site is using windows authentication for user management.
Application Configuration	Enables you to manage your application's configuration settings.
Provider Configuration	Enables you to specify where and how to store administration data used by your Web site.

FIGURE 40-15

SUMMARY

This chapter has provided an overview of web application creation with ASP.NET. You have seen how you can use C# in combination with web server controls to provide a truly rich development environment. You have developed an event-booking sample application which illustrates many of the techniques available, such as the variety of server controls that exist, and data binding with ADO.NET.

Specifically, you have seen the following:

- ➤ An introduction to ASP.NET and how it fits in with .NET development in general
- ➤ How the basic syntax of ASP.NET works, how state management is achieved, and how to integrate C# code with ASP.NET pages
- ➤ How to create an ASP.NET web application using Visual Studio, and what options exist for hosting and testing web sites
- ➤ A summary of the web controls available to ASP.NET developers, and how they work together to deliver dynamic and/or data-driven content
- ➤ How to work with event handlers to both detect and act on user interaction with controls and customize controls via page and rendering events

- How to bind data to web controls, and format the data displayed using templates and data-binding expressions
- How to put all this together to build a meeting room booker application

With this information, you are already at a point where you could assemble powerful web applications of your own. However, we've only scratched the surface of what's possible. So, before you put down this book and dive into your own web development, we recommend that you keep reading. In Chapter 41, you expand your knowledge of ASP.NET by looking at some more important web topics, including master pages, skinning, and personalization. And trust us — the results are worth it!

41 ASP.NET Features

WHAT'S IN THIS CHAPTER?

- User and custom controls
- Master pages
- Site navigation
- Security
- Themes
- Web Parts
- ASP.NET AJAX

In this chapter you look at some of the techniques that ASP.NET supplies to enhance your web sites and applications. These techniques make it easier for you to create web sites and applications, make it possible for you to add advanced functionality, and improve the user experience.

Sometimes the built-in web controls, however powerful, don't quite match up with your requirements for a specific project. In the first part of this chapter, you examine the options available to control developers and assemble some simple user controls of your own. You also look at the basics of more advanced control construction.

Next, you look at master pages, a technique that enables you to provide templates for your web sites. Using master pages you can implement complex layouts on web pages throughout a web site with a great deal of code reuse. You also see how you can use the navigation web server controls in combination with a master page to provide consistent navigation across a web site.

Site navigation can be made user-specific, such that only certain users (those that are registered with the site, or site administrators, say) can access certain sections. You also look at site security and how to log in to web sites — something that is made extremely easy via the login web server controls.

After that, you look at some more advanced techniques, namely, providing and choosing themes for web sites, and how to use Web Parts to enable your users to dynamically personalize web pages by positioning and customizing controls on a page.

Finally, in the largest section of this chapter, you look at ASP.NET AJAX. This technology is a powerful way to enhance the user experience. It enables web sites and applications to become more responsive by updating sections of a page independently, as well as streamlining the process of adding client-side functionality.

Throughout much of this chapter, you will refer to a large example web site that includes all the techniques that you have seen in this and the previous chapter. This web site, `PCSDemoSite`, is available for download (along with the other code for this chapter) at `www.wrox.com`. The relevant sections of code are examined as necessary, and the additional code (mostly dummy content or simple code you have already seen) is left for you to examine at your convenience.

USER AND CUSTOM CONTROLS

Sometimes, a given control doesn't quite work as you would like it to, or perhaps one section of code, intended for reuse on several pages, is too complex in the hands of multiple developers. In such cases, there is a strong argument for building your own controls.

The .NET Framework provides an ideal setting for the creation of custom controls, using simple programming techniques. Every aspect of ASP.NET server controls is exposed for you to customize, including such capabilities as templating and client-side scripting. However, there is no need to write code for all these eventualities; simpler controls can be a lot easier to create.

In addition, the dynamic discovery of assemblies that is inherent in a .NET system makes installation of web sites and applications on a new web server as simple as copying the directory structure containing your code. To make use of the controls you have created, you simply copy the assemblies containing those controls along with the rest of the code. You can even place frequently used controls in an assembly located in the global assembly cache (GAC) on the web server, so that all web sites and applications on the server have access to them.

This chapter discusses two different kinds of controls:

- ➤ **User controls** and how to convert existing ASP.NET pages into controls
- ➤ **Custom controls** and how to group the functionality of several controls, extend existing controls, and create new controls from scratch

User controls are illustrated with a simple control that displays a card suit (club, diamond, heart, or spade), so that you can embed it in other ASP.NET pages with ease. We won't go into too much depth for custom controls, although we show you the basic principles and direct you to more information beyond this book.

User Controls

User controls are controls that you create using ASP.NET code, just as you use in standard ASP.NET web pages. The difference is that after you have created a user control you can reuse it in multiple ASP.NET pages.

For example, say that you have created a page that displays some information from a database, perhaps information about an order. Instead of creating a fixed page that does this, you can to place the relevant code into a user control, and then insert that control into as many different web pages as you want.

In addition, you can define properties and methods for user controls. For example, you can specify a property for the background color for displaying your database table in a web page, or a method to re-run a database query to check for changes.

To start, you create a simple user control.

A Simple User Control

In Visual Studio, create a new empty web site called PCSUserCWebApp1 in the directory C:\ProCSharp\Chapter41. After the web site has been generated, select the Website ➪ Add New Item ... menu option and add a Web User Control called PCSUserC1.ascx.

The files added to your project, with the extensions .ascx and .ascx.cs, work in a very similar way to the .aspx files that you have seen already. The .ascx file contains your ASP.NET code and looks very similar to a normal .aspx file. The .ascx.cs file is your code-behind file, which defines custom code for the user control, much in the same way that forms are extended by .aspx.cs files.

The .ascx files can be viewed in Design or Source view, just like .aspx files. Looking at the file in Source view reveals an important difference: there is no HTML code present, and in particular no <form> element. This is because user controls are inserted inside ASP.NET forms in other files and so don't need a <form> tag of their own. The generated code is as follows:

```
<%@ Control Language="C#" AutoEventWireup="true" CodeFile="PCSUserC1.ascx.cs"
    Inherits="PCSUserC1" %>
```

code snippet PCSUserCWebApp1/PCSUserC1.ascx

This is very similar to the <%@ Page %> directive generated in .aspx files, except that Control is specified rather than Page. The CodeFile attribute specifies the code-behind file and Inherits specifies the class defined in the code-behind file from which the page inherits. The code in the .ascx.cs file contains, as in auto-generated .aspx.cs files, a class definition that is empty apart from a Page_Load() event handler method.

Your simple control will be one that displays a graphic corresponding to one of the four standard suits in cards (club, diamond, heart, or spade). The graphics required for this were shipped as part of a previous version of Visual Studio; you can find them in the downloadable code for this chapter, in the CardSuitImages directory, with the filenames CLUB.BMP, DIAMOND.BMP, HEART.BMP, and SPADE.BMP. Copy these files into a new Images subdirectory of your project's directory, so that you can use them in a moment. If you do not have access to this download, you can use any images you like for this example because they are not important to the functionality of the code.

Note that unlike earlier versions of Visual Studio, changes you make to the web site structure outside of Visual Studio are automatically reflected in the IDE. You have to hit the refresh button in the Solution Explorer window, but you should see the new Images *directory and bitmap files appear automatically.*

Adding Content to the Control

Now add some code to your new control. In the HTML view of PCSUserC1.ascx, add the following:

```
<%@ Control Language="C#" AutoEventWireup="true" CodeFile="PCSUserC1.ascx.cs"
    Inherits="PCSUserC1" %>
<table cellspacing="4">
  <tr valign="middle">
    <td>
      <asp:Image Runat="server" ID="suitPic" ImageURL="~/Images/club.bmp"/>
    </td>
```

```
        <td>
          <asp:Label Runat="server" ID="suitLabel">Club</asp:Label>
        </td>
      </tr>
    </table>
```

This defines a default state for your control, which is a picture of a club along with a label. The ~ in the path to the image means "start at the root directory of the web site." Before you add functionality, you will test this default by adding this control to a web page, so before continuing, add a new web page called `Default.aspx` to the web site.

To use a custom control in an `.aspx` file, you first need to specify how you will refer to it, that is, the name of the tag that will represent the control in your HTML. To do this, you use the `<%@ Register %>` directive at the top of the code in `Default.aspx`, as follows:

```
<%@ Register TagPrefix="pcs" TagName="UserC1" Src="PCSUserC1.ascx" %>
```

code snippet PCSUserCWebApp1/Default.aspx

The `TagPrefix` and `TagName` attributes specify the tag name to use (in the form `<TagPrefix:TagName>`), and you use the `Src` attribute to point to the file containing your user control. Now you can use the control by replacing the existing `<form>` element in the file with code as follows adding the following element:

```
      <form id="Form1" method="post" runat="server">
        <div>
          <pcs:UserC1 Runat="server" ID="myUserControl"/>
        </div>
      </form>
```

This is all you need to do to test your user control. Figure 41-1 shows the results of running this code.

FIGURE 41-1

As it stands, this control groups two existing controls, an image and a label, in a table layout. Therefore, it falls into the category of a composite control.

Adding a Suit Property

To gain control over the displayed suit, you can use an attribute on the `<PCS:UserC1>` element. Attributes on user control elements are automatically mapped to properties on user controls, so all you have to do to make this work is add a property to the code behind your control, `PCSUserC1.ascx.cs`. Call this property `Suit`, and let it take any suit value. To make it easier for you to represent the state of the control, you define an enumeration to hold the four suit names. The best way to do this is to add an `App_Code` directory to your web site, and then add a `.cs` file called `Suit.cs` in this directory. `App_Code` is another "special" directory, like `App_Data`, whose functionality is defined for you — in this case it holds additional code files for your web site. You can add this directory by right-clicking the web site in Solution Explorer and clicking Add ASP.NET Folder ➪ App_Code. When you have done this, add `Suit.cs` with code as follows:

```
using System;

public enum Suit
{
    Club, Diamond, Heart, Spade
}
```

code snippet PCSUserCWebApp1/App_Code/Suit.cs

The `PCSUserC1` class needs a member variable to hold the suit type, `currentSuit`:

```
public partial class PCSUserC1 : System.Web.UI.UserControl
{
   protected Suit currentSuit;
```

code snippet PCSUserCWebApp1/PCSUserC1.ascx.cs

And a property to access this member variable, `Suit`:

```
   public Suit Suit
   {
      get
      {
         return currentSuit;
      }
      set
      {
         currentSuit = value;
         suitPic.ImageUrl = "~/Images/" + currentSuit.ToString() + ".bmp";
         suitLabel.Text = currentSuit.ToString();
      }
   }
```

The `set` accessor here sets the URL of the image to one of the files you copied earlier, and the text displayed to the suit name.

Accessing the New Property

Next, you must add code to `Default.aspx` so that you can access this new property. You could simply specify the suit using the property you have just added (if you compile the project the options will even appear in IntelliSense for you):

```
<PCS:UserC1 Runat="server" id="myUserControl" Suit="diamond"/>
```

code snippet PCSUserCWebApp1/Default.aspx

The ASP.NET processor is intelligent enough to get the correct enumeration item from the string provided. To make things a bit more interesting and interactive, though, you will use a radio button list to select a suit:

```
  <form id="form1" runat="server">
    <div>
      <pcs:UserC1 id="myUserControl" runat="server" />
      <asp:RadioButtonList Runat="server" ID="suitList" AutoPostBack="True">
        <asp:ListItem Value="Club" Selected="True">Club</asp:ListItem>
        <asp:ListItem Value="Diamond">Diamond</asp:ListItem>
        <asp:ListItem Value="Heart">Heart</asp:ListItem>
        <asp:ListItem Value="Spade">Spade</asp:ListItem>
      </asp:RadioButtonList>
    </div>
  </form>
```

You also need to add an event handler for the `SelectedIndexChanged` event of the list, which you can do simply by double-clicking the radio button list control in Design view.

The `suitList_SelectedIndexChanged()` method requires the following code in `Default.aspx.cs`:

```
public partial class Default
{
   protected void suitList_SelectedIndexChanged(object sender, EventArgs e)
   {
      myUserControl.Suit = (Suit)Enum.Parse(typeof(Suit),
                                            suitList.SelectedItem.Value);
   }
}
```

code snippet PCSUserCWebApp1/Default.aspx.cs

You know that the `Value` attributes on the `<ListItem>` elements represent valid values for the suit enumeration you defined earlier, so you simply parse these as enumeration types and use them as values of the `Suit` property of your user control. You cast the returned object type to `Suit` using simple casing syntax, because this cannot be achieved implicitly.

Now you can change the suit when you run your web site (see Figure 41-2).

FIGURE 41-2

Now that you have created your user control, you can use it in any other web page simply by using the `<%@ Register %>` directive and the two source code files (`PCSUserC1.ascx` and `PCSUserC1.ascx.cs`) you have created for the control.

User Controls in PCSDemoSite

In PCSDemoSite, the meeting room booker web site from the previous chapter has been converted into a user control for ease of reuse. To see the control, you have to log in to the site as User1, with password User1!!, and navigate to the Meeting Room Booker page, as shown in Figure 41-3. (You learn how the logging-in system works later in this chapter, in the “Security” section.)

- Planetary Conquest
- Homecoming Celebration
- Dalek Reunion Ball
- Romantic meal for two

My Birthday

Date: 17 September 2010
Room: The Happy Room
Attendees: Iggy Pop (5), Sean Connery (7), Albert Einstein (10), George Clooney (14), Jules Verne (18), Robin Hood (20), and Karli Watson

FIGURE 41-3

Apart from the obvious change in style, which is achieved by themes, as you see later in this chapter, the major modifications are as follows:

- ➤ The username is automatically taken from user details.
- ➤ There is no extra data display at the bottom of the page, and corresponding `DataBind()` calls are removed from the code behind.
- ➤ There is no result label beneath the control — the user gets enough feedback by seeing events added to the calendar and event list, without being told that event addition was successful.
- ➤ The page containing the user control uses navigation controls and a master page.

The code modifications to achieve all this are remarkably simple. You won't look at them here, but you will come back to this control later in this chapter.

Custom Controls

Custom controls go a step beyond user controls in that they are entirely self-contained in C# assemblies, requiring no separate ASP.NET code. This means that you don't need to go through the process of assembling a user interface (UI) in an `.ascx` file. Instead, you have complete control over what is written to the output stream, that is, the exact HTML generated by your control.

In general, it will take longer to develop custom controls than user controls because the syntax is more complex, and you often have to write significantly more code to get results. A user control may be as simple as a few other controls grouped together, as you have seen, whereas a custom control can do just about anything short of making you a cup of coffee.

Creating and Referencing Custom Controls

To get the most customizable behavior for your custom controls, you can derive a class from `System.Web.UI.WebControls.WebControl`. If you do this, you are creating a full custom control. Or, you can extend the functionality of an existing control, creating a derived custom control. Finally, you can group existing controls together, much as you did in the last section but with a more logical structure, to create a composite custom control.

Whatever you create can be used in ASP.NET pages in pretty much the same way. All you need to do is place the generated assembly in a location where it can be found by the web site or application that uses it, and register the element names to use with the `<%@ Register %>` directive. For this location, you have two options: you can either put the assembly in the bin directory of the web site or application, or place it in the GAC if you want all web sites and applications on the server to have access to it. Or, if you are just using a user control on a single web site, you can just put the `.cs` file for the control in the `App_Code` directory for the site.

The `<%@ Register %>` directive takes a slightly different syntax for custom controls:

```
<%@ Register TagPrefix="PCS" Namespace="PCSCustomWebControls"
             Assembly="PCSCustomWebControls"%>
```

You use the `TagPrefix` option in the same way as before, but you don't use the `TagName` or `Src` attributes. This is because the custom control assembly you use may contain several custom controls, and each of these will be named by its class, so `TagName` is redundant. Plus, because you can use the dynamic discovery capabilities of the .NET Framework to find your assembly, you simply have to name it and the namespace in it that contains your controls.

In the previous line of code, you are instructing the program to use an assembly called `PCSCustomWebControls.dll` with controls in the `PCSCustomWebControls` namespace, and use the tag prefix `PCS`. If you have a control called `Control1` in this namespace, you could use it with the ASP.NET code:

```
<PCS:Control1 Runat="server" ID="MyControl1"/>
```

The `Assembly` attribute of the `<%@ Register %>` directive is optional — if you have custom controls in the `App_Code` directory of your site, you can omit this, and the web site will look at code here for controls. One thing though — the `Namespace` attribute is *not* optional. You must include a namespace in code files for custom controls, or the ASP.NET runtime will not be able to find them.

With custom controls, it is also possible to reproduce some of the control nesting behavior that exists in list controls, for example the way that you can nest `<asp:ListItem>` controls inside a list control to populate the list control:

```
<asp:DropDownList ID="roomList" Runat="server" Width="160px">
   <asp:ListItem Value="1">The Happy Room</asp:ListItem>
   <asp:ListItem Value="2">The Angry Room</asp:ListItem>
   <asp:ListItem Value="3">The Depressing Room</asp:ListItem>
   <asp:ListItem Value="4">The Funked Out Room</asp:ListItem>
</asp:DropDownList>
```

You can create controls that should be interpreted as being children of other controls in a very similar way to this. This is one of the more advanced techniques that you won't be looking at in this book.

Custom Control Sample

Now it's time to put some of this theory into practice. You will use a single web site called `PCSCustomCWebSite1` in the `C:\ProCSharp\Chapter41\` directory (made using the empty web site template), with a custom control in its `App_Code` directory to illustrate a simple custom control. The control here will be a multicolored version of the existing `Label` control, with the ability to cycle through a set of colors for each letter in its text.

The code for the control, `RainbowLabel`, in the file `App_Code\RainbowLabel.cs`, starts with the following `using` statements:

```
using System.Drawing;
using System.Web.UI;
using System.Web.UI.WebControls;
```

code snippet PCSCustomCWebSite1/RainbowLabel.cs

The `System.Drawing` namespace is required for the `Color` enumeration, and the `Web` namespaces for the ASP.NET control references. The class maintains an array of colors to use for letters in its text in a private `Color` array called `colors`:

```
namespace PCSCustomWebControls
{
   public class RainbowLabel : Label
   {
      private Color[] colors = new Color[] {Color.Red,
                                            Color.Orange,
                                            Color.Yellow,
                                            Color.GreenYellow,
                                            Color.Blue,
                                            Color.Indigo,
                                            Color.Violet};
```

Also notice that the namespace `PCSCustomWebControls` is used to contain the control. As discussed earlier, this is necessary so that web pages can reference the control correctly.

To enable color cycling, you also store an integer offset value in a private `offset` property:

```
      private int offset
      {
         get
         {
            object rawOffset = ViewState["_offset"];
            if (rawOffset != null)
            {
               return (int)rawOffset;
            }
            else
            {
               ViewState["_offset"] = 0;
               return 0;
            }
         }
         set
         {
            ViewState["_offset"] = value;
         }
      }
```

Note that this property isn't as simple as just storing a value in a member field. This is due to the way ASP.NET maintains state, as discussed in the previous chapter. Controls are instantiated on each postback operation, so to store values you must make use of view state. This is easy to access — you simply use the `ViewState` collection, which can store any object that is serializable. Otherwise, `offset` would revert to its initial value between each postback.

To modify `offset`, you use a method called `Cycle()`:

```
        public void Cycle()
        {
           offset = ++offset;
        }
```

This simply increments the value stored in the view state for `offset`.

Finally, you come to perhaps the most important method override for any custom control — `Render()`. This is where you output HTML, and as such it can be a very complicated method to implement. If you were to take into account all the browsers that may view your controls, and all the variables that could affect rendering, this method could get very big. Fortunately, for this example, it's quite simple:

```
        protected override void Render(HtmlTextWriter output)
        {
           string text = Text;
           for (int pos = 0; pos < text.Length; pos++)
           {
              int rgb = colors[(pos + offset) % colors.Length].ToArgb()
                                                            & 0xFFFFFF;
              output.Write(string.Format(
                 "<font color=\"#{0:X6}\">{1}</font>", rgb, text[pos]));
           }
        }
     }
  }
```

This method gives you access to the output stream to display your control content. There are only two cases where you don't need to implement this method:

- When you are designing a control that has no visual representation (usually known as a component)
- When you are deriving from an existing control and don't need to change its display characteristics

Custom controls can also expose custom methods, raise custom events, and respond to child controls (if any). In the case of `RainbowLabel`, you don't have to worry about any of this.

Next, you need to add a web page, `Default.aspx`, and add code to view the control and provide access to `Cycle()`, as follows:

```
<%@ Register TagPrefix="pcs" Namespace="PCSCustomWebControls" %>

...

  <form id="form1" runat="server">
    <div>
      <pcs:RainbowLabel runat="server" ID="rainbowLabel1"
        Text="Multicolored label!" />
      <asp:Button Runat="server" ID="cycleButton" Text="Cycle colors"
        OnClick="cycleButton_Click" />
    </div>
  </form>
```

code snippet PCSCustomCWebSite1/Default.aspx

The required code in `Default.aspx.cs` is simply this:

```
protected void cycleButton_Click(object sender, EventArgs e)
{
   rainbowLabel1.Cycle();
}
```

code snippet PCSCustomCWebSite1/Default.aspx.cs

Now you can view the sample and cycle the colors in the sample text, as shown in Figure 41-4.

FIGURE 41-4

You can do a lot more with custom controls; indeed, the possibilities are practically limitless, but you will have to experiment with these possibilities on your own.

MASTER PAGES

Master pages provide an excellent way to make your web sites easier to design. Putting all (or at least most) of your page layout in a single file allows you to concentrate on the more important things for the individual web pages of your site.

Master pages are created in files with the extension `.master`, and can be added via the Website ➪ Add New Item ... menu item, like any other site content. At first glance, the code generated for a master page is much like that for a standard `.aspx` page:

```
<%@ Master Language="C#" AutoEventWireup="true"
  CodeFile="MyMasterPage.master.cs" Inherits="MyMasterPage" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
  "http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml">
<head runat="server">
  <title></title>
  <asp:ContentPlaceHolder id="head" runat="server">
  </asp:ContentPlaceHolder>
</head>
<body>
  <form id="form1" runat="server">
    <div>
      <asp:ContentPlaceHolder ID="ContentPlaceHolder1" Runat="server">
      </asp:ContentPlaceHolder>
    </div>
  </form>
</body>
</html>
```

The differences are:

- A `<%@ Master %>` directive is used instead of a `<%@ Page %>` directive, although the attributes are the same.
- A `ContentPlaceHolder` control with an `ID` of `head` is placed in the page header.
- A `ContentPlaceHolder` control with an `ID` of `ContentPlaceHolder1` is placed in the page body.

The `ContentPlaceHolder` controls are what make master pages so useful. You can have any number of these on a page, and they are used by `.aspx` pages using the master page to "plug in" content. You can put default content inside a `ContentPlaceHolder` control, but `.aspx` pages can override this content.

For an `.aspx` page to use a master page, you need to modify the `<%@ Page %>` directive as follows:

```
<%@ Page Language="C#" AutoEventWireup="true" CodeFile="Default.aspx.cs"
  Inherits="_Default" MasterPageFile="~/MyMasterPage.master"
  Title="Page Title" %>
```

Here you have added two new attributes: a `MasterPageFile` attribute saying which master page to use and a `Title` attribute that sets the content of the `<title>` element in the master page.

Or, when you add an `.aspx` page to a web site that contains master pages, you can choose to select a master page. The Add New Item Wizard contains a "Select master page" check box, and if you select this option, the next page of the wizard gives you a list of master pages to choose from in the web application. The generated code for the page will then include the MasterPageFile attribute as previously described.

The `.aspx` page doesn't have to contain any other code, if you want to use the default master page content. Also, you must not include a `Form` control, because a page may only have one of these and there is one in the master page.

`.aspx` pages that use a master page can contain no root-level content other than directives, script elements, and `Content` controls. You can have as many `Content` controls as you like, where each one inserts content into one of the `ContentPlaceHolder` controls in the master page. The only thing to look out for is to make sure that the `ContentPlaceHolderID` attribute of the `Content` control matches the `ID` of the `ContentPlaceHolder` control where you want to insert content. So, to add content into the master page shown earlier, you would simply need the following in the `.aspx` file:

```
<%@ Page Language="C#" MasterPageFile="~/MyMasterPage.master"
  AutoEventWireup="true" CodeFile="Default.aspx.cs" Inherits="_Default"
  Title="Untitled Page" %>

<asp:Content ID="Content1" ContentPlaceHolderID="head" Runat="Server">
</asp:Content>
<asp:Content ID="Content2" ContentPlaceHolderID="ContentPlaceHolder1"
  runat="Server">
  Custom content!
</asp:Content>
```

The true power of master pages comes when you surround the `ContentPlaceHolder` controls in your master pages with other content, such as navigation controls, site logos, and HTML. You can supply multiple `ContentPlaceHolder` controls for main content, sidebar content, footer text, and so on.

You can omit `Content` controls on a page if you do not wish to supply content for a specific `ContentPlaceHolder`. For example, you can remove the `Content1` control from the preceding code without affecting the resultant display.

Accessing Master Page Content from Web Pages

When you add a master page to a web page, you will sometimes need to access the master page from code in your web page. To do this, you can use the `Page.Master` property, which will return a reference to the master page in the form of a `MasterPage` object. You can cast this to the type of the master page as defined by the master page file (for the example in the previous section, this class would be called `MyMasterPage`). After you have this reference, you can access any public members of the master page class.

Also, you can use the `MasterPage.FindControl()` method to locate controls on the master page by their identifier. This enables you to manipulate content on the master page that is outside of content placeholders.

One typical use of this might be if you define a master page that is used for a standard form, with a submit button. You can locate the submit button in the child page and add an event handler for the submit button in the master page. In this way, you can provide, for example, custom validation logic in response to a form submission.

Nested Master Pages

The "Select master page" option is also available when you create a new master page. By using this option, you can create a *nested* master page that is based on a parent master page. For example, you can create a master page called `MyNestedMasterPage` that uses `MyMasterPage` as follows:

```
<%@ Master Language="C#" MasterPageFile="~/MyMasterPage.master"
  AutoEventWireup="false" CodeFile="MyNestedMasterPage.master.cs"
  Inherits="MyNestedMasterPage" %>

<asp:Content ID="Content1" ContentPlaceHolderID="head" Runat="Server">
  <!--Disabled for child controls.-->
</asp:Content>
<asp:Content ID="Content2" ContentPlaceHolderID="ContentPlaceHolder1"
  Runat="Server">
  First nested place holder:
  <asp:ContentPlaceHolder ID="NestedContentPlaceHolder1" runat="server">

  </asp:ContentPlaceHolder>
  <br />
  <br />
  Second nested place holder:
  <asp:ContentPlaceHolder ID="NestedContentPlaceHolder2" runat="server">

  </asp:ContentPlaceHolder>
</asp:Content>
```

Pages that use this master page would supply content for `NestedContentPlaceHolder1` and `NestedContentPlaceHolder2`, but would not have direct access to the `ContentPlaceHolder` controls specified in `MyMasterPage`. In this example, `MyNestedMasterPage` fixes the content for the `head` control and supplies a template for the `ContentPlaceHolder1` control.

By creating a family of nested master pages, you can provide alternate layouts for pages while leaving some aspects of the base master pages untouched. For example, the root master page might include navigation and basic layout, and nested master pages could provide layouts with different amounts of columns. You could then use the nested master pages in the pages of your site and quickly switch between these alternate layouts on different pages.

Master Pages in PCSDemoSite

In PCSDemoSite, the single master page `MasterPage.master` (the default name for a master page) is used, with code as follows:

```
<%@ Master Language="C#" AutoEventWireup="true"
CodeFile="MasterPage.master.cs"
  Inherits="MasterPage" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.1//EN"
  "http://www.w3.org/TR/xhtml11/DTD/xhtml11.dtd">
<html xmlns="http://www.w3.org/1999/xhtml">
<head runat="server">
  <link rel="stylesheet" href="StyleSheet.css" type="text/css" />
  <title></title>
</head>
<body>
  <form id="form1" runat="server">
    <div id="header">
      <h1><asp:literal ID="Literal1" runat="server"
        text="<%$ AppSettings:SiteTitle %>" /></h1>
      <asp:SiteMapPath ID="SiteMapPath1" Runat="server"
        CssClass="breadcrumb" />
    </div>
```

```
      <div id="nav">
        <div class="navTree">
          <asp:TreeView ID="TreeView1" runat="server"
            DataSourceID="SiteMapDataSource1" ShowLines="True" />
        </div>
        <br />
        <br />
        <asp:LoginView ID="LoginView1" Runat="server">
          <LoggedInTemplate>
            You are currently logged in as
            <b><asp:LoginName ID="LoginName1" Runat="server" /></b>.
            <asp:LoginStatus ID="LoginStatus1" Runat="server" />
          </LoggedInTemplate>
        </asp:LoginView>
      </div>
      <div id="body">
        <asp:ContentPlaceHolder ID="ContentPlaceHolder1" Runat="server" />
      </div>
    </form>
    <asp:SiteMapDataSource ID="SiteMapDataSource1" Runat="server" />
  </body>
  </html>
```

code snippet PCSDemoSite/MasterPage.master

Many of the controls here are ones that you haven't looked at yet, and you will come back to those shortly. The important things to note here are the `<div>` elements that hold the various content sections (header, navigation bar, and body), and the use of `<%$ AppSettings:SiteTitle %>` to obtain the site title from the `web.config` file:

```
<appSettings>
  <add key="SiteTitle" value="Professional C# Demo Site"/>
</appSettings>
```

code snippet PCSDemoSite/web.config

There is also a style sheet link to `StyleSheet.css`:

```
<link rel="stylesheet" href="StyleSheet.css" type="text/css" />
```

This CSS style sheet contains the basic layout information for the `<div>` elements on this page, as well as for a section of the meeting room booker control. Note that none of the style information in this file includes colors, fonts, and so on. This is achieved by style sheets within themes, which you see later in this chapter. The only information here is layout information, such as `<div>` sizes.

Note that web site best practices have been adhered to in this chapter whenever possible. Using CSS for layout rather than tables is fast becoming the industry standard for web site layout and is well worth learning about. In the preceding code, `#` symbols are used to format `<div>` elements with specific `id` attributes, whereas `.mrbEventList` will format an HTML element with a specific `class` attribute.

SITE NAVIGATION

The three navigation web server controls, `SiteMapPath`, `Menu`, and `TreeView`, can work with an XML site map that you provide for your web site, or a site map provided in a different format if you implement an alternative site map provider. When you have created such a data source, these navigation web server controls are able to automatically generate location and navigation information for users.

You see an example XML site map later in this section.

You can also use a `TreeView` control to display other structured data, but it really comes into its own with site maps, and gives you an alternative view of navigation information.

The navigation web server controls are shown in the following table.

CONTROL	DESCRIPTION
`SiteMapPath`	Displays breadcrumb-style information, allowing users to see where they are in the structure of a site and navigate to parent areas. You can supply various templates, such as `NodeStyle` and `CurrentNodeStyle`, to customize the appearance of the breadcrumb trail.
`Menu`	Links to site map information via a `SiteMapDataSource` control, and enables a view of the complete site structure. The appearance of this control can be customized by templates.
`TreeView`	Allows the display of hierarchical data, such as a table of contents, in a tree structure. Tree nodes are stored in a `Nodes` property, with the selected node stored in `SelectedNode`. Several events allow for server-side processing of user interaction, including `SelectedNodeChanged` and `TreeNodeCollapsed`. This control is typically data-bound.

Adding a Site Map File

To provide a site map XML file for your site, you can add a site map file (`.sitemap`) using the Website ➪ Add New Item ... menu item. You link to site maps via providers. The default XML provider looks for a file called `Web.sitemap` in the root of your site, so unless you are going to use a different provider, you should accept the default filename supplied.

A site map XML file contains a root `<siteMap>` element containing a single `<siteMapNode>` element, which in turn can contain any number of nested `<siteMapNode>` elements.

Each `<siteMapNode>` element uses the attributes shown in the following table.

ATTRIBUTE	DESCRIPTION
`Title`	Page title, used as the text for links in site map displays
`url`	Page location, used as the hyperlink location in site map displays
`Roles`	The user roles that are allowed to see this site map entry in menus and so on
`description`	Optional text used for tooltip pop-ups for site map displays

When a site has a `Web.sitemap` file, adding a breadcrumb trail is as simple as putting the following code on your page:

```
<asp:SiteMapPath ID="SiteMapPath1" Runat="server" />
```

This will use the default provider and the current URL location to format a list of links to parent pages.

Adding a menu or tree view menu requires a `SiteMapDataSource` control, but again this can be very simple:

```
<asp:SiteMapDataSource ID="SiteMapDataSource1" Runat="server" />
```

When using a custom provider, the only difference is that you can supply the provider ID via a `SiteMapProvider` attribute. You can also remove upper levels of the menu data (such as the root `Home` item) using `StartingNodeOffset`; remove just the top-level link using `ShowStartingNode="False"`; start from the current location using `StartFromCurrentNode="True"`; and override the root node using `StartingNodeUrl`.

The data from this data source is consumed by `Menu` and `TreeView` controls simply by setting their `DataSourceID` to the ID of the `SiteMapDataSource`. Both controls include numerous styling properties and can be themed, as you see later in this chapter.

Navigating in PCSDemoSite

The site map for PCSDemoSite is as follows:

```
<?xml version="1.0" encoding="utf-8" ?>
<siteMap>
  <siteMapNode url="~/Default.aspx" title="Home">
    <siteMapNode url="~/About/Default.aspx" title="About" />
    <siteMapNode url="~/MRB/Default.aspx" title="Meeting Room Booker"
      roles="RegisteredUser,SiteAdministrator" />
    <siteMapNode url="~/Configuration/Default.aspx" title="Configuration"
      roles="RegisteredUser,SiteAdministrator">
      <siteMapNode url="~/Configuration/Themes/Default.aspx" title="Themes"
        roles="RegisteredUser,SiteAdministrator"/>
    </siteMapNode>
    <siteMapNode url="~/Users/Default.aspx" title="User Area"
      roles="SiteAdministrator" />
    <siteMapNode url="~/Login.aspx" title="Login Details" />
  </siteMapNode>
</siteMap>
```

code snippet PCSDemoSite/Web.sitemap

The PCSDemoSite web site uses a custom provider to obtain information from `Web.sitemap` — which is necessary because the default provider ignores the `roles` attributes. The provider is defined in the `web.config` file for the web site as follows:

```
<siteMap defaultProvider="CustomProvider">
  <providers>
    <add name="CustomProvider"
      type="System.Web.XmlSiteMapProvider"
      siteMapFile="Web.sitemap" securityTrimmingEnabled="true" />
  </providers>
</siteMap>
```

code snippet PCSDemoSite/web.config

The only difference between this and the default provider is the addition of `securityTrimmingEnabled="true"`, which instructs the provider to supply data for just those nodes that this current user is allowed to see. This visibility is determined by the role membership of the user, as you see in the next section.

The `MasterPage.master` page in PCSDemoSite includes `SiteMapPath` and `TreeView` navigation displays along with a data source, as follows:

```
<div id="header">
  <h1><asp:literal ID="Literal1" runat="server"
    text="<%$ AppSettings:SiteTitle %>" /></h1>
  <asp:SiteMapPath ID="SiteMapPath1" Runat="server"
    CssClass="breadcrumb" />
</div>
<div id="nav">
  <div class="navTree">
    <asp:TreeView ID="TreeView1" runat="server"
      DataSourceID="SiteMapDataSource1" ShowLines="True" />
  </div>
  <br />
  <br />
```

```
      <asp:LoginView ID="LoginView1" Runat="server">
        <LoggedInTemplate>
          You are currently logged in as
          <b><asp:LoginName ID="LoginName1" Runat="server" /></b>.
          <asp:LoginStatus ID="LoginStatus1" Runat="server" />
        </LoggedInTemplate>
      </asp:LoginView>
    </div>
    <div id="body">
      <asp:ContentPlaceHolder ID="ContentPlaceHolder1" Runat="server" />
    </div>
  </form>
  <asp:SiteMapDataSource ID="SiteMapDataSource1" Runat="server" />
```

code snippet PCSDemoSite/MasterPage.master

The only point to note here is that CSS classes are supplied for both `SiteMapPath` and `TreeView`, to facilitate theming (discussed later in this chapter).

SECURITY

Security and user management have often been seen as quite complicated to implement in web sites, and with good reason. You have to consider a number of factors, including:

- What sort of user management system will I implement? Will users map to Windows user accounts, or will I implement something independent?
- How do I implement a login system?
- Do I let users register on the site; if so, how?
- How do I let some users see and do only some things, while supplying other users with additional privileges?
- What happens in the case of forgotten passwords?

With ASP.NET, you have a whole suite of tools at your disposal for dealing with questions such as these, and it can in fact take only a matter of minutes to implement a user system on your site. You have three types of authentication at your disposal:

- Windows Authentication, whereby users have Windows accounts, typically used with intranet sites or Wide Area Network (WAN) portals
- Forms Authentication, whereby the web site maintains its own list of users and handles its own authentication
- Microsoft Live ID Authentication (formerly known as Passport authentication), whereby Microsoft provides a centralized authentication service for you to use

A full discussion of security in ASP.NET would take up at least a full chapter, but we provide a brief look in this section to give you an idea of how things work. You concentrate on Forms Authentication here, because it is the most versatile system and very quick to get up and running.

The quickest way to implement Forms Authentication is via the web site ASP.NET Configuration tool, which you saw briefly in the previous chapter. This tool has a Security tab, and on it a Security Setup Wizard. This wizard lets you choose an authentication type, add roles, add users, and secure areas of your site.

Adding Forms Authentication Using the Security Setup Wizard

For the purposes of this explanation, create a new empty web site called `PCSAuthenticationDemo` in the directory `C:\ProCSharp\Chapter41\`. After you create the site, configure security using the following example steps:

1. Open the web site ASP.NET Configuration tool.
2. Navigate to the Security tab.

3. Click the "Use the security Setup Wizard to configure the security step by step" link.
4. Click Next in Step 1 of the wizard after reading the information there.
5. In Step 2 of the wizard, select "From the internet" to select Forms Authentication and click Next.
6. Click Next again after confirming that you will be using the default "Advanced provider settings" provider to store security information.

This provider information is configurable via the Provider tab, where you can choose to store information elsewhere, such as in an SQL Server database, but the default SQL Server Express database is fine for illustrative purposes.

7. Check the "Enable roles for this Web site" option and click Next.
8. Add two roles, Administrator and User, and click Next.
9. Add two user accounts, also called Administrator and User. Note that the default security rules for passwords (defined in `machine.config`) are quite strong; there is a seven-character minimum, including at least one symbol character and a mix of uppercase and lowercase.

In the downloadable code for this chapter, the password for both the User and Administrator account is `Pa$$w0rd`.

10. Click Next, and then Next again, skipping the Add New Access Rules page.

By default, all users and roles will have access to all areas of your site. From the Add New Access Rules page you can restrict areas by role, by user, or for anonymous users. You can do this for each directory in your site because this is achieved via `web.config` *files in directories, as you will see shortly.*

11. Click Finish.
12. On the main page for the Security tab, click Manage users.
13. Click Edit Roles for each user in turn, and add the Administrator user to both roles and the User user to just the User role.

After you have done all this, you are pretty much there. You have a user system in place, as well as roles and users.

To illustrate what this makes possible, you have to add a few controls to your web site to make things work. The example code in the following sections assumes that the web site is configured with the User and Administrator roles and users as described in this section.

Implementing a Login System

If you open `web.config` after running the security wizard you will see that it has been modified with the following content:

```
<roleManager enabled="true" />
```

and:

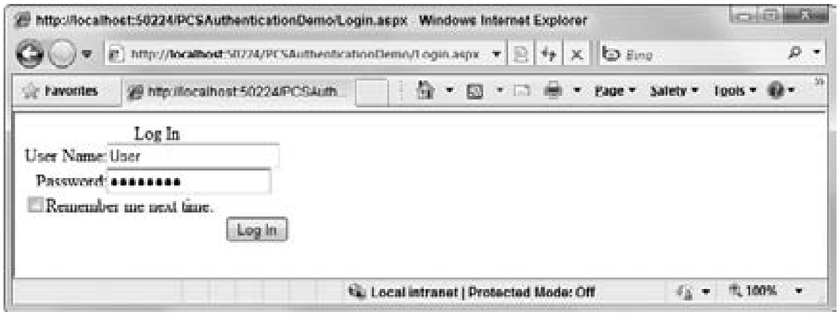
```
<authentication mode="Forms" />
```

This doesn't seem like a lot for the work that you have put in, but remember that a lot of information is stored in an SQL Server Express database, which you can see in the `App_Data` directory (you may need to click the refresh button in the Solution Explorer to see this file), called `ASPNETDB.MDF`. You can inspect the data that has been stored in this file using any standard database management tool, including Visual Studio. You can even add users and roles directly to this database, if you are careful.

By default, logging in is achieved via a page called `Login.aspx` in the root of your web site. If users attempt to navigate to a location that they don't have permission to access, they will automatically be redirected to this page and returned to the desired location after successfully logging in.

Add two Web Forms called `Default.aspx` and `Login.aspx` to the PCSAuthenticationDemo site and drag a `Login` control onto the `Login.aspx` form from the toolbox.

This is all you need to do to enable users to log in to your web site. Open the site in a browser, and navigate to `Login.aspx` (you have to do this manually for now as you haven't restricted access to `Default.aspx`). Enter the details for a user you added in the Security Setup Wizard, as shown in Figure 41-5.



http://localhost:50224/PCSAuthenticationDemo/Login.aspx - Windows Internet Explorer

FIGURE 41-5

After you have logged in, you will be sent to `Default.aspx`, currently a blank page.

Login Web Server Controls

The Login section of the toolbox contains several controls, as shown in the following table.

CONTROL	DESCRIPTION
`Login`	As you have seen, this control allows users to log in to your web site. Most of the properties of this control are for styling the supplied template. You can also use `DestinationPageUrl` to force redirection to a specific location after logging in, and `VisibleWhenLoggedIn` to determine whether the control is visible to logged-in users. And, you can use various text properties such as `CreateUserText` to output helpful messages to users.
`LoginView`	This control enables you to display content that varies depending on whether users are logged in, or what roles users are in. You can put content in `<AnonymousTemplate>` and `<LoggedInTemplate>`, as well as `<RoleGroups>` to control the output of this control.
`PasswordRecovery`	This control enables users to have their password mailed to them, and it can use the password recovery question defined for a user. Again, most properties are for display formatting, but there are properties such as `MailDefinition-Subject` for configuring the e-mail to be sent to the user's address, and `SuccessPageUrl` to redirect the users after they have requested a password.
`LoginStatus`	This control displays a Login or Logout link, with customizable text and images, to users depending on whether they are logged in.

continues

(continued)

CONTROL	DESCRIPTION
`LoginName`	This control outputs the username for the currently logged-in user.
`CreateUserWizard`	This control displays a form that users can use to register with your site and to be added to the user list. As with other login controls, there are a large number of properties relating to layout formatting, but the default is perfectly serviceable.
`ChangePassword`	This control enables users to change their passwords. There are three fields, for the old password, the new password, and the confirmation. There are many styling properties.

You see some of these in action in the "Security in PCSDemoSite" section.

Securing Directories

One final thing to discuss is how to restrict access to directories. You can do this via the Site Configuration tool, as noted earlier, but it's actually quite easy to do this yourself.

Add a directory to PCSAuthenticationDemo called `SecureDirectory`, as well as a `Default.aspx` web page in this directory, and a new `web.config` file. Replace the contents of `web.config` with the following:

```
<?xml version="1.0" ?>
<configuration>
  <system.web>
    <authorization>
      <deny users="?" />
      <allow roles="Administrator" />
      <deny roles="User" />
    </authorization>
  </system.web>
</configuration>
```

code snippet PCSAuthenticationDemo/SecureDirectory/web.config

The `<authorization>` element can contain one or more `<deny>` or `<allow>` elements representing permission rules, each of which can have a `users` or `roles` attribute saying what the rule applies to. The rules are applied from top to bottom, so more specific rules should generally be near the top if the membership of rules overlaps. In this example, `?` refers to anonymous users, who will be denied access to this directory, along with users in the `User` role. Note that users in both the `User` and `Administrator` roles will be allowed access only if the `<allow>` rule shown here comes before the `<deny>` rule for the `User` role — all of a user's roles are taken into account, but the rule order still applies.

Now when you log in to the web site and try to navigate to `SecureDirectory/Default.aspx`, you will be permitted only if you are in the `Admin` role. Other users, or users that are not authenticated, will be redirected to the login page.

Security in PCSDemoSite

The PCSDemoSite site uses the `Login` control that you have already seen, as well as a `LoginView` control, a `LoginStatus` control, a `LoginName` control, a `PasswordRecovery` control, and a `ChangePassword` control.

One difference is that a `Guest` role is included, and one consequence of this is that guest users should not be able to change their password — an ideal use for `LoginView`, as illustrated by `Login.aspx`:

```
<asp:Content ID="Content1" ContentPlaceHolderID="ContentPlaceHolder1"
  Runat="server">
  <h2>Login Page</h2>
```

```
    <asp:LoginView ID="LoginView1" Runat="server">
      <RoleGroups>
        <asp:RoleGroup Roles="Guest">
          <ContentTemplate>
            You are currently logged in as <b>
            <asp:LoginName ID="LoginName1" Runat="server" /></b>.
            <br />
            <br />
            <asp:LoginStatus ID="LoginStatus1" Runat="server" />
          </ContentTemplate>
        </asp:RoleGroup>
        <asp:RoleGroup Roles="RegisteredUser,SiteAdministrator">
          <ContentTemplate>
            You are currently logged in as <b>
            <asp:LoginName ID="LoginName2" Runat="server" /></b>.
            <br />
            <br />
            <asp:ChangePassword ID="ChangePassword1" Runat="server">
            </asp:ChangePassword>
            <br />
            <br />
            <asp:LoginStatus ID="LoginStatus2" Runat="server" />
          </ContentTemplate>
        </asp:RoleGroup>
      </RoleGroups>
      <AnonymousTemplate>
        <asp:Login ID="Login1" Runat="server">
        </asp:Login>
        <asp:PasswordRecovery ID="PasswordRecovery1" Runat="Server" />
      </AnonymousTemplate>
    </asp:LoginView>
  </asp:Content>
```

code snippet PCSAuthenticationDemo/Login.aspx

The view here displays one of several pages:

- For anonymous users a `Login` and a `PasswordRecovery` control are shown.
- For `Guest` users `LoginName` and `LoginStatus` controls are shown, giving the logged-in username and the facility to log out if required.
- For `RegisteredUser` and `SiteAdministrator` users `LoginName`, `LoginStatus`, and `ChangePassword` controls are shown.

The site also includes various `web.config` files in various directories to limit access, and the navigation is also restricted by role.

Note that the configured users for the site are shown on the About page, or you can add your own. The users in the base site (and their passwords) are User1 (User1!!), Admin (Admin!!), and Guest (Guest!!).

One point to note here is that although the root of the site denies anonymous users, the Themes directory (described in the next section) overrides this setting by permitting anonymous users. This is necessary because without this, anonymous users would see a themeless site, because the theme files would not be accessible. In addition, the full security specification in the root `web.config` file is as follows:

```
    <location path="StyleSheet.css">
      <system.web>
        <authorization>
          <allow users="?"/>
        </authorization>
    </system.web>
  </location>
  <system.web>
    <authorization>
      <deny users="?" />
    </authorization>
    ...
  </system.web>
```

code snippet PCSDemoSite/web.config

Here a `<location>` element is used to override the default setting for a specific file specified using a `path` attribute, in this case for the file `StyleSheet.css`. `<location>` elements can be used to apply any `<system.web>` settings to specific files or directories, and can be used to centralize all directory-specific settings in one place, if desired (as an alternative to multiple `web.config` files). In the preceding code, permission is given for anonymous users to access the root style sheet for the web site, which is necessary because this file defines the layout of the `<div>` elements in the master page. Without this, the HTML shown on the login page for anonymous users would be difficult to read.

Another point to note is in the code-behind file for the meeting room booker user control, in the `Page_Load()` event handler:

```
void Page_Load(object sender, EventArgs e)
{
   if (!this.IsPostBack)
   {
      nameBox.Text = Context.User.Identity.Name;
      DateTime trialDate = DateTime.Now;
      calendar.SelectedDate = GetFreeDate(trialDate);
   }
}
```

code snippet PCSDemoSite/MRB/MRB.ascx.cs

Here the username is extracted from the current context. Note that in your code-behind files you will probably also use `Context.User.IsInRole()` frequently to check access.

THEMES

By combining ASP.NET pages with master pages and CSS style sheets, you can go a long way in separating form and function, whereby the look and feel of your pages are defined separately from their operation. With themes you can take this a step further and dynamically apply this look and feel from one of several themes that you supply yourself.

A theme consists of the following:

- A name for the theme
- An optional CSS style sheet
- Skin (`.skin`) files allowing individual control types to be styled

These can be applied to pages in two different ways — with Theme or `StyleSheetTheme` attributes:

- **Theme —** All skin properties are applied to controls, overriding any properties that the controls on the page may already have.
- **StyleSheetTheme —** Existing control properties take precedence over properties defined in skin files.

CSS style sheets work in the same way whichever method is used because they are applied in the standard CSS way.

Applying Themes to Pages

You can apply a theme to a page in several ways, declaratively or programmatically. The simplest declarative way to apply a theme is via the `<%@ Page %>` directive, using the `Theme` or `StyleSheetTheme` attribute:

```
<%@ Page Theme="myTheme" ... %>
```

or:

```
<%@ Page StyleSheetTheme="myTheme" ... %>
```

Here `myTheme` is the name defined for the theme.

Alternatively, you can specify a theme to use for all pages in a site, using an entry in the `web.config` file for your web site:

```
<configuration>
  <system.web>
    <pages Theme="myTheme" />
  </system.web>
</configuration>
```

Again, you can use `Theme` or `StyleSheetTheme` here. You can also be more specific by using `<location>` elements to override this setting for individual pages or directories, in the same way as this element was used in the previous section for security information.

Programmatically, you can apply themes in the code-behind file for a page. There is only one place where you are allowed to do this — in the `Page_PreInit()` event handler, which is triggered very early on in the lifecycle of the page. In this event, you simply have to set the `Page.Theme` or `Page.StyleSheetTheme` property to the name of the theme you want to apply, for example:

```
protected override void OnPreInit(EventArgs e)
{
   Page.Theme = "myTheme";
}
```

Because you are using code to do this, you can dynamically apply a theme file from a selection of themes. This technique is used in the “Themes in PCSDemoSite” section.

Defining Themes

Themes are defined in yet another of the “special” directories in ASP.NET — in this case `App_Themes`. The `App_Themes` directory can contain any number of subdirectories, one per theme, where the name of the subdirectory defines the name of the theme.

Defining a theme involves putting the required files for the theme in the theme subdirectory. For CSS style sheets, you don’t have to worry about the filename; the theme system simply looks for a file with a `.css` extension. Similarly, `.skin` files can have any filename, although it is recommended that you use multiple `.skin` files, one for each control type you want to skin, and each named after the control it skins.

Skin files contain server control definitions in exactly the same format as you would use in standard ASP.NET pages. The difference is that the controls in skin files are never added to your page; they are simply used to extract properties. A definition for a button skin, typically placed in a file called `Button.skin`, might be as follows:

```
<asp:Button Runat="server" BackColor="#444499" BorderColor="#000000"
  ForeColor="#ccccff" />
```

This skin is actually taken from the `DefaultTheme` theme in PCSDemoSite, and is responsible for the look of the button on the Meeting Room Booker page you saw earlier in this chapter.

When you create a skin for a control type in this way you don’t use an `ID` property.

Themes in PCSDemoSite

The PCSDemoSite web site includes three themes that you can select on the `/Configuration/Themes/Default.aspx` page — as long as you are logged in as a member of either the `RegisteredUser` or `SiteAdministrator` role. This page is shown in Figure 41-6.

FIGURE 41-7

This sort of theme is useful in, for example, printable versions of web pages. The `BareTheme` directory actually consists of no files at all — the only file in use here is the root `StyleSheet.css` style sheet.

The demo site also contains a third theme, called `LuridTheme`. This brightly colored and difficult-to-read theme is just a bit of fun, really, but it does show how the look of a site can be dramatically changed using themes. On a more serious note, themes similar to this can be used to provide high-contrast or large-text versions of web sites for accessibility purposes.

In PCSDemoSite, the currently selected theme is stored in session state, so the theme is maintained when you navigate around the site. The code-behind file for `/Configuration/Themes/Default.aspx` is as follows:

```
public partial class _Default : MyPageBase
{
   private void ApplyTheme(string themeName)
   {
      if (Session["SessionTheme"] != null)
      {
         Session.Remove("SessionTheme");
      }
      Session.Add("SessionTheme", themeName);
      Response.Redirect("~/Configuration/Themes", true);
   }

   void applyDefaultTheme_Click(object sender, EventArgs e)
   {
      ApplyTheme("DefaultTheme");
   }

   void applyBareTheme_Click(object sender, EventArgs e)
   {
      ApplyTheme("BareTheme");
   }

   void applyLuridTheme_Click(object sender, EventArgs e)
   {
      ApplyTheme("LuridTheme");
   }
}
```

code snippet PCSDemoSite/Configuration/Themes/Default.aspx.cs

The key functionality here is in `ApplyTheme()`, which puts the name of the selected theme into session state, using the key `SessionTheme`. It also checks to see if there is already an entry here, and if so, removes it.

As mentioned earlier, themes must be applied in the `Page_PreInit()` event handler. This isn't accessible from the master page that all pages use, so if you want to apply a selected theme to all pages, you are left with two options:

- ➤ Override the `Page_PreInit()` event handler in all pages where you want themes to be applied.
- ➤ Provide a common base class for all pages where you want themes to be applied, and override the `Page_PreInit()` event handler in this base class.

PCSDemoSite uses the second option, with a common page base class provided in `Code/MyPageBase.cs`:

```
public class MyPageBase : Page
{
   protected override void OnPreInit(EventArgs e)
   {
      // theming
      if (Session["SessionTheme"] != null)
      {
            Page.Theme = Session["SessionTheme"] as string;
         }
         else
         {
            Page.Theme = "DefaultTheme";
         }

         // base call
         base.OnPreInit(e);
      }
   }
```

code snippet PCSDemoSite/App_Code/MyPageBase.cs

This event handler checks the session state for an entry in `SessionTheme` and applies the selected theme if there is one; otherwise `DefaultTheme` is used.

Note also that this class inherits from the usual page base class `Page`. This is necessary because, otherwise, the page wouldn't function as an ASP.NET web page.

For this to work, it is also necessary to specify this base class for all web pages. There are several ways of doing this, the most obvious being either in the `<@ Page %>` directive for a page or in the code behind a page. The former strategy is fine for simple pages but precludes the use of custom code behind for a page, as the page will no longer use the code in its own code-behind file. The other alternative is to change the class that the page inherits from in the code-behind file. By default, new pages inherit from `Page`, but you can change this. In the code-behind file for the theme selection page shown earlier, you may have noticed the following code:

```
   public partial class _Default : MyPageBase
   {
      ...
   }
```

code snippet PCSDemoSite/Configuration/Themes/Default.aspx.cs

Here `MyPageBase` is specified as the base of the `Default` class, and thus the method override in `MyPageBase.cs` is used.

WEB PARTS

ASP.NET contains a group of server controls known as Web Parts, which are designed to enable users to personalize web pages. You may have seen this in action, for example, in SharePoint-based web sites or on the My MSN home page: `http://my.msn.com/`. When you use Web Parts, the resulting functionality is as follows:

- Users are presented with a default page layout that you supply. This layout consists of a number of component Web Parts, each of which has a title and content.
- Users can change the position of the Web Parts on a page.
- Users can customize the appearance of Web Parts on a page or remove them from the page completely.
- Users can be supplied with a catalog of Web Parts that they can add to the page.
- Users can export Web Parts from a page, and then import them on a different page or site.
- Connections can exist between Web Parts. For example, the content displayed in a Web Part could be a graphical representation of the content displayed in another Web Part.
- Any changes that users make persist between site visits.

ASP.NET supplies a complete framework for implanting Web Parts functionality, including management and editing controls.

The use of Web Parts is a complex topic, and this section does not describe all available functionality or list all the properties and methods that the Web Part components supply. However, you do see enough to get a flavor of Web Parts and to understand the basic functionality that is possible.

Web Parts Application Components

The Web Parts section of the toolbox contains 13 controls, as described in the following table. The table also introduces some of the key concepts for Web Parts pages.

CONTROL	DESCRIPTION
`WebPartManager`	Every page that uses Web Parts must have one (and only one) instance of the `WebPartManager` control. You can place it on a master page if you wish, although if you do you should use the master page only when you want to use Web Parts on a page. This control is responsible for the majority of Web Parts functionality, which it supplies without much intervention. You may not need to do much more than place it on a web page, depending on the functionality you require. For more advanced functionality, you can use the large number of properties and events that this control exposes.
`ProxyWebPartManager`	If you place the `WebPartManager` control on a master page, it can be difficult to configure it on individual pages — and impossible to do so declaratively. This is particularly relevant for the definition of static connections between Web Parts. The `ProxyWebPartManager` control enables you to define static connections declaratively on a web page, which circumvents the problem of not being able to have two `WebPartManager` controls on the same page.
`WebPartZone`	The `WebPartZone` control is used to define a region of a page that can contain Web Parts. You will typically use more than one of these controls on a page. For example, you might use three of them in a three-column layout on a page. Users can move Web Parts between `WebPartZone` regions or reposition them within a single `WebPartZone`.
`CatalogZone`	The `CatalogZone` control enables users to add Web Parts to a page. This control contains controls that derive from `CatalogPart`, of which three are supplied for you — the next three entries in this table describe these controls. Whether the `CatalogZone` control and the controls it contains are visible depends on the current display mode set by `WebPartManager`.
`DeclarativeCatalogPart`	The `DeclarativeCatalogPart` control enables you to define Web Part controls inline. These controls will then be available to the user through the `CatalogZone` control.
`PageCatalogPart`	Users can remove (close) Web Parts that are displayed on a page. To retrieve them, the `PageCatalogPart` control provides a list of closed Web Parts that can be replaced on the page.
`ImportCatalogPart`	The `ImportCatalogPart` control enables Web Parts that have been exported from a page to be imported to another page through the `CatalogPart` interface.
`EditorZone`	The `EditorZone` control contains controls that enable users to edit various aspects of Web Part display and behavior, depending on what controls it contains. It can contain controls that derive from `EditorPart`, including the four that are listed in the next four rows of this table. As with `CatalogZone`, the display of this control depends on the current display mode.
`AppearanceEditorPart`	This control enables users to modify the look and size of Web Part controls, as well as to hide them.

continues

(continued)

CONTROL	DESCRIPTION
`BehaviorEditorPart`	This control enables users to configure the behavior of Web Parts by using a variety of properties that control, for example, whether a Web Part can be closed or what URL the title of a Web Part links to.
`LayoutEditorPart`	This control enables users to change layout properties of a Web Part, such as what zone it is contained in and whether it is displayed in a minimized state.
`PropertyGridEditorPart`	This is the most general Web Part editor control that enables you to define properties that can be edited for custom Web Part controls. Users can then edit these properties.
`ConnectionsZone`	This control enables users to create connections between Web Parts that expose connection functionality. Unlike `CatalogZone` and `EditorZone`, there are no controls to place inside this control. The user interface that this control generates depends on the controls on the page that are available for connections. The visibility of this control is dependent on the display mode.

You may notice that this list of controls does not include any Web Parts. This is because you create these yourself. Any control that you put into a `WebPartZone` region automatically becomes a Web Part — including (most importantly) user controls. By using user controls, you can group together other controls to provide the user interface and functionality of a Web Part control.

Web Parts Example

To illustrate the functionality of Web Parts, you can look at another of the example web sites in the downloadable code for this chapter, called PCSWebParts. This example uses the same security database as the PCSAuthenticationDemo example. It has two users with usernames of User and Administrator and a password of Pa$$w0rd for both. You can log in as a user, manipulate the Web Parts on the page, log out, log in as the other user, and manipulate the Web Parts in a completely different way. The personalization for both users is retained between site visits.

After you have logged in to the site, the initial display (with user logged in) is as shown in Figure 41-8.

FIGURE 41-8

This page contains the following controls:

- A `WebPartManager` control (which doesn't have a visual component).
- Three `WebPartZone` controls.
- Three Web Parts (Date, Events, and User Info); one in each `WebPartZone`. Two of the Web Parts are connected by a static connection — if you change the date in Date, the date displayed in Events updates.
- A drop-down list for changing the display mode. This list doesn't contain all the possible display modes, just the available ones. The available modes are obtained from the `WebPartManager` control, as you see shortly. The modes listed are:
    - Browse — This mode is the default and allows you to view and use Web Parts. In this mode, each Web Part can be minimized or closed by using the drop-down menu accessible in the top right of each Web Part.
    - Design — In this mode, you can reposition Web Parts.
    - Edit — In this mode, you can edit Web Part properties. An additional item in the drop-down menu for each Web Part becomes available: Edit.
    - Catalog — In this mode, you can add new Web Parts to the page.
- A link to reset the Web Part layout to the default (for the current user only).
- An `EditorZone` control (visible only in Edit mode).
- A `CatalogZone` control (visible only in Catalog mode).
- One additional Web Part in the catalog that you can add to the page.

Each of the Web Parts is defined in a user control.

Web Parts in Action

To illustrate how layout can be changed, use the drop-down list to change the display mode to Design. You will notice that each `WebPartZone` is then labeled with an `ID` value (`LeftZone`, `CenterZone`, and `RightZone`, respectively). You will also be able to move Web Parts simply by dragging their titles — and will even see visual feedback as you drag. This is illustrated in Figure 41-9, which shows the Date Web Part being moved.

You can edit and apply property values for Web Parts by using this interface.

After making changes, confirm that they are stored for the user by logging off and logging in as a different user, and then switching back to the first user.

Web Part Host Page Code

Now, you might think that this functionality requires quite a lot of code. In fact, the code in this example is remarkably simple. Look at the code for the Web Parts page. The `<form>` element starts with a `WebPartManager` control:

```
<form id="form1" runat="server">
  <asp:WebPartManager ID="WebPartManager1" runat="server"
    OnDisplayModeChanged="WebPartManager1_DisplayModeChanged">
    <StaticConnections>
      <asp:WebPartConnection ID="dateConnection"
        ConsumerConnectionPointID="DateConsumer"
        ConsumerID="EventListControl1"
        ProviderConnectionPointID="DateProvider"
        ProviderID="DateSelectorControl1" />
    </StaticConnections>
  </asp:WebPartManager>
```

code snippet PCSWebParts/Default.aspx

There is an event handler for the `DisplayModeChanged` event of this control, which is used to show or hide the editor `<div>` at the bottom of the page. There is also a specification for a static connection between the Date and Events Web Parts. This is achieved by defining named endpoints for the connection in the two user controls for these Web Parts and referring to those endpoints here. You see the code for this shortly.

Next, the title, display mode changer, and reset link are defined:

```
  <div class="mainDiv">
    <h1>Web Parts Page</h1>
    Display mode:
    <asp:DropDownList ID="displayMode" runat="server" AutoPostBack="True"
      OnSelectedIndexChanged="displayMode_SelectedIndexChanged" />
    <br />
    <asp:LinkButton runat="server" ID="resetButton" Text="Reset Layout"
      OnClick="resetButton_Click" />
    <br />
    <br />
```

The display mode drop-down list is populated in the `Page_Load()` event handler by using the `WebPartManager1.SupportedDisplayModes` property. The reset button uses the `WebPartManager1.Personalization.ResetPersonalizationState()` method to reset the personalization state for the current user.

Next come the three `WebPartZone` controls, each of which contains a user control that is loaded as a Web Part:

```
    <div class="innerDiv">
      <div class="zoneDiv">
        <asp:WebPartZone ID="LeftZone" runat="server">
          <ZoneTemplate>
            <uc1:DateSelectorControl ID="DateSelectorControl1" runat="server"
              title="Date" />
          </ZoneTemplate>
        </asp:WebPartZone>
      </div>
      <div class="zoneDiv">
        <asp:WebPartZone ID="CenterZone" runat="server">
          <ZoneTemplate>
            <uc2:EventListControl ID="EventListControl1" runat="server"
              title="Events" />
          </ZoneTemplate>
        </asp:WebPartZone>
      </div>
```

```
          <div class="zoneDiv">
            <asp:WebPartZone ID="RightZone" runat="server">
              <ZoneTemplate>
                <uc4:UserInfo ID="UserInfo1" runat="server" title="User Info" />
              </ZoneTemplate>
            </asp:WebPartZone>
          </div>
```

And finally you have the `EditorZone` and `CatalogZone` controls, containing an `AppearanceEditor` control and `PageCatalogPart` and `DeclarativeCatalogPart` controls, respectively:

```
          <asp:PlaceHolder runat="server" ID="editorPH" Visible="false">
            <div class="footerDiv">
              <asp:EditorZone ID="EditorZone1" runat="server">
                <ZoneTemplate>
                  <asp:AppearanceEditorPart ID="AppearanceEditorPart1"
                    runat="server" />
                </ZoneTemplate>
              </asp:EditorZone>
              <asp:CatalogZone ID="CatalogZone1" runat="server">
                <ZoneTemplate>
                  <asp:PageCatalogPart ID="PageCatalogPart1" runat="server" />
                  <asp:DeclarativeCatalogPart ID="DeclarativeCatalogPart1"
                    runat="server">
                    <WebPartsTemplate>
                      <uc3:LinksControl ID="LinksControl1" runat="server"
                        title="Links" />
                    </WebPartsTemplate>
                  </asp:DeclarativeCatalogPart>
                </ZoneTemplate>
              </asp:CatalogZone>
            </div>
          </asp:PlaceHolder>
        </div>
      </div>
    </form>
```

The `DeclarativeCatalogPart` control contains a fourth user control, which is the `Links` control that users can add to the page.

Web Part Code

The code for the Web Parts is equally simple. The Links Web part, for example, simply contains the following code:

```
<%@ Control Language="C#" AutoEventWireup="true"
CodeFile="LinksControl.ascx.cs"
  Inherits="LinksControl" %>
<a href="http://www.msn.com/">MSN</a>
<br />
<a href="http://www.microsoft.com/">Microsoft</a>
<br />
<a href="http://www.wrox.com/">Wrox Press</a>
```

code snippet PCSWebParts/LinksControl.ascx

No additional markup is required to make this user control work as a Web Part. The only point to note here is that the `<uc3:LinksControl>` element for the user control (as used in `Default.aspx`) has a `title` attribute — even though the user control doesn't have a `Title` property. This attribute is used by the `DeclarativeCatalogPart` control to infer a title to display for the Web Part (which you can edit at runtime with the `AppearanceEditorPart`).

Connecting Controls

The connection between the Date and Events controls is achieved by passing an interface reference from `DateSelectorControl` to `EventListControl` (the two user control classes used by these Web Parts):

```
public interface IDateProvider
{
   SelectedDatesCollection SelectedDates
   {
      get;
   }
}
```

code snippet PCSWebParts/App_Code/IDateProvider.cs

`DateSelectorControl` supports this interface, and so can pass an instance of `IDateProvider` by using `this`. The reference is passed by an endpoint method in `DateSelectorControl`, which is decorated with the `ConnectionProvider` attribute:

```
[ConnectionProvider("Date Provider", "DateProvider")]
public IDateProvider ProvideDate()
{
   return this;
}
```

code snippet PCSWebParts/DateSelectorControl.ascx.cs

This is all that is required to mark a Web Part as a provider control. You can then reference the provider by its endpoint ID, in this case `DateProvider`.

To consume a provider, you use the `ConnectionConsumer` attribute to decorate a consumer method in `EventListControl`:

```
[ConnectionConsumer("Date Consumer", "DateConsumer")]
public void GetDate(IDateProvider provider)
{
   this.provider = provider;
   IsConnected = true;
   SetDateLabel();
}
```

code snippet PCSWebParts/EventListControl.ascx.cs

This method stores a reference to the `IDateProvider` interface passed, sets a flag, and changes the label text in the control.

There is not a lot more to look at in this example. There are a few minor cosmetic sections of code, and details for the event handlers in `Page_Load()`, but nothing that you really need to see here. You can investigate further by examining the downloadable code for this chapter.

There is, however, a whole lot more to Web Parts than this. The Web Parts framework is extremely powerful and richly featured. Whole books are devoted to the subject. Hopefully, though, this section has enabled you to get an insight into Web Parts and has demystified some of their functionality.

ASP.NET AJAX

Web application programming is subject to continuous change and improvement. If you spend much time on the Internet, you may have noticed that more recent web sites are significantly better, in terms of usability, than older web sites. Many of today's best web sites provide rich user interfaces that feel almost as responsive as Windows applications. They achieve this by using client-side processing, primarily through JavaScript code, and increasingly through a technology known as Ajax.

Ajax is not a new technology. Rather, it is a combination of standards that makes it possible to realize the rich potential functionality of current web browsers.

Perhaps the key defining feature of Ajax-enabled web applications is the ability for the web browser to communicate with the web server in out-of-band operations; this is known as asynchronous, or partial-page, postbacks. In practice, this means that the user can interact with server-side functionality and data without needing a full-page refresh. For example, when a link is followed to move to the second page of data in a table, Ajax makes it possible to refresh just the table's content rather than the entire web page. This means that there is less traffic required across the Internet, which leads to a more responsive web application.

You will be using Microsoft's implementation of Ajax in the code, known as ASP.NET AJAX. This implementation takes the Ajax model and applies it to the ASP.NET Framework. ASP.NET AJAX provides a number of server controls and client-side techniques that are specifically targeted at ASP.NET developers and that enable you to add Ajax functionality to your web applications with surprisingly little effort.

This section introduces you to:

- ➤ Ajax and the technologies that make Ajax possible.
- ➤ ASP.NET AJAX and its component parts, as well as the functionality that ASP.NET AJAX offers.
- ➤ How to use ASP.NET AJAX in your web applications, by using both server-side and client-side code. This coverage forms the largest part of this section.

WHAT IS AJAX?

Ajax lets you enhance the user interfaces of web applications by means of asynchronous postbacks and dynamic client-side web page manipulation. The term Ajax was invented by Jesse James Garrett and is shorthand for Asynchronous JavaScript and XML.

Note that Ajax is not an acronym, which is why it is not capitalized as AJAX. However, it is capitalized in the product name ASP.NET AJAX, which is Microsoft's implementation of Ajax, as you will see in the next section of this chapter.

By definition, Ajax involves both JavaScript and XML. However, Ajax programming requires the use of other technologies as well, which are described in the following table.

TECHNOLOGY	DESCRIPTION
HTML/XHTML	HTML (Hypertext Markup Language) is the presentation and layout language used by web browsers to render information in a graphical user interface. You have already seen how HTML achieves this functionality and how ASP.NET generates HTML code. Extensible HTML (XHTML) is a stricter definition of HTML that uses XML structure.
CSS	CSS (cascading style sheets) is a means by which HTML elements can be styled according to rules defined in a separate style sheet. This enables you to apply styles simultaneously to multiple HTML elements and to swap styles to change the way a web page looks without HTML modifications. CSS includes both layout and style information, so you can also use CSS to position HTML elements on a page.
DOM	The DOM (Document Object Model) is a means of representing and manipulating (X)HTML code in a hierarchical structure. This enables you to access, for example, "the second column of the third row in table x" in a web page, rather than having to locate this element using more primitive text processing.

continues

(continued)

TECHNOLOGY	DESCRIPTION
JavaScript	JavaScript is a client-side scripting technology that enables you to execute code inside a web browser. The syntax of JavaScript is similar to other C-based languages, including C#, and provides variables, functions, branching code, looping statements, and other familiar programming elements. However, unlike C#, JavaScript is not strongly typed, and debugging JavaScript code can be difficult. In terms of Ajax programming, JavaScript is a key technology because it allows dynamic modifications to web pages by way of DOM manipulation — among other functionality.
XML	XML, as you have seen throughout this book, is a platform-neutral way to mark up data and is crucial to Ajax both as a way to manipulate data and as a language for communication between the client and the server.
`XMLHttpRequest`	Since Internet Explorer 5, browsers have supported the `XMLHttpRequest` API as a means of performing asynchronous communication between the client and server. This was originally introduced by Microsoft as a technology to access e-mail stored in an Exchange server over the Internet, in a product known as Outlook Web Access. Since then, it has become the standard way to perform asynchronous communications in web applications, and is a core technology of Ajax-enabled web applications. Microsoft's implementation of this API is known as XMLHTTP, which communicates over what is often called the XMLHTTP protocol.

Ajax also requires server-side code to handle partial-page postbacks as well as full-page postbacks. This can include both event handlers for server-control events and Web services. Figure 41-13 shows how these technologies fit together in the Ajax web browser model, in contrast to the "traditional" web browser model.

Prior to Ajax, the first four technologies listed in the preceding table (HTML, CSS, the DOM, and JavaScript) were used to create what was known as Dynamic HTML (DHTML) web applications. These applications were notable for two reasons: they provided a much better user interface, and they generally worked on only one type of web browser.

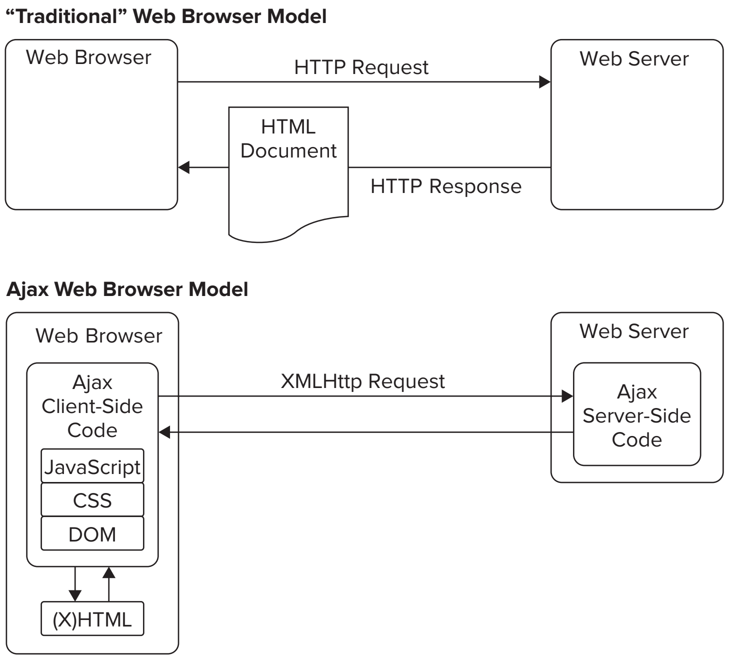

FIGURE 41-13

Since DHTML, standards have improved, along with the level of adherence to standards in web browsers. However, there are still differences, and an Ajax solution must take these differences into account. This has meant that most developers have been quite slow to implement Ajax solutions. Only with the advent of more abstracted Ajax frameworks (such as ASP.NET AJAX) has Ajax-enabled web site creation really become a viable option for enterprise-level development.

What Is ASP.NET AJAX?

ASP.NET AJAX is Microsoft's implementation of the Ajax framework and is specifically targeted at ASP.NET developers. It is part of the core ASP.NET functionality. It is also available for use with previous versions of ASP.NET from the web site `http://ajax.asp.net`. This web site also has documentation, forums, and sample code that you may find useful for whichever version of ASP.NET you are using.

ASP.NET AJAX provides the following functionality:

- A server-side framework that enables ASP.NET web pages to respond to partial-page postback operations
- ASP.NET server controls that make the implementation of Ajax functionality easy
- An HTTP handler that enables ASP.NET Web services to communicate with client-side code by using JavaScript Object Notation (JSON) serialization in partial-page postback operations
- Web services that enable client-side code to gain access to ASP.NET application services, including authentication and personalization services
- A web site template for creating ASP.NET AJAX-enabled web applications
- A client-side JavaScript library that provides a number of enhancements to JavaScript syntax as well as code to simplify the implementation of Ajax functionality

These server controls and the server-side framework that makes them possible are collectively known as the ASP.NET Extensions. The client-side part of ASP.NET AJAX is known as the AJAX Library.

There are several additional downloads that you can obtain from `http://ajax.asp.net`, including the following important ones:

- **ASP.NET AJAX Control Toolkit —** This download contains additional server controls that have been created by the developer community. These controls are shared-source controls that you can inspect and modify as you see fit.
- **Microsoft AJAX Library 3.5 —** This download contains the JavaScript client-side framework that is used by ASP.NET AJAX to implement Ajax functionality. You will not need this if you are developing ASP.NET AJAX applications. Instead, this download is intended to be used with other languages, for example PHP, to implement Ajax functionality using the same codebase as ASP.NET AJAX. This is beyond the scope of this chapter.

There is also a preview download for the next version of ASP.NET AJAX available on the web site. This download is not covered in this chapter.

Together these downloads provide you with a richly featured framework that you can use to add Ajax functionality to your ASP.NET web applications. In the following sections, you learn more about what is contained in the various component parts of ASP.NET AJAX.

Core Functionality

The core functionality of ASP.NET AJAX is divided into two parts, the AJAX Extensions and the AJAX Library.

AJAX Extensions

ASP.NET AJAX functionality is contained in two assemblies that are installed in the GAC:

- `System.Web.Extensions.dll` — This assembly contains the ASP.NET AJAX functionality, including the AJAX Extensions and the AJAX Library JavaScript files, which are available through the `ScriptManager` component (which is described shortly).
- `System.Web.Extensions.Design.dll` — This assembly contains ASP.NET Designer components for the AJAX Extensions server controls. This is used by the ASP.NET Designer in Visual Studio or Visual web developer.

Much of the AJAX Extensions component of ASP.NET AJAX is concerned with enabling partial-page postbacks and JSON serialization for Web services. This includes various HTTP handler components and extensions to the existing ASP.NET Framework. All this functionality can be configured through the `web.config` file for a web site. There are also classes and attributes that you can use for additional configuration. However, most of this configuration is transparent, and you will rarely need to change the defaults.

Your main interaction with AJAX Extensions will be using server controls to add Ajax functionality to your web applications. There are several of these, which you can use to enhance your applications in various ways. The following table shows a selection of the server-side components. You see these components in action later in this chapter.

CONTROL	DESCRIPTION
`ScriptManager`	This control is central to ASP.NET AJAX functionality and is required on every page that uses partial-page postbacks. Its main purpose is to manage client-side references to the AJAX Library JavaScript files, which are served from the ASP.NET AJAX assembly. The AJAX Library is used extensively by the AJAX Extensions server controls, which all generate their own client-side code. This control is also responsible for the configuration of Web services that you intend to access from client-side code. By supplying Web service information to the `ScriptManager` control, you can generate client-side and server-side classes to manage asynchronous communication with Web services transparently. You can also use the `ScriptManager` control to maintain references to your own JavaScript files.
`UpdatePanel`	The `UpdatePanel` control is an extremely useful one and is perhaps the ASP.NET AJAX control that you will use most often. This control acts like a standard ASP.NET placeholder and can contain any other controls. More important, it also marks a section of a page as a region that can be updated independently of the rest of the page, in a partial-page postback. Any controls contained by an `UpdatePanel` control that cause a postback (a `Button` control, for example) will not cause full-page postbacks. Instead, they cause partial-page postbacks that will update only the contents of the `UpdatePanel`. In many situations, this control is all you need to implement Ajax functionality. For example, you can place a `GridView` control in an `UpdatePanel` control, and any pagination, sorting, and other postback functionality of the control will take place in a partial-page postback.
`UpdateProgress`	This control enables you to provide feedback to users when a partial page postback is in progress. You can supply a template for this control that will be displayed when an `UpdatePanel` is updating. For example, you could use a floating `<div>` control to display a message such as "`Updating...`" so that the user is aware that the application is busy. Note that partial-page postbacks do not interfere with the rest of a web page, which will remain responsive.

CONTROL	DESCRIPTION
`Timer`	The ASP.NET AJAX `Timer` control is a useful way to cause an `UpdatePanel` to update periodically. You can configure this control to trigger postbacks at regular intervals. If this control is contained in an `UpdatePanel` control, then the `UpdatePanel` will be updated every time the `Timer` control is triggered. This control also has an associated event so that you can carry out periodic server-side processing.
`AsyncPostBackTrigger`	You can use this control to trigger `UpdatePanel` updates from controls that aren't contained in the `UpdatePanel`. For example, you can enable a drop-down list elsewhere on a web page to cause an `UpdatePanel` containing a `GridView` control to update.

The AJAX Extensions also include the `ExtenderControl` abstract base class for extending existing ASP.NET server controls. This is used, for example, by various classes in the ASP.NET AJAX Control Toolkit, as you will see shortly.

AJAX Library

The AJAX Library consists of JavaScript files that are used by client-side code in ASP.NET AJAX-enabled web applications. There is a lot of functionality included in these JavaScript files, some of which is general code that enhances the JavaScript language and some of which is specific to Ajax functionality. The AJAX Library contains layers of functionality that are built on top of each other, as shown in the following table.

LAYER	DESCRIPTION
Browser compatibility	The lowest-level code in the AJAX Library consists of code that maps various JavaScript functionality according to the client web browser. This is necessary because there are differences in the implementation of JavaScript in different browsers. By providing this layer, JavaScript code in other layers does not have to worry about browser compatibility, and you can write browser-neutral code that will work in all client environments.
Core services	This layer contains the enhancements to the JavaScript language, in particular OOP functionality. By using the code in this layer you can define namespaces, classes, derived classes, and interfaces using JavaScript script files. This is of particular interest to C# developers, because it makes writing JavaScript code much more like writing .NET code (by using C# and encouraging reusability).
Base class library	The client base class library (BCL) includes many JavaScript classes that provide low-level functionality to classes further down the AJAX Library hierarchy. Most of these classes are not intended to be used directly.
Networking	Classes in the networking layer enable client-side code to call server-side code asynchronously. This layer includes the basic framework for making a call to a URL and responding to the result in a callback function. For the most part, this is also functionality that you will not use directly; instead, you will use classes that wrap this functionality. This layer also contains classes for JSON serialization and deserialization. You will find most of the networking classes on the client-side `Sys.Net` namespace.
User interface	This layer contains classes that abstract user interface elements such as HTML elements and DOM events. You can use the properties and methods of this layer to write language-neutral JavaScript code to manipulate web pages from the client. User interface classes are contained in the `Sys.UI` namespace.
Controls	The final layer of the AJAX Library contains the highest-level code, which provides Ajax behaviors and server control functionality. This includes dynamically generated code that you can use, for example, to call Web services from client-side JavaScript code.

You can use the AJAX Library to extend and customize the behavior of ASP.NET AJAX-enabled web applications, but it is important to note that you don't have to. You can go a long way without using any additional JavaScript in your applications — it becomes a requirement only when you require more advanced functionality. If you do write additional client-side code, however, you will find that it is much easier with the functionality that the AJAX Library offers.

ASP.NET AJAX Control Toolkit

The AJAX Control Toolkit is a collection of additional server controls, including extender controls, that have been written by the ASP.NET AJAX community. Extender controls are controls that enable you to add functionality to an existing ASP.NET server control, typically by associating a client-side behavior with it. For example, one of the extenders in the AJAX Control Toolkit extends the `TextBox` control by placing "watermark" text in the `TextBox`, which appears when the user hasn't yet added any content to the text box. This extender control is implemented in a server control called `TextBoxWatermark`.

You can use the AJAX Control Toolkit to add quite a lot more functionality to your sites, beyond what is in the core download. These controls are also interesting simply to browse and will probably give you plenty of ideas about enhancing your web applications. However, because the AJAX Control Toolkit is separate from the core download, you should not expect the same level of support for these controls.

ASP.NET AJAX Web Site Example

Now that you have seen the component parts of ASP.NET AJAX, it is time to start looking at how to use them to enhance your web sites. In this section, you see how web applications that use ASP.NET AJAX work, and how to use the various aspects of functionality that ASP.NET AJAX includes. You start by examining a simple application, and then add functionality in subsequent sections.

The ASP.NET Web Site template includes all the ASP.NET AJAX core functionality. You can also use the AJAX Control Toolkit Web Site template (after it is installed) to include controls from the AJAX Control Toolkit. For the purposes of this example, you can create a new web site that uses the empty web site template in the `C:\ProCSharp\Chapter41` directory, called `PCSAjaxWebSite1`.

Add a web form called `Default.aspx` and modify its code as follows:

```
<%@ Page Language="C#" AutoEventWireup="true" CodeFile="Default.aspx.cs"
  Inherits="_Default" %>

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
 "http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml">
<head runat="server">
  <title>Pro C# ASP.NET AJAX Sample</title>
</head>
<body>
  <form id="form1" runat="server">
    <asp:ScriptManager ID="ScriptManager1" runat="server" />
    <div>
      <h1>Pro C# ASP.NET AJAX Sample</h1>
      This sample obtains a list of primes up to a maximum value.
      <br />
      Maximum:
      <asp:TextBox runat="server" id="MaxValue" Text="2500" />
      <br />
      Result:
      <asp:UpdatePanel runat="server" ID="ResultPanel">
        <ContentTemplate>
          <asp:Button runat="server" ID="GoButton" Text="Calculate " />
          <br />
          <asp:Label runat="server" ID="ResultLabel" />
          <br />
          <small>
            Panel render time: <% =DateTime.Now.ToLongTimeString() %>
          </small>
        </ContentTemplate>
      </asp:UpdatePanel>
      <asp:UpdateProgress runat="server" ID="UpdateProgress1">
        <ProgressTemplate>
         <div style="position: absolute; left: 100px; top: 200px;
             padding: 40px 60px 40px 60px; background-color: lightyellow;
             border: black 1px solid; font-weight: bold; font-size: larger;
             filter: alpha(opacity=80);">Updating.</div>
        </ProgressTemplate>
      </asp:UpdateProgress>
      <small>Page render time: <% =DateTime.Now.ToLongTimeString() %></small>
    </div>
  </form>
</body>
</html>
```

code snippet PCSAjaxWebSite1/Default.aspx

Switch to design view (note that the ASP.NET AJAX controls such as `UpdatePanel` and `UpdateProgress` have visual designer components), and double-click the Calculate button to add an event handler. Modify the code as follows:

```
protected void GoButton_Click(object sender, EventArgs e)
{
   int maxValue = 0;
   System.Text.StringBuilder resultText = new System.Text.StringBuilder();
   if (int.TryParse(MaxValue.Text, out maxValue))
   {
      for (int trial = 2; trial <= maxValue; trial++)
      {
         bool isPrime = true;
         for (int divisor = 2; divisor <= Math.Sqrt(trial); divisor++)
         {
            if (trial % divisor == 0)
            {
               isPrime = false;
               break;
            }
         }
         if (isPrime)
         {
            resultText.AppendFormat("{0} ", trial);
         }
      }
   }
   else
   {
      resultText.Append("Unable to parse maximum value.");
   }
   ResultLabel.Text = resultText.ToString();
}
```

code snippet PCSAjaxWebSite1/Default.aspx.cs

Save your modifications and press F5 to run the project. If prompted, enable debugging in `web.config`.

When the web page appears as shown in Figure 41-14, note that the two render times shown are the same.

Click the Calculate button to display prime numbers less than or equal to 2500. Unless you are running on a slow machine, this should be almost instantaneous. Note that the render times are now different — only the one in the `UpdatePanel` has changed.

Finally, add some zeros to the maximum value to introduce a processing delay (about three more should be enough on a fast PC) and click the Calculate button again. This time, before the result is displayed, note that the `UpdateProgress` control displays a partially transparent feedback message, as shown in Figure 41-15.

While the application updates, the page remains responsive. You can, for example, scroll through the page.

Close the browser to return to Visual Studio.

ASP.NET AJAX-Enabled Web Site Configuration

Most of the configuration required for ASP.NET AJAX is supplied for you by default, and you only really need to add to `web.config` if you want to change these defaults. For example, you can add a `<system.web.extensions>` section to provide additional configuration. Most of the configuration that you can add with this section concerns Web services and is contained in an element called `<webServices>`, which in turn is placed in a `<scripting>` element. First, you can add a section to enable access to the ASP.NET authentication service through a Web service (you can choose to enforce SSL here if you wish):

```
<system.web.extensions>
  <scripting>
    <webServices>
      <authenticationService enabled="true" requireSSL="true"/>
```

Next, you can enable and configure access to ASP.NET personalization functionality through the profile Web service:

```
      <profileService enabled="true"
        readAccessProperties="propertyname1,propertyname2"
        writeAccessProperties="propertyname1,propertyname2" />
```

The last Web service-related setting is for enabling and configuring access to ASP.NET role functionality through the role Web service:

```
      <roleService enabled="true"/>
    </webServices>
```

Finally, the `<system.web.extensions>` section can contain an element that enables you to configure compression and caching for asynchronous communications:

```
    <scriptResourceHandler enableCompression="true" enableCaching="true" />
  </scripting>
</system.web.extensions>
```

Additional Configuration for the AJAX Control Toolkit

To use the controls in the AJAX Control Toolkit, you can add the following configuration to `web.config`:

```
<controls>
  ...
  <add namespace="AjaxControlToolkit" assembly="AjaxControlToolkit"
    tagPrefix="ajaxToolkit"/>
</controls>
```

This maps the toolkit controls to the `ajaxToolkit` tag prefix. These controls are contained in the `AjaxControlToolkit.dll` assembly, which should be in the `/bin` directory for the web application.

Alternatively, you could register the controls individually on web pages using the `<%@ Register %>` directive:

```
<%@ Register Assembly="AjaxControlToolkit" Namespace="AjaxControlToolkit"
  TagPrefix="ajaxToolkit" %>
```

Adding ASP.NET AJAX Functionality

The first step in adding Ajax functionality to a web site is to add a `ScriptManager` control to your web pages. Next, you add server controls such as `UpdatePanel` controls to enable partial-page rendering and dynamic controls such as those supplied in the AJAX Control Toolkit to add usability and glitz to your application. You may also add client-side code, and you can use the AJAX Library for further assistance in customizing and enhancing the functionality of your application.

In this section, you learn about the functionality you can add using server controls. Later in this chapter you look at client-side techniques.

The ScriptManager Control

As mentioned earlier in the chapter, the `ScriptManager` control must be included on all pages that use partial-page postbacks and several other aspects of ASP.NET AJAX functionality.

> *A great way to ensure that all the pages in your web application contain the* `ScriptManager` *control is to add this control to the master page (or master pages) that your application uses.*

As well as enabling ASP.NET AJAX functionality, you can also use properties to configure this control. The simplest of these properties is `EnablePartialRendering`, which is `true` by default. If you set this property to `false`, you will disable all asynchronous postback processing, such as that provided by `UpdatePanel` controls. This can be useful, for example, if you want to compare your AJAX-enabled web site with a traditional web site; perhaps if you are giving a demonstration to a manager.

You can use the `ScriptManager` control for several reasons, such as in the following common situations:

- To determine whether server-side code is being called as a result of a partial-page postback
- To add references to additional client-side JavaScript files
- To reference Web services
- To return error messages to the client

These configuration options are covered in the following sections.

Detect Partial-Page Postbacks

The `ScriptManager` control includes a Boolean property called `IsInAsyncPostBack`. You can use this property in server-side code to detect whether a partial-page postback is in progress. Note that the `ScriptManager` for a page may actually be on a master page. Rather than accessing this control through the master page, you can obtain a reference to the current `ScriptManager` instance by using the static `GetCurrent()` method, for example:

```
ScriptManager scriptManager = ScriptManager.GetCurrent(this);
if (scriptManager != null && scriptManager.IsInAsyncPostBack)
{
   // Code to execute for partial-page postbacks.
}
```

You must pass a reference to a `Page` control to the `GetCurrent()` method. For example, if you use this method in a `Page_Load()` event handler for an ASP.NET web page, you can use `this` as your `Page` reference. Also, remember to check for a `null` reference to avoid exceptions.

Client-Side JavaScript References

Rather than adding code to the HTML page header, or in `<script>` elements on the page, you can use the `Scripts` property of the `ScriptManager` class. This centralizes your script references and makes it easier to maintain them. You can do this declaratively by adding a child `<Scripts>` element to the `<UpdatePanel>` control element, and then adding `<asp:ScriptReference>` child control elements to `<Scripts>`. You use the `Path` property of a `ScriptReference` control to reference a custom script.

The following sample shows how to add references to a custom script file called `MyScript.js` in the root folder of the web application:

```
<asp:ScriptManager runat="server" ID="ScriptManager1">
  <Scripts>
    <asp:ScriptReference Path="~/MyScript.js" />
  </Scripts>
</asp:ScriptManager>
```

Web Service References

To access Web services from client-side JavaScript code, ASP.NET AJAX must generate a proxy class. To control this behavior, you use the `Services` property of the `ScriptManager` class. As with `Scripts`, you can specify this property declaratively, this time with a `<Services>` element. You add `<asp:ServiceReference>` controls to this element. For each `ServiceReference` object in the `Services` property, you specify the path to the Web service by using the `Path` property.

The `ServiceReference` class also has a property called `InlineScript`, which defaults to `false`. When this property is `false`, client-side code obtains a proxy class to call the Web service by requesting it from the server. To enhance performance (particularly if you use a lot of Web services on a page), you can set `InlineScript` to `true`. This causes the proxy class to be defined in the client-script for the page.

ASP.NET Web services use a file extension of `.asmx`. Without wanting to get into too much detail in this chapter, to add a reference to a Web service called `MyService.asmx` in the root folder of a web application, you would use code as follows:

```
<asp:ScriptManager runat="server" ID="ScriptManager1">
  <Services>
    <asp:ServiceReference Path="~/MyService.asmx" />
  </Services>
</asp:ScriptManager>
```

You can only add references to local Web services (that is, Web services in the same web application as the calling code) in this way. You can call remote Web services indirectly via local web methods.

Later in this chapter you see how to make asynchronous web method calls from client-side JavaScript code that uses proxy classes generated in this way.

Client-Side Error Messages

If an exception is thrown as part of a partial-page postback, the default behavior is to place the error message contained in the exception into a client-side JavaScript alert message box. You can customize the message that is displayed by handling the `AsyncPostBackError` event of the `ScriptManager` instance. In the event handler, you can use the `AsyncPostBackErrorEventArgs.Exception` property to access the exception that is thrown and the `ScriptManager.AsyncPostBackErrorMessage` property to set the message that is displayed to the client. You might do this to hide the exception details from users.

If you want to override the default behavior and display a message in a different way, you must handle the `endRequest` event of the client-side `PageRequestManager` object by using JavaScript. This is described later in this chapter.

Using UpdatePanel Controls

The `UpdatePanel` control is perhaps the control that you will use most often when you write ASP.NET AJAX-enabled web applications. This control, as you have seen in the simple example earlier in the chapter, enables you to wrap a portion of a web page so that it is capable of participating in a partial-page postback operation. To do this, you add an `UpdatePanel` control to the page and fill its child `<ContentTemplate>` element with the controls that you want it to contain:

```
<asp:UpdatePanel runat="Server" ID="UpdatePanel1">
  <ContentTemplate>
    ...
  </ContentTemplate>
</asp:UpdatePanel>
```

The contents of the `<ContentTemplate>` template are rendered in either a `<div>` or `<span>` element according to the value of the `RenderMode` property of the `UpdatePanel`. The default value of this property is `Block`, which will result in a `<div>` element. To use a `<span>` element, set `RenderMode` to `Inline`.

Multiple UpdatePanel Controls on a Single Web Page

You can include any number of `UpdatePanel` controls on a page. If a postback is caused by a control that is contained in the `<ContentTemplate>` of any `UpdatePanel` on the page, a partial-page postback will occur instead of a full-page postback. This will cause all the `UpdatePanel` controls to update according to the value of their `UpdateMode` property. The default value of this property is `Always`, which means that the `UpdatePanel` will update for a partial-page postback operation on the page, even if this operation occurs in a different `UpdatePanel` control. If you set this property to `Conditional`, the `UpdatePanel` updates only when a control that it contains causes a partial-page postback or when a trigger that you have defined occurs. Triggers are covered shortly.

If you have set `UpdateMode` to `Conditional`, you can also set the `ChildrenAsTriggers` property to `false` to prevent controls that are contained by the `UpdatePanel` from triggering an update of the panel. Note, though, that in this case these controls still trigger a partial-page update, which may result in other `UpdatePanel` controls on the page being updated. For example, this will update controls that have an `UpdateMode` property value of `Always`. This is illustrated in the following code:

```
<asp:UpdatePanel runat="Server" ID="UpdatePanel1" UpdateMode="Conditional"
  ChildrenAsTriggers="false">
  <ContentTemplate>
    <asp:Button runat="Server" ID="Button1" Text="Click Me" />
    <small>Panel 1 render time: <% =DateTime.Now.ToLongTimeString() %></small>
  </ContentTemplate>
</asp:UpdatePanel>
<asp:UpdatePanel runat="Server" ID="UpdatePanel2">
  <ContentTemplate>
    <small>Panel 2 render time: <% =DateTime.Now.ToLongTimeString() %></small>
  </ContentTemplate>
</asp:UpdatePanel>
<small>Page render time: <% =DateTime.Now.ToLongTimeString() %></small>
```

In this code, the `UpdatePanel2` control has an `UpdateMode` property of `Always`; the default value. When the button is clicked, it will cause a partial-page postback, but only `UpdatePanel2` will be updated. Visually, you will notice that only the "Panel 2 render time" label is updated.

Server-Side UpdatePanel Updates

Sometimes when you have multiple `UpdatePanel` controls on a page, you might decide not to update one of them unless certain conditions are met. In this case, you would configure the `UpdateMode` property of the panel to `Conditional` as shown in the previous section and possibly also set the `ChildrenAsTriggers` property to `false`. Then, in your server-side event-handler code for one of the controls on the page that causes a partial-page update, you would (conditionally) call the `Update()` method of the `UpdatePanel`. For example:

```
protected void Button1_Click(object sender, EventArgs e)
{
   if (TestSomeCondition())
   {
      UpdatePanel1.Update();
   }
}
```

UpdatePanel Triggers

You can cause an `UpdatePanel` control to be updated by a control elsewhere on the web page by adding triggers to the `Triggers` property of the control. A trigger is an association between an event of a control elsewhere on the page and the `UpdatePanel` control. All controls have default events (for example, the default event of a `Button` control is `Click`), so specifying the name of an event is optional. There are two types of triggers that you can add, represented by the following two classes:

- ➤ AsyncPostBackTrigger — This class causes the UpdatePanel to update when the specified event of the specified control is triggered.
- ➤ PostBackTrigger — This class causes a full-page update to be triggered when the specified event of the specified control is triggered.

You will mostly use AsyncPostBackTrigger, but PostBackTrigger can be useful if you want a control inside an UpdatePanel to trigger a full-page postback.

Both of these trigger classes have two properties: ControlID, which specifies the control that causes the trigger by its identifier, and EventName, which specifies the name of the event for the control that is linked to the trigger.

To extend an earlier example, consider the following code:

```
<asp:UpdatePanel runat="Server" ID="UpdatePanel1" UpdateMode="Conditional"
  ChildrenAsTriggers="false">
  <Triggers>
    <asp:AsyncPostBackTrigger ControlID="Button2" />
  </Triggers>
  <ContentTemplate>
    <asp:Button runat="Server" ID="Button1" Text="Click Me" />
    <small>Panel 1 render time: <% =DateTime.Now.ToLongTimeString() %></small>
  </ContentTemplate>
</asp:UpdatePanel>
<asp:UpdatePanel runat="Server" ID="UpdatePanel2">
  <ContentTemplate>
    <asp:Button runat="Server" ID="Button2" Text="Click Me" />
    <small>Panel 2 render time: <% =DateTime.Now.ToLongTimeString() %></small>
  </ContentTemplate>
</asp:UpdatePanel>
<small>Page render time: <% =DateTime.Now.ToLongTimeString() %></small>
```

The new Button control, Button2, is specified as a trigger in the UpdatePanel1. When this button is clicked, both UpdatePanel1 and UpdatePanel2 will be updated: UpdatePanel1 because of the trigger, and UpdatePanel2 because it uses the default UpdateMode value of Always.

Using UpdateProgress

The UpdateProgress control, as you saw in the earlier example, enables you to display a progress message to the user while a partial-page postback is in operation. You use the ProgressTemplate property to supply an ITemplate for the progress display. You will typically use the <ProgressTemplate> child element of the control to do this.

You can place multiple UpdateProgress controls on a page by using the AssociatedUpdatePanelID property to associate the control with a specific UpdatePanel. If this is not set (the default), the UpdateProgress template will be displayed for any partial-page postback, regardless of which UpdatePanel causes it.

When a partial-page postback occurs, there is a delay before the UpdateProgress template is displayed. This delay is configurable through the DisplayAfter property, which is an int property that specifies the delay in milliseconds. The default is 500 milliseconds.

Finally, you can use the Boolean DynamicLayout property to specify whether space is allocated for the template before it is displayed. For the default value of true for this property, space on the page is dynamically allocated, which may result in other controls being moved out of the way for an inline progress template display. If you set this property to false, space will be allocated for the template before it is displayed, so the layout of other controls on the page will not change. You will set this property according to the effect you want to achieve when displaying progress. For a progress template that is positioned by using absolute coordinates, as in the earlier example, you should leave this property set to the default value.

Using Extender Controls

The core ASP.NET AJAX download includes a class called `ExtenderControl`. The purpose of this control is to enable you to extend (that is, add functionality to) other ASP.NET server controls. This is used extensively in the AJAX Control Toolkit to great effect, and you can use the ASP.NET AJAX Server Control Extender project template to create your own extended controls. `ExtenderControl` controls all work in a similar way — you place them on a page, associate them with target controls, and add further configuration. The extender then emits client-side code to add functionality.

To see this in action in a simple example, create a new empty web site called `PCSExtenderDemo` in the `C:\ProCSharp\Chapter41` directory, add the AJAX Control Toolkit assembly to the bin directory of the web site, and then add the following code to a new web form called `Default.aspx`:

```
<%@ Page Language="C#" AutoEventWireup="true" CodeFile="Default.aspx.cs"
  Inherits="_Default" %>
<%@ Register Assembly="AjaxControlToolkit" Namespace="AjaxControlToolkit"
  TagPrefix="ajaxToolkit" %>

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
 "http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml">
<head runat="server">
  <title>Color Selector</title>
</head>
<body>
  <form id="form1" runat="server">
    <asp:ScriptManager ID="ScriptManager1" runat="server" />
    <div>
      <asp:UpdatePanel runat="server" ID="updatePanel1">
        <ContentTemplate>
          <span style="display: inline-block; padding: 2px;">
            My favorite color is:
          </span>
          <asp:Label runat="server" ID="favoriteColorLabel" Text="green"
            style="color: #00dd00; display: inline-block; padding: 2px;
                   width: 70px; font-weight: bold;" />
          <ajaxToolkit:DropDownExtender runat="server" ID="dropDownExtender1"
            TargetControlID="favoriteColorLabel"
            DropDownControlID="colDropDown" />
          <asp:Panel ID="colDropDown" runat="server"
            Style="display: none; visibility: hidden; width: 60px;
                   padding: 8px; border: double 4px black;
                   background-color: #ffffdd; font-weight: bold;">
            <asp:LinkButton runat="server" ID="OptionRed" Text="red"
              OnClick="OnSelect" style="color: #ff0000;" /><br />
            <asp:LinkButton runat="server" ID="OptionOrange" Text="orange"
              OnClick="OnSelect" style="color: #dd7700;" /><br />
            <asp:LinkButton runat="server" ID="OptionYellow" Text="yellow"
              OnClick="OnSelect" style="color: #dddd00;" /><br />
            <asp:LinkButton runat="server" ID="OptionGreen" Text="green"
              OnClick="OnSelect" style="color: #00dd00;" /><br />
            <asp:LinkButton runat="server" ID="OptionBlue" Text="blue"
              OnClick="OnSelect" style="color: #0000dd;" /><br />
            <asp:LinkButton runat="server" ID="OptionPurple" Text="purple"
              OnClick="OnSelect" style="color: #dd00ff;" />
          </asp:Panel>
        </ContentTemplate>
      </asp:UpdatePanel>
    </div>
  </form>
</body>
</html>
```

code snippet PCSExtenderDemo/Default.aspx

You also need to add the following event handler to the code behind this file:

```
protected void OnSelect(object sender, EventArgs e)
{
   favoriteColorLabel.Text = ((LinkButton)sender).Text;
   favoriteColorLabel.Style["color"] = ((LinkButton)sender).Style["color"];
}
```

code snippet PCSExtenderDemo/Default.aspx.cs

In the browser, not very much is visible at first, and the extender seems to have no effect. This is shown in Figure 41-16.

FIGURE 41-17

When you click one of the links in the drop-down list, the text changes accordingly (after a partial-page postback operation).

There are two important points to note about this simple example:

- It was extremely easy to associate the extender with target controls.
- The drop-down list was styled using custom code — meaning that you can place whatever content you like in the list. This simple extender is a great way to add functionality to your web applications, and it is very simple to use.

The extenders that are contained in the AJAX Control Toolkit are continually being added to and updated, so check `http://www.asp.net/ajax/AjaxControlToolkit/Samples/` regularly. This web page includes live demonstrations of all the current extenders so that you can see them in action.

In addition to the extender controls that are supplied by the AJAX Control Toolkit, you can create your own. To create an effective extender, you must use the AJAX Library.

Using the AJAX Library

There is a great deal of functionality available in the AJAX Library that you can use to further enhance your web applications. However, to do this you need at least a working knowledge of JavaScript. In this section, you see some of this functionality, although this is not an exhaustive tutorial.

The basic principles behind the use of the AJAX Library are much the same as for adding any type of client-side script to a web application. You will still use the core JavaScript language, and you will still interact with the DOM. However, there are many areas where the AJAX Library makes things easier for you. This section explains many of these areas and provides a foundation that you can build on with further experimentation and study of the online AJAX Library documentation.

The techniques covered in this section are illustrated in the `PCSLibraryDemo` project, which is referred to throughout the rest of this chapter.

Adding JavaScript to a Web Page

The first thing you need to know is how to add client-side JavaScript to a web page. You have three options here:

- Add JavaScript inline in ASP.NET web pages by using the `<script>` element.
- Add JavaScript to separate JavaScript files with the extension `.js` and reference these files from `<script>` elements or (preferably) by using the `<Scripts>` child element of the `ScriptManager` control.
- Generate JavaScript from server-side code, such as code behind or custom extender controls.

Each of these techniques has its own benefits. For prototyping code, there is no substitute for inline code because it is so quick and easy to use. You will also find it easy to associate client-side event handlers of HTML elements and server controls with client-side functions, because everything is in the same file.

Having separate files is good for reusability, because you may create your own library of classes much like the existing AJAX Library JavaScript files.

Generating code from code-behind can be tricky to implement because you will not usually have access to IntelliSense for JavaScript programming when you use C# code. However, you will be able to generate code dynamically in response to application state, and sometimes this is the only way to do things.

The extenders that you can create with the AJAX Control Toolkit include a separate JavaScript file that you use to define behaviors, which gets around some of the problems of exposing client-side code from the server.

In this chapter, you use the inline code technique, because it is simplest and allows you to concentrate on the JavaScript functionality.

Global Utility Functions

One of the features supplied by the AJAX Library that you will use most often is the set of global functions that wrap other functionality. These include the following:

- `$get()` — This function enables you to get a reference to a DOM element by supplying its client-side `id` value as a parameter, with an optional second parameter to specify the parent element to search in.
- `$create()` — This function enables you to create objects and perform initialization at the same time. You can supply between one and five parameters to this function. The first parameter is the type you want to instantiate, which will typically be a type defined by the AJAX Library. The other parameters enable you to specify initial property values, event handlers, references to other components, and the DOM element that the object is attached to, respectively.
- `$addHandler()` — This function provides a shorthand for adding an event handler to an object.

There are more global functions, but these are the ones you will use most often. `$create()` in particular is a very useful way to reduce the amount of code required to create and initialize an object.

Using the AJAX Library JavaScript OOP Extensions

The AJAX Library includes an enhanced framework for defining types that uses an OOP-based system that maps closely to .NET Framework techniques. You can create namespaces, add types to namespaces, add constructors, methods, properties, and events to types, and even use inheritance and interfaces in type definitions.

In this section, you see how to implement the basics of this functionality, but you won't look at events and interfaces here. These constructs are beyond the scope of this chapter.

Defining Namespaces

To define a namespace, you use the `Type.registerNamespace()` function, for example:

```
Type.registerNamespace("ProCSharp");
```

After you have registered a namespace you can add types to it.

Defining Classes

Defining a class is a three-stage process. First, you define the constructor. Next, you add properties and methods. Finally, you register the class.

To define a constructor, you define a function using a namespace and class name, for example:

```
ProCSharp.Shape = function(color, scaleFactor) {
  this._color = color;
  this._scaleFactor = scaleFactor;
}
```

This constructor takes two parameters and uses them to set local fields (note that you do not have to explicitly define these fields — you just have to set their values).

To add properties and methods, you assign them to the `prototype` property of the class as follows:

```
ProCSharp.Shape.prototype = {

  get_Color : function() {
    return this._color;
  },

  set_Color : function(color) {
    this._color = color;
  },

  get_ScaleFactor : function() {
    return this._scaleFactor;
  },

  set_ScaleFactor : function(scaleFactor) {
    this._scaleFactor = scaleFactor;
  }

}
```

This code defines two properties by their get and set accessors.

To register a class, you call its `registerClass()` function:

```
ProCSharp.Shape.registerClass('ProCSharp.Shape');
```

Inheritance

You derive a class in much the same way as creating a class but with some slight differences. You use the `initializeBase()` function to initialize the base class in the constructor, passing parameters in the form of an array:

```
ProCSharp.Circle = function(color, scaleFactor, diameter) {
  ProCSharp.Circle.initializeBase(this, [color, scaleFactor]);
  this._diameter = diameter;
}
```

You define properties and methods in the same way as before:

```
ProCSharp.Circle.prototype = {

  get_Diameter : function() {
    return this._diameter;
  },

  set_Diameter : function(diameter) {
    this._diameter = diameter;
  },

  get_Area : function() {
    return Math.PI * Math.pow((this._diameter * this._scaleFactor) / 2, 2);
  },

  describe : function() {
    var description = "This is a " + this._color + " circle with an area of "
      + this.get_Area();
    alert(description);
  }
}
```

When you register the class, you provide the base class type as a second parameter:

```
ProCSharp.Circle.registerClass('ProCSharp.Circle', ProCSharp.Shape);
```

You can implement interfaces by passing them as additional parameters, although, to keep things simple, you won't see details of that here.

Using User-Defined Types

After you have defined classes in this way, you can instantiate and use them with simple syntax. For example:

```
var myCircle = new ProCSharp.Circle('red', 1.0, 4.4);
myCircle.describe();
```

This code would result in a JavaScript alert box, as shown in Figure 41-18.

The PageRequestManager and Application Objects

Among the most useful classes that the AJAX Library provides are the `PageRequestManager` and `Application` classes. You will find `PageRequestManager` in the `Sys.WebForms` namespace and `Application` in the `Sys` namespace. The important thing about these classes is that they expose several events that you can attach JavaScript event handlers to. These events occur at particularly interesting points in the lifecycle of a page (for `Application`) or partial-page postback (for `PageRequestManager`) and enable you to perform operations at these critical times.

The AJAX Library defines event handlers in a similar way to event handlers in the .NET Framework. Every event handler has a similar signature, with two parameters. The first parameter is a reference to the object that generated the event. The second parameter is an instance of the `Sys.EventArgs` class or an instance of a class that derives from this class. Many of the events exposed by `PageRequestManager` and `Application` include specialized event argument classes that you can use to determine more information about the event. The following table lists these events in the order they will occur in a page that is loaded, triggers a partial-page postback, and is then closed.

EVENT	DESCRIPTION
`Application.init`	This event is the first to occur in the lifecycle of a page. It is raised after all the JavaScript files have been loaded but before any objects in the application have been created.
`Application.load`	This event fires after the objects in the application have loaded and been initialized. You will often use an event handler attached to this event to perform actions when the page is first loaded. You can also provide an implementation for a function called `pageLoad()` on a page, which is automatically defined as an event handler for this event. It sends event arguments by using a `Sys.ApplicationLoadEventArgs` object, which includes the `isPartialLoad` property that you can use to determine if a partial-page postback has occurred. Access this property with the `get_isPartialLoad()` accessor.
`PageRequestManager.initializeRequest`	This event occurs before a partial-page postback, before the request object is created. You can use the `Sys.WebForms.InitializeRequestEventArgs` event argument properties to access the element that triggered the postback (`postBackElement`) and the underlying request object (`request`).
`PageRequestManager.beginRequest`	This event occurs before a partial-page postback, after the request object is created. You can use the `Sys.WebForms.BeginRequestEventArgs` event argument properties to access the element that triggered the postback (`postBackElement`) and the underlying request object (`request`).
`PageRequestManager.pageLoading`	This event is raised after a partial-page postback, before any subsequent processing occurs. This processing can include `<div>` elements that will be deleted or updated, which you can reference through the `Sys.WebForms.PageLoadingEventArgs` object by using the `panelsDeleting` and `panelsUpdating` properties.

continues

(continued)

EVENT	DESCRIPTION
`PageRequestManager.pageLoaded`	This event is raised after a partial-page postback, after `UpdatePanel` controls have been processed. This processing can include `<div>` elements that have been created or updated, which you can reference through the `Sys.WebForms.PageLoadedEventArgs` object by using the `panelsCreated` and `panelsUpdated` properties.
`PageRequestManager.endRequest`	This event occurs after the processing of a partial-page postback has completed. The `Sys.WebForms.EndRequestEventArgs` object passed to the event handler enables you to detect and process server-side errors (by using the `error` and `errorHandled` properties) as well as to access the response object through `response`.
`Application.unload`	This event is raised just before the objects in the application are disposed, which gives you a chance to perform final actions or clean up if necessary.

You can add an event handler to an event of the `Application` object by using the static `add_xxx()` functions, for example:

```
Sys.Application.add_load(LoadHandler);

function LoadHandler(sender, args)
{
  // Event handler code.
}
```

The process is similar for `PageRequestManager`, but you must use the `get_instance()` function to obtain an instance of the current object, for example:

```
Sys.WebForms.PageRequestManager.getInstance().add_beginRequest(
  BeginRequestHandler);

function BeginRequestHandler(sender, args)
{
  // Event handler code.
}
```

In the `PCSLibraryDemo` application, an event handler is added to the `PageRequestManager.endRequest` event. This event handler responds to server-side processing errors and displays an error message in a `<span>` element with an `id` of `errorDisplay`. To test this method, click the Test Client-Side Error Display button, as shown in Figure 41-19.

Sys.WebForms.PageRequestManagerServerErrorException: This is the message set in the exception on the server.

32.7 x 84.2 = Click button to calculate.

FIGURE 41-19

The code that achieves this is:

```
Sys.WebForms.PageRequestManager.getInstance().add_endRequest(
  EndRequestHandler);

function EndRequestHandler(sender, args)
{
  if (args.get_error() != undefined)
  {
    var errorMessage = args.get_error().message;
    args.set_errorHandled(true);
    $get('errorDisplay').innerHTML = errorMessage;
  }
}
```

Note that the `errorHandled` property of the `EndRequestEventArgs` object is set to `true`. This prevents the default behavior, which is to display the error message in a dialog box, by using the JavaScript `alert()` function.

The error itself is generated by throwing an exception on the server as follows:

```
protected void testErrorDisplay_Click(object sender, EventArgs e)
{
   throw new ApplicationException(
      "This is the message set in the exception on the server.");
}
```

There are many other situations when you will want to use event handling techniques to act on the `Application` and `PageRequestManager` events.

JavaScript Debugging

In the past, JavaScript has had a reputation of being difficult to debug. However, this has been addressed in the latest version of Visual Studio. You can now add breakpoints and step through JavaScript code just like C# code. You can also interrogate object state in break mode, change property values, and so on. The IntelliSense that is available when you write JavaScript code is also vastly improved in the latest version of Visual Studio.

However, there will still be times when you will want to add debug and trace code to report information as code is executed. For example, you might want to use the JavaScript `alert()` function to show information in dialog boxes.

There are also some third-party tools that you can use to add a client-side UI for debugging. These include:

- **Fiddler —** This tool, which you can obtain from `www.fiddlertool.com`, enables you to log all HTTP traffic between your computer and a web application — including partial-page postbacks. There are also additional tools that you can use to look at what occurs during the processing of web pages in more detail.
- **Nikhil's Web Development Helper —** This tool, available at `http://projects.nikhilk.net/WebDevHelper`, can also log HTTP traffic. In addition, this tool contains a number of utilities specifically aimed at ASP.NET and ASP.NET AJAX development, for example, the ability to examine view state and to execute immediate JavaScript code. This latter feature is particularly useful to test objects that you may have created on the client. The Web Development Helper also displays extended error information when JavaScript errors occur, which makes it easier to track down bugs in JavaScript code.

The AJAX Library also provides the `Sys.Debug` class, which you can use to add some extra debugging features to your application. One of the most useful features of this class is the `Sys.Debug.traceDump()` function, which enables you to analyze objects. One way to use this function is to place a `textarea` control on your web page with an `id` attribute of `TraceConsole`. Then, all output from `Debug` will be sent to this control. For example, you can use the `traceDump()` method to output information about the `Application` object to the console:

```
Sys.Application.add_load(LoadHandler);

function LoadHandler(sender, args)
{
  Sys.Debug.traceDump(sender);
}
```

This results in output along the lines of the following:

```
traceDump {Sys._Application}
    _updating: false
    _id: null
    _disposing: false
    _creatingComponents: false
    _disposableObjects {Array}
    _components {Object}
    _createdComponents {Array}
    _secondPassComponents {Array}
    _loadHandlerDelegate: null
    _events {Sys.EventHandlerList}
        _list {Object}
            load {Array}
                [0] {Function}
    _initialized: true
    _initializing: true
```

You can see all the properties of this object in this output. This technique can be extremely useful for ASP.NET AJAX development.

Making Asynchronous Web Method Calls

One of the most powerful features of ASP.NET AJAX is the ability to call web methods from client-side script. This gives you access to data, server-side processing, and all manner of other functionality.

You will not be looking at web methods in this book until Chapter 43, "Windows Communication Foundation," so we will save the details until then and cover the basics here. Put simply, a *web method* is a method that you can expose from a Web service that enables you to access remote resources over the Internet. In ASP.NET AJAX, you can also expose web methods as static methods of server-side web page code-behind code. You can use parameters and return values in web methods just as you do in other method types.

In ASP.NET AJAX, web methods are called asynchronously. You pass parameters to a web method and define a callback function, which is called when the web method call completes. You use this callback function to process the web method response. You can also provide an alternative callback function to call in the event of a call failure.

In the `PCSLibraryDemo` application, you can see a web method call being performed by clicking the Call Web Method button, as shown in Figure 41-20.

Test OOP Functionality

Test Client-Side Error Display Sys.WebForms.PageRequestManagerServerErrorException: This is the message set in the exception on the server.

Call Web Method 32.7 x 84.2 = 2753.34

FIGURE 41-20

Before you can use a web method from client-side script, you must generate a client-side proxy class to perform the communication. The easiest way to do this is simply to reference the URL of the Web service that contains the web method in the `ScriptManager` control:

```
<asp:ScriptManager ID="ScriptManager1" runat="server">
  <Services>
    <asp:ServiceReference Path="~/SimpleService.asmx" />
  </Services>
</asp:ScriptManager>
```

ASP.NET Web services use the extension `.asmx`, as shown in this code. To use a client-side proxy to access a web method in a Web service, you must apply the `System.Web.Script.Services.ScriptService` attribute to the Web service.

For web methods in the code behind for the web page, you do not need this attribute, or this reference in `ScriptManager`, but you must use static methods and apply the `System.Web.Services.WebMethod` attribute to the methods.

After you have generated a client-side stub, you can access the web method by its name, which is defined as a function of a class with the same name as the Web service. In `PCSLibraryDemo`, the `SimpleService.asmx` Web service has a web method called `Multiply()`, which multiplies two double parameters. When you call this method from client-side code, you pass the two parameters required by the method (obtained from HTML `<input>` elements in the example) and can pass one or two callback function references. If you pass one reference, this is the callback function that is used when the call returns a success result. If you pass two references, the second one is the callback function that is used for web method failure.

In `PCSLibraryDemo`, a single callback function is used, which takes the result of the web method call and assigns it to the `<span>` with the `id` of `webMethodResult`:

```
function callWebMethod()
{
  SimpleService.Multiply(parseFloat($get('xParam').value),
    parseFloat($get('yParam').value), multiplyCallBack);
}

function multiplyCallBack(result)
{
  $get('webMethodResult').innerHTML = result;
}
```

This method is a very simple one but illustrates the ease with which you can call Web services asynchronously from client-side code.

ASP.NET Application Services

ASP.NET AJAX includes three specialized Web services that you can use to access ASP.NET application services. These services are accessed through the following client-side classes:

- `Sys.Services.AuthenticationService` — This service includes methods to log in or log out a user or determine whether a user is logged in.
- `Sys.Services.ProfileService` — This service enables you to get and set profile properties for the currently logged-on user. The profile properties are configured in the `web.config` file for the application.
- `Sys.Services.RoleService` — This service enables you to determine role membership for the currently logged-on user.

Used properly, these classes enable you to implement extremely responsive user interfaces that include authorization, profile, and membership functionality.

These services are beyond the scope of this chapter, but you should be aware of them — plus they are well worth investigating.

SUMMARY

In this chapter you looked at several advanced techniques for creating ASP.NET pages and web sites, and you saw these techniques in action in a demonstration web site called PCSDemoSite. You also learned how you can use ASP.NET AJAX to enhance ASP.NET web sites. ASP.NET AJAX contains a wealth of functionality that makes web sites far more responsive and dynamic and can provide a much better user experience.

First, you learned how to create reusable ASP.NET server controls by using C#. You saw how to create simple user controls from existing ASP.NET pages, as well as how to create custom controls from scratch. You also saw how the meeting room booker sample from the previous chapter can be reformatted as a user control.

You then looked at master pages, and how to provide a template for the pages of your web site, which is another way to reuse code and simplify development. In PCSDemoSite, in the downloadable code for this chapter, you saw a master page that included navigation web server controls to enable users to move around the site. The PCSDemoSite sample also laid the framework for themes, which are an excellent way to separate functionality from design and can be a powerful accessibility technique.

You also took a brief look at security and how you can implement forms-based authentication on your web sites with minimal effort.

Next, you investigated Web Parts and how to use the Web Parts server controls to put together a basic application that illustrated some of the possibilities that this technology offers.

In the last part of this chapter, you learned about ASP.NET AJAX. You saw what Ajax is, and how to use Microsoft's implementation of Ajax, ASP.NET AJAX. This included both the server-side techniques for creating ASP.NET AJAX-enabled web sites and applications, and client-side techniques implemented by using the AJAX Library.

We hope that this chapter has given you an appetite for creating web sites with ASP.NET, and in particular for using the exciting new capabilities that ASP.NET AJAX offers. Ajax has blossomed across the Web, and ASP.NET AJAX is an excellent way to integrate Ajax functionality with ASP.NET applications. This product is also very well supported, and the community-based releases, such as the AJAX Control Toolkit, provide you with even more great functionality that you are free to use in your applications.

Even though you may find yourself having to learn the JavaScript language you never thought you would need, the end result is well worth the effort. By using ASP.NET AJAX you will make far better, more functional, and more dynamic web sites than you could with ASP.NET alone. And with the latest release of Visual Studio you have tools that make ASP.NET AJAX much easier to use. The most recent version of ASP.NET AJAX includes much more functionality than there was space to cover in this chapter, such as client-side templates and live data binding. It is well worth researching these advances (and more) by keeping an eye on developer blogs and the `http://www.asp.net` web site.

In the next chapter you will look at some of the latest techniques for structuring ASP.NET web sites and applications — dynamic data sites and the MVC framework — as well as an enabling technology, ASP.NET routing.

42 ASP.NET Dynamic Data and MVC

WHAT'S IN THIS CHAPTER?

- ➤ Using routing to implement URLs
- ➤ Building web sites with dynamic data
- ➤ Building web applications with ASP.NET MVC

In the previous two chapters, you have learned about how to use ASP.NET to create web sites, and how to add advanced functionality to streamline those web sites. In this chapter, you will look at frameworks that you can use to both accelerate the creation of web sites and include best-practice techniques to make the best sites possible.

There are currently two of these frameworks that ship with ASP.NET as part of .NET 4, both of which have grown from years of research by Microsoft and the ASP.NET development community. These are:

- ➤ Dynamic data
- ➤ ASP.NET MVC (Model-View-Controller)

The first of these, dynamic data, enables you to build a web site from preexisting data that you have in a database. The wizards that VS supplies make it possible to generate dynamic data web sites very quickly, which you can then go on to customize to get the look and feel you want. Advanced template capabilities are included in dynamic data web sites so that you can get up and running quickly. Dynamic data isn't suitable for all types of web sites, but for many types — including e-commerce sites and data manipulation sites — it provides a perfect starting point for development.

MVC is a framework for creating all sorts of sites that has emerged from a desire for both a cleaner separation of user interface and business logic and the ability to unit test that business logic independently. This aspect is becoming more important as the world moves toward test-driven development (TDD) models. Traditionally, ASP.NET web sites have been hard to test along these lines, as some way of directly interacting with web pages is required. Separating design and functionality makes things much easier.

There are other advantages of MVC, as you will see later in this chapter, and it leads to very clean, easy to understand code that is perfect for enterprise-level web site development and makes unit testing much simpler.

Both dynamic data and MVC make use of another methodology that was introduced in .NET 3.5, routing. This makes it possible for URLs to be simplified and to include additional information, and is the first thing you will look at in this chapter. After routing, this chapter moves on to dynamic data and MVC in turn, with a final section about how to combine these technologies.

Both dynamic data and MVC are large subjects to cover and would require multiple chapters to cover in depth. This chapter gives a general overview of using these frameworks, which will hopefully give you enough information to get started before finding more in-depth resources if you want to use them in more depth.

ROUTING

ASP.NET routing is a technology that enables you to assign sensible, human-readable URLs to web pages. Essentially, this means that the URL for a web page that a user sees in the address bar of a browser doesn't necessarily match the physical location of a web page. Instead, the URL will include information that your web site can use to map to a page that you define, and can pass parameters to that page.

At first glance, this may seem a little counterintuitive. Why wouldn't you want users to see the address of a web page? Surely not exposing this information will make it more difficult to locate resources. In fact, as you will see in this section, mapping URLs can make it much easier for users, and it has several other benefits as well.

As an example, consider the following URL:

```
http://www.myecommercesite.com/products/kites/reddragon
```

Without knowing anything about the web site that uses this URL, you can probably take a good guess at what you'd find on the page. From the words in the URL, you would expect to see a product page for a kite called "Red Dragon."

The advantages of this type of URL are as follows:

- Users can see at a glance what pages are.
- URLs are easy for users to remember, even without creating bookmarks.
- Users can modify URLs manually to navigate (for example, a user might replace the last section of the above URL with `/products/balloons`).
- Search engine results are optimized for these descriptive URLs, so the page ranking will be higher.

There are essentially two ways to implement URLs of this form. You can either create a page for every possible URL, or you can use a framework that maps URLs to pages that can display data for multiple URLs. This first possibility is worth mentioning, as it isn't necessarily out of the question — it is possible to create static HTML sites that are generated from back-end data. However, this requires a fair amount of maintenance and, in most situations, can be more trouble than it's worth. Now that the tools have matured the second scenario is more practical.

In fact, ASP.NET has included the capability to use URLs like this for some time, although "URLrewriting" (as it was known in earlier versions of ASP.NET) required an in-depth knowledge of the ASP .NET architecture and could be quite tricky to implement. With the advent of ASP.NET routing, things have become much easier.

In this section, you will look at the following:

- **Query string parameters** — Before looking at routing specifically, it is worth understanding the case for including additional data in URLs in more detail. Query string parameters provide an alternative way of doing this, and have existed since the very beginnings of the web. However, while simpler than routing, they do not include all of the advantages.

- **Defining routes** — ASP.NET routing requires you to define the routes that are available in your web site so that they can be used.
- **Using route parameters** — Once a route has been detected in a URL, the target page can make use of routing parameters.

The downloadable code for this chapter includes a simple solution called `PCSRoutingDemo` that will be referred to from this section to illustrate the techniques.

Query String Parameters

While surfing the web, you've probably noticed that a lot of web pages include information in their URLs in addition to their location. For example, in an e-commerce web site, you might see a URL that looks a little like the following:

```
http://www.myecommercesite.com/products.aspx?id=4
```

In this URL the target page is `products.aspx`, but after the identifier for this page, you can see additional information in the form of a query string. The `?` character indicates the start of the query string, and the remainder of the URL consists of a name/value pair, with an equals character (`=`) separating the name (`id`) from the value (`4`). In fact, URLs can contain several query string name/value pairs, separated by `&` symbols.

When users navigate to an ASP.NET page with a query string (perhaps by clicking on a link that you have rendered from database data), you can write code to render the page accordingly. In this example, you might use the value of the `id` query string parameter to extract data from a database, for a product with the corresponding ID. This means that you don't have to create a page for every product in your database; you can, instead, create a single page that can show the details for any product.

In practice, ASP.NET pages receive query string information in the form of a `NameValueCollection` object. This is passed in the `QueryString` property of the `HttpRequest` object that is available in code-behind through the inherited `Request` property. The query string collection is indexed by name and index, so to get the value of the `id` query string parameter shown above, you could use either of the following lines of code:

```
string idValue = Request.QueryString[0];
```

or:

```
string idValue = Request.QueryString["id"];
```

Note that all query string values are passed as strings, so to get an integer value for `id` you'd need to parse the value.

The use of query string parameters is illustrated in the PCSRoutingDemo web site for this chapter. If you view the web site in a browser and click the "Navigation with query string" link, you will see the query string parameters displayed, as shown in Figure 42-1.

The code that displays these values is in the code-behind for the master page and is as follows:

```
if (Request.QueryString.Count == 0)
{
    this.NoQuerystringLabel.Text = "None.";
}
else
{
    GridView1.DataSource = from string key in Request.QueryString.Keys
                           select
                               new
                               {
                                   Name = key,
                                   Value = Request.QueryString[key]
                               };
    GridView1.DataBind();
}
```

code snippet PCSRoutingDemo/MasterPage.master.cs

Here, the collection of query string parameters is transformed into a collection of objects with `Name` and `Value` properties that can be data bound to a `GridView` control and displayed.

This method of passing data with query string parameters is well established and extremely useful, but ASP .NET routing achieves the same results in a much neater way, with all of the advantages.

Defining Routes

In order to use ASP.NET routing, you need to configure the routes that are available in your web site. Once you have done this, typically in the `HttpApplication.Application_Start` event handler, users will be able to use those routes and your web site can make use of the parameters passed.

A route definition consists of the following:

- ➤ A name for the route (which can be omitted)
- ➤ A URL pattern for the route, including parameter specifications where required
- ➤ A handler for the route, which determines which target URL the route is mapped to
- ➤ An optional collection of default values to use for route parameters if they are not included in the URL
- ➤ An optional collection of constraints for parameters, which are used to determine if a route is valid

As you might expect, ASP.NET includes classes that make it easy to specify all of this.

An ASP.NET web site maintains a collection of route specifications that are checked when a URL is requested to see if there is a match. This collection is accessible in your code through the static `RouteTable.Routes` property. This property is a collection of routes defined by an optional name and an object that derives from the abstract `RouteBase` class. Unless you want to create your own class to represent a route, you can add instances of the `Route` class to this collection.

The `Route` class has a number of constructors that you can use to define a route, the simplest of which includes a path and a route handler. The path is specified as a string, with parameters included and delimited with curly braces. The route handler is an object that implements the `IRouteHandler` interface, such as the system-defined `PageRouteHandler` class. When instantiating `PageRouteHandler` you specify a target page path, and, optionally, whether to check the physical path for authorization with the ASP.NET security model (more on this later). The simplest way to add a route is, therefore, as follows:

```
RouteTable.Routes.Add("RouteName",
                      new Route("path/{pathparameter}",
                                new PageRouteHandler("target.aspx")));
```

Here, a route called `RouteName` is added to the route definitions. This route matches URLs of the form:

```
http://<domain>/path/{pathparameter}
```

Any matching URLs will be mapped to the `target.aspx` file.

For example, if a user requested the following URL:

```
http://<domain>/path/oranges
```

The web site would detect this as a matching URL for the `RouteName` route, and the user would be redirected to the `target.aspx` page. If the code for this page requested the value of the `pathparameter` parameter, it would receive the value `oranges`.

In the sample PCSRoutingDemo web site for this chapter, you can see a route in action by clicking the "Navigation with routing" link, which results in the display shown in Figure 42-2.

FIGURE 42-2

This route is defined in `Global.cs` in `App_Code` (the code-behind file used for `Global.asax`) as follows:

```
RouteTable.Routes.Add("TestRoute",
                      new Route("Target/{targetparameter}",
                                new PageRouteHandler("~/Target.aspx")));
```

code snippet PCSRoutingDemo/App_Code/Global.cs

You'll see how the parameter is rendered on the page shortly.

Route Authorization

Since there are effectively two URLs taking part in routing — the one requested by the user and the one that is used for the physical file location that generates the page — ASP.NET authorization can take place in two places. The default behavior is to check both of these URLs to determine whether the user has access to the page. You can override this in the constructor for `PageRouteHandler` with a second parameter as follows:

```
RouteTable.Routes.Add("RouteName",
                      new Route("path/{pathparameter}",
                                new PageRouteHandler("~/target.aspx", false)));
```

If you do this, then only the requested URL will be checked for authorization, not the physical URL. By doing this, you can place the physical URL in a location that is not directly accessible to the user, which can be useful if you want to prevent direct navigation to that URL.

Default Parameter Values

The default behavior for routes is that all parameters must be specified in order to match the requested URL to a route path. In the preceding example, this means that the following URL is invalid:

```
http://<domain>/path
```

However, you can if you wish specify default values for route parameters, in which case this URL would be valid and the default value for `pathparameter` would be used.

To do this, you supply a `RouteValueDictionary` collection, which is a collection of name/value pairs of route parameters and default values. You can pass this collection to the `Route` constructor; for example:

```
RouteTable.Routes.Add("RouteName",
                      new Route("path/{pathparameter}",
                                new RouteValueDictionary
                                {
                                   { "pathparameter", "defaultValue" }
                                },
                                new PageRouteHandler("~/target.aspx")));
```

In this code a default value of `defaultvalue` is specified for the `pathparameter` parameter, which will be used if no value is matched in the URL.

Parameter Constraints

Route parameters will accept any value from the user by default, but sometimes you might want to restrict the allowed values. Then, if the user passes a value that isn't allowed, the path will not match.

Parameter constraints are also defined with a `RouteValueDictionary` collection, in this case containing a collection of name/value pairs of route parameters and constraints. A constraint can either be a regular expression or an object that implements the `IRouteConstraint` interface. As with defaults, constraints can be specified in the `Route` constructor, for example:

```
RouteTable.Routes.Add("RouteName",
                      new Route("path/{pathparameter}",
                                new RouteValueDictionary
                                {
                                   { "pathparameter", "yes" }
                                },
                                new RouteValueDictionary
                                {
                                   { "pathparameter", "yes|no" }
                                },
                                new PageRouteHandler("~/target.aspx")));
```

Here, only the values `yes` and `no` are valid values for `pathparameter`. If a different value is specified the route won't be matched.

Route Order and Data Tokens

When you define routes, the order in which you add them to the `RouteTable.Routes` collection is important. This is because ASP.NET will attempt to match URLs to routes in the order that they appear in the collection. If no match is found after looking at all the routes, then the URL is used directly. If a single match is found, then that route is used. If more than one route matches the URL, then the first one is used.

This can be used to good effect in combination with constraints. For example, you could add two routes, the first being the constrained route shown in the previous section, and the second as follows:

```
RouteTable.Routes.Add("RouteName",
                      new Route("path/{pathparameter}",
                                new PageRouteHandler("~/alternatetarget.aspx")));
```

This would mean that a URL containing a `pathparameter` value of `yes` or `no` would map to `target.aspx` as before, but if any other parameter value was passed, then the URL would map instead to `alternatetarget.aspx`, rather than returning a 404 not found error.

However, if these two routes were added in reverse order, then all values of `pathparameter` would result in a call to `alternatetarget.aspx`, as this route would always provide a match before the constrained route was checked.

If you have two routes that map to the same URL, you may want to determine which route was matched. To do so, you can include additional data that is passed to the page as a data token. Data tokens are supplied with another `RouteValueDictionary` collection, containing a collection of name/value pairs of route parameters and data tokens. For example:

```
RouteTable.Routes.Add("RouteName",
                      new Route("path/{pathparameter}",
                                new RouteValueDictionary
                                {
                                   { "pathparameter", "yes" }
                                },
                                new RouteValueDictionary
                                {
                                   { "pathparameter", "yes|no" }
                                },
                                new RouteValueDictionary
                                {
                                   { "customdatatoken", "yesnomatch" }
                                },
                                new PageRouteHandler("~/target.aspx")));
```

If this route is matched a data token called `customdatatoken` with a string value of `yesnomatch` is passed to the target URL, so that pages can identify that this route was used.

You can pass whatever data you like as a data token for a parameter, so this is only one example of how you might use it.

Using Route Parameters

Reading and using parameter values that are passed to pages through ASP.NET routing is very similar to doing the same for query string parameters. Instead of using `Request.QueryString`, you use `Page.RouteData`, which is populated by ASP.NET when your page is loaded. This contains all of the information you need to extract route parameters or data tokens.

Parameter values are also available for use in ASP.NET markup, through expression builders and data query parameter values.

RouteData Values

The route parameters are available in code through the `Page.RouteData.Values` property, which is another instance of the `RouteValueDictionary` class. Similarly, data tokens are available through `Page.RouteData.DataTokens`. In the example web site, values are extracted from the `Values` property and displayed through a `DataGrid` with the following code:

```
if (Page.RouteData.Values.Count == 0)
{
    this.NoRoutingLabel.Text = "None.";
}
else
{
    GridView2.DataSource = from entry in Page.RouteData.Values
                           select
                               new
                               {
                                   Name = entry.Key,
                                   Value = entry.Value
                               };
    GridView2.DataBind();
}
```

code snippet PCSRoutingDemo/MasterPage.master.cs

Alternatively, you can extract parameters by name as they are indexed in the collection; for example:

```
string parameterValue = Page.RouteData.Values["pathparameter"] as string;
```

Expression Builders

There are two expression builders that you can use in ASP.NET markup files to extract and use route parameter values: `RouteValue` and `RouteUrl`.

`RouteValue` can be used inline to output the value of a parameter, as follows:

```
<%$ RouteValue:parameterName %>
```

For example, in the PCSRoutingDemo web site, the `Target.aspx` file includes the following line of markup code:

```
targetparameter = <asp:Label runat="server"
                             Text="<%$ RouteValue:targetparameter %>" />
```

code snippet PCSRoutingDemo/Target.aspx

This sets the `Text` property of a `Label` control to the value of the `targetparameter` parameter.

`RouteUrl` is used to construct URLs to match a route. This is a great feature when you are putting links in your ASP.NET code, as a URL created in this way will change if the route definition ever changes. To use this expression builder, you use markup inline as follows:

```
<%$ RouteUrl:parameterName=parameterValue %>
```

You can include more than one parameter by separating name/value pairs with commas. The expression builder will attempt to match the parameters you specify to a route by the names of the parameters you use. In some cases, you might have more than one route that uses the same parameters, in which case you can identify the specific route to use by name as follows:

```
<%$ RouteUrl:parameterName=parameterValue,routename=routeName %>
```

In PCSRoutingDemo, there are two separate links in the master page, one of which uses this expression builder:

```
<asp:HyperLink ID="HyperLink3" runat="server" NavigateUrl="~/Target/Trevor"
  >Navigation with routing</asp:HyperLink>

<asp:HyperLink ID="HyperLink4" runat="server"
  NavigateUrl="<%$ RouteUrl:targetparameter=Reginald,routename=TestRoute %>"
  >Navigation with routing and expression builder</asp:HyperLink>
```

code snippet PCSRoutingDemo/MasterPage.master

The second version of this link shows the best way to include links in your markup, as it allows you to change the route specification later, as noted above.

Data Query Parameters

Another way to use route parameters in your code is to supply them directly to data queries. This technique enables you to fetch data from a database directly from markup code, rather than having to extract parameter values and use them in the code-behind.

To do this, you use an `<asp:routeparameter>` in the parameters for a query. For example, you could use the following in an `<asp:sqldatasource>` data source:

```
<asp:sqldatasource id="SqlDataSource1" runat="server"
    connectionstring="<%$ ConnectionStrings:ProductDatabase %>"
    selectcommand="SELECT ProductName,ProductId,ProductDescription FROM Products
                   WHERE ProductName = @productname"
  <selectparameters>
    <asp:routeparameter name="productname" RouteKey="productnameparameter" />
  </selectparameters>
</asp:sqldatasource>
```

This code extracts the value from a route parameter called `productnameparameter` and passes this value to the `@productname` parameter in a SQL query.

DYNAMIC DATA

If you think about data-driven web sites (which these days includes most web sites), you will probably realize that a lot of their functionality is very similar. Such a web site is likely to include one or more of the following concepts:

- Render HTML that is shaped dynamically based on data in an underlying data source (such as a database table or individual database row)
- Include pages in a site map that map directly or indirectly to entries in a data source (such as a database table)
- Have a structure that relates directly or indirectly to the structure of the underlying data source (a section of the site may map to a database table, such as About or Products, for example)
- Allow modification to the underlying data source that will be reflected on pages

If you wanted to build a data-driven site, you would probably use fairly standardized code to achieve the above. You might bind ASP.NET elements such as tables of data directly to a database table, or you might include an intermediate layer of data objects to represent data in the database and bind to those. You have seen a lot of the code you would use for that in earlier chapters.

However, because this situation is so common, there is an alternative. You could instead use a framework that provides a lot of the code for you to save yourself a lot of tedious coding. ASP.NET dynamic data is just such a framework, and it makes creating a data-driven web site much easier. As well as giving you the code outlined above (referred to in dynamic data web sites as *scaffolding*), dynamic data web sites provide a lot of additional functionality, as you will see shortly.

In this section, you will see how to create a dynamic data site and look at some of the features that it offers.

Creating Dynamic Data Web Sites

The best way to get a taste of what dynamic data web sites have to offer is to build one in Visual Studio, which is a surprisingly simple thing to do. In order to create a dynamic data web site you need to have some source data. You can use whatever data you like, but if you want you can use the sample data that is included in the downloadable code for this chapter. This data is a SQL Server Express database with the filename `MagicShop.mdf`. Figure 42-3 shows the tables that are included in this database.

The `MagicShop.mdf` database represents a simple structure that you could use in an e-commerce web site. The types of and relationships between data will serve to illustrate how dynamic data sites work.

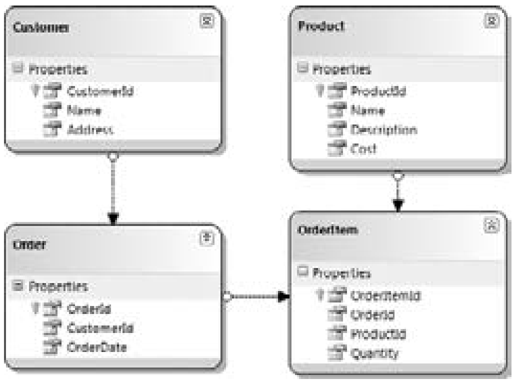

FIGURE 42-3

Choosing a Data Access Model

When you create a dynamic data site through the File ➪ New ➪ Web Site… menu item, you will notice that there are two templates available:

- Dynamic Data Linq to SQL Web Site
- Dynamic Data Entities Web Site

These two templates are identical, apart from the way your data will be accessed: through LINQ to SQL or the ADO.NET Entity Framework, respectively. Which of these templates you choose depends entirely on personal preference. The core functionality of a dynamic data web site is the same for both templates.

The downloadable code for this chapter includes two web sites, PCSDynamicDataDemoLinq and PCSDynamic DataDemoEntities, that contain uncustomized versions of sites that use the `MagicShop.mdf` database.

Adding a Data Source

Once you have created a site using either of the templates that are available, the next thing to do is to add a data source. This means adding a new item to your project, using either the LINQ to SQL classes or ADO.NET Entity Model template (either of which should be added to the `App_Code` directory of a web site as a best practice). Before you do that, you may also want to add a local copy of your database to the `App_Data` directory of your web site, unless you are using a remote data source.

If you are using the `MagicShop.mdf` database as a test, then depending on the site template you are using, you can do the following (after adding the database to the `App_Data` directory):

- For LINQ to SQL, add LINQ to SQL classes with the filename `MagicShop.dbml`, and then once the file is added, add all tables from the `MagicShop.mdf` database to the designer.
- For ADO.NET Entities, add an entity model called `MagicShop.edmx`, and in the Add New Item Wizard, use the default settings and add entities for all tables in the database.

Configuring Scaffolding

There is one more step to perform before the initial build of your dynamic data web site is complete. You must configure your data model for scaffolding in the `Global.asax` file for the web site. Apart from differences in explanatory comments, this file is identical in both site template types. If you inspect the file, you will see that scaffolding for the web site is configured through a model, which is defined at the application level as follows:

```
private static MetaModel s_defaultModel = new MetaModel();
public static MetaModel DefaultModel
{
    get
    {
        return s_defaultModel;
    }
}
```

The `Global.asax` file accesses this model in the `RegisterRoutes()` method, called in the `Application_Start()` handler. This method also configures dynamic data routing in the web site, which you'll look at later in this chapter. The method contains the following commented-out line of code (split over two lines here for clarity):

```
    //DefaultModel.RegisterContext(typeof(YourDataContextType),
    //   new ContextConfiguration() { ScaffoldAllTables = false });
```

Configuring the model simply requires you to uncomment this code and supply the appropriate data context type for your data model. You can also change the `ScaffoldAllTables` property to `true` initially to instruct the model to provide scaffolding for all available tables. Later, you may want to revert this change, as you will probably want a finer degree of control over exactly what scaffolding is created (including what data is visible in the site, what is editable, and so on), as you will see later in this chapter.

The following code is required for a LINQ to SQL site accessing the MagicShop.mdf database with the LINQ to SQL classes as described in the previous section:

```
    DefaultModel.RegisterContext(typeof(MagicShopDataContext),
        new ContextConfiguration() { ScaffoldAllTables = true });
```

code snippet PCSDynamicDataDemoLinq/Global.asax

For the ADO.NET Entities version of this site, the code is as follows:

```
DefaultModel.RegisterContext(typeof(MagicShopModel.MagicShopEntities),
    new ContextConfiguration() { ScaffoldAllTables = true });
```

code snippet PCSDynamicDataDemoEntities/Global.asax

Exploring the Result

At this point, everything is in place to test the default dynamic data web sites. The end result is identical regardless of which template you use. If you look at `Default.aspx` in a browser, the display appears as shown in Figure 42-4.

FIGURE 42-4

This page shows a list of links to each of the tables in the database along with some additional information, defined in the `Default.aspx` page as follows:

```
<%@ Page Language="C#" MasterPageFile="~/Site.master" CodeFile="Default.aspx.cs"
         Inherits="_Default" %>

<asp:Content ID="headContent" ContentPlaceHolderID="head" Runat="Server">
</asp:Content>

<asp:Content ID="Content1" ContentPlaceHolderID="ContentPlaceHolder1"
  Runat="Server">
  <asp:ScriptManagerProxy ID="ScriptManagerProxy1" runat="server" />

  <h2 class="DDSubHeader">My tables</h2>

  <br /><br />

  <asp:GridView ID="Menu1" runat="server" AutoGenerateColumns="false"
    CssClass="DDGridView" RowStyle-CssClass="td" HeaderStyle-CssClass="th"
    CellPadding="6">
    <Columns>
      <asp:TemplateField HeaderText="Table Name" SortExpression="TableName">
        <ItemTemplate>
          <asp:DynamicHyperLink ID="HyperLink1" runat="server"><%#
            Eval("DisplayName") %></asp:DynamicHyperLink>
            </ItemTemplate>
          </asp:TemplateField>
        </Columns>
      </asp:GridView>
    </asp:Content>
```

code snippet PCSDynamicDataDemoEntities/Default.aspx and PCSDynamicDataDemoLinq/Default.aspx

A lot of the display code is contained in the master page and the CSS file for the web site, which won't be listed here to save space. The important section of the preceding code is the `GridView` control, which contains a `DynamicHyperLink` control that renders the link to a table. Data is bound to the `GridView` control from code-behind as follows (reformatted slightly for clarity):

```
protected void Page_Load(object sender, EventArgs e)
{
    System.Collections.IList visibleTables =
        ASP.global_asax.DefaultModel.VisibleTables;
    if (visibleTables.Count == 0)
    {
        throw new InvalidOperationException(
            "There are no accessible tables. Make sure that at least one data"
            + " model is registered in Global.asax and scaffolding is enabled"
            + " or implement custom pages.");
    }
    Menu1.DataSource = visibleTables;
    Menu1.DataBind();
}
```

code snippets PCSDynamicDataDemoEntities/Default.aspx.cs and PCSDynamicDataDemoLinq/Default.aspx.cs

This extracts the list of visible tables from the model (in this case, all the tables, because scaffolding is provided for all of them as discussed earlier), each of which is described by a `MetaTable` object. The `DynamicHyperLink` controls intelligently render links to pages for the tables based on properties of these objects. For example, the link for the Customers table is as follows:

```
/PCSDynamicDataDemoLinq/Customers/List.aspx
```

Obviously, the web site has no such page defined; instead, routing is used as described in the first part of this chapter to generate content for this link. If you click on the link, you'll see a listing page for the Customers table, as shown in Figure 42-5.

FIGURE 42-6

The template system used by a dynamic data web site enables you to customize what is shown for each column in a table according to what data type it is. Or you can make further customizations that are unique to columns that you specify; you really do have a lot of flexibility here.

> *The ID values used in the* `MagicShop.mdf` *database are stored as integer values. It is also common for databases to use GUID ID values (using the* `uniqueidentifier` *SQL type). These are currently not handled perfectly by dynamic data web sites and, although workarounds are possible, there is currently no ideal solution.*

What you have seen in this section is that, even with the default settings, dynamic data can get you up and running very quickly. Now, you may think that this ease of use comes at a cost, namely flexibility. In fact, this is not the case. Using some very simple techniques, you can completely customize how dynamic data web sites work, as you will see in the next section.

Customizing Dynamic Data Web Sites

There are a number of ways in which you can customize dynamic data web sites to get exactly the effect you want. These range from simply modifying the HTML and CSS for the templates to customizing the way in which data is rendered though code and attribute modifications. In this section, you'll look at a few of these, starting with how to customize scaffolding — which, among other things, can affect the visibility of primary key values as noted in the previous section.

Controlling Scaffolding

In the sample dynamic data web sites you have seen so far in this chapter, scaffolding was configured automatically for all tables (and all columns of those tables). This was achieved by setting the

ScaffoldAllTables property of the ContextConfiguration for the sites to true, as illustrated in this code for the LINQ to SQL site:

```
DefaultModel.RegisterContext(typeof(MagicShopDataContext),
    new ContextConfiguration() { ScaffoldAllTables = true });
```

code snippet PCSDynamicDataDemoLinq/Global.asax

If the value is changed to false, then the default behavior is not to provide any scaffolding for any tables or columns. In order to instruct the dynamic data framework to scaffold a table of column, you must provide metadata in your data model. This metadata will then be read by the dynamic data runtime, and scaffolding will be generated for you. Metadata can also provide information for other things — such as validation logic — as you will see shortly.

To supply metadata for a table, you must do two things:

- Create a metadata class definition for each table you want to supply metadata for, with members that map to columns.
- Associate the metadata classes with the data model table classes.

All data model items, in both LINQ to SQL and ADO.NET Entities, are generated for you as partial class definitions. In the sample code, for example, there is a class called Customer (contained in the MagicShopModel namespace in the ADO.NET Entities version) that is used for rows in the Customer table. To supply metadata for Customer rows, you might create a class called CustomerMetadata. Once you have done that, you can supply a second partial class definition for Customer and use the MetadataType attribute to link the classes together.

In the .NET Framework, metadata is supported through *data annotations*. As such it should come as no surprise that the MetadataType attribute, along with other metadata attributes, is found in the System.ComponentModel.DataAnnotations namespace. The MetadataType attribute uses a Type parameter to specify the metadata type. The two attributes that control scaffolding are ScaffoldTable and ScaffoldColumn. Both of these attributes have a Boolean parameter to specify whether scaffolding will be generated for a table or column.

The following code shows an example of how this is achieved:

```
using System.ComponentModel.DataAnnotations;

...

[MetadataType(typeof(CustomerMetadata))]
public partial class Customer { }
```

code snippets PCSDynamicDataDemoEntities/App_Code/Customer.cs and PCSDynamicDataDemoLinq/App_Code/Customer.cs

```
using System.ComponentModel.DataAnnotations;

...

[ScaffoldTable(true)]
public class CustomerMetadata
{
    [ScaffoldColumn(false)]
    public object Address { get; set; }
}
```

code snippets PCSDynamicDataDemoEntities/App_Code/CustomerMetadata.cs and PCSDynamicDataDemoLinq/App_Code/CustomerMetadata.cs

Here, the ScaffoldTable attribute specifies that scaffolding will be generated for the Customer table, and the ScaffoldColumn attribute is used to ensure that the Address column will have no scaffolding. Note that columns are represented by `object` type properties, regardless of the type. You just have to ensure that the name of the property matches the name of the column.

The code shown here can be used with the example web sites introduced in the previous section to hide the addresses of customers.

Customizing Templates

As mentioned earlier in the chapter, dynamic data is generated through a system of templates. There are page templates that are used for laying out controls within different types of list and details pages, and field templates for displaying different data types in display, edit, and foreign key selection modes.

All of these templates are located in the DynamicData subfolder of a dynamic data web site, which has the nested subfolders described in the following table.

Dynamic Data Template Directories

DIRECTORY	DESCRIPTION
Content	This folder contains images that are used in other templates as well as the template for pagination (which is applied automatically when lists of data are long).
CustomPages	Use this directory if you want to supply custom pages.
EntityTemplates	This directory contains user control templates that are used for displaying a single row of data on a page, in either view, edit, or insert mode.
FieldTemplates	This directory contains user control templates that are used to display individual column data.
Filters	This directory contains user control templates that are used to display filters for foreign key relationships. In the default code, these are drop-down lists. For example, the list page for Orders includes a filter to display only those orders that are associated with a particular user.
PageTemplates	This directory contains the main templates that are used to display single or multiple rows of data in various modes of operation. The body of these pages uses the user control templates from the other directories to build its content.

It is worth digging into these templates and their code-behind to see how everything fits together. For example, text columns are displayed using two field templates in the FieldTemplates directory. The first of these, `Text.ascx`, is as follows:

```
<asp:Literal runat="server" ID="Literal1" Text="<%# FieldValueString %>" />
```

This code is fairly self-explanatory — it simply outputs the text value of a column in a `Literal` control. If, though, the column is in an editable mode, `Text_Edit.ascx` is used instead:

```
<asp:TextBox ID="TextBox1" runat="server" Text='<%# FieldValueEditString %>'
  CssClass="DDTextBox"></asp:TextBox>

<asp:RequiredFieldValidator runat="server" ID="RequiredFieldValidator1"
  CssClass="DDControl" ControlToValidate="TextBox1" Display="Dynamic"
  Enabled="false" />
<asp:RegularExpressionValidator runat="server" ID="RegularExpressionValidator1"
  CssClass="DDControl" ControlToValidate="TextBox1" Display="Dynamic"
  Enabled="false" />
<asp:DynamicValidator runat="server" ID="DynamicValidator1" CssClass="DDControl"
  ControlToValidate="TextBox1" Display="Dynamic" />
```

A `TextBox` control is used here to render the control so that it is editable, and a combination of the three validation controls is used to provide validation functionality if required. Exactly how these validation controls work is determined by the data model and its associated metadata. Non-nullable columns, for example, will result in the `RequiredFieldValidator` being active. The `DynamicValidator` control is used in conjunction with metadata attributes, for example, `StringLength`, which you can use to set the maximum permitted length of a string.

Configuring Routing

One of the most important concepts to grasp when dealing with dynamic data sites is that pages are generated according to *actions*. An action is a way of defining what a page should do in response to, for example, the user clicking on a particular link. There are four page actions that are defined for you by default: List, Details, Edit, and Insert.

Each of the page templates defined for a dynamic data site (which are also known as *views*) can function differently according to what action is currently being performed. The routing configuration for the web site associates actions with views, and each route can optionally be constrained by the tables that it should apply to. For example, you might create a new view that is intended for listing customers. That view might function differently from the default `List.aspx` view. To create the new view, you must configure routing so that the correct view will be used.

The default routing for a dynamic data web site is configured in `Global.asax` as follows:

```
routes.Add(new DynamicDataRoute("{table}/{action}.aspx")
{
    Constraints = new RouteValueDictionary(
        new { action = "List|Details|Edit|Insert" }),
    Model = DefaultModel
});
```

code snippet PCSDynamicDataDemoEntities/Global.asax and PCSDynamicDataDemoLinq/Global.asax

This uses the routing framework described earlier in the chapter, although here routes use the `DynamicDataRoute` type. This class derives from `Route` and provides specialized functionality for dealing with actions, views, and tables.

You will notice in this code that this route includes the name of a table and the name of an action — where the value of the action is constrained to the four predefined page action types. To take the example of using a different view for listing customers, you might add the following route (before the existing one, or that one would take precedence):

```
routes.Add(new DynamicDataRoute("Customers/List.aspx")
{
    Table = "Customers",
    Action = PageAction.List,
    ViewName = "ListCustomers",
    Model = DefaultModel
});
```

This route associates the `/Customers/List.aspx` URL with the view `ListCustomers.aspx`, and so for this code to work, you must supply a file of this name in the PageTemplates directory. You can also see that the `Table` and `Action` properties are specified here, as they are not available in the URL any more. The way the dynamic data routing works is that `{table}` and `{action}` routing parameters are used to populate the `Table` and `Action` properties, and in this URL these parameters are not present.

You can build up as complex a system of routing as you wish in this manner, providing specialized pages for tables and actions as you see fit. You can also make use of the `ListDetails.aspx` view, which is a master-detail view of data that enables row selection and inline editing. To use this view, you can supply alternative routes, or simply uncomment the following routes that the dynamic data site template provides:

```
//routes.Add(new DynamicDataRoute("{table}/ListDetails.aspx")
//{
//    Action = PageAction.List,
//    ViewName = "ListDetails",
//    Model = DefaultModel
//});
```

```
            //routes.Add(new DynamicDataRoute("{table}/ListDetails.aspx")
            //{
            //    Action = PageAction.Details,
            //    ViewName = "ListDetails",
            //    Model = DefaultModel
            //});
```

These routes will cause the `ListDetails.aspx` view to be used whenever the List or Details page actions are used. The Edit and Insert page actions are then not required, since (as mentioned earlier) editing capabilities are provided inline. An example of this is shown in Figure 42-7.

Further Development

This section has really only scratched the surface of what is possible with dynamic data. By combining custom code with the framework provided, you will find that the possibilities are vast. Having the framework in place can drastically reduce the work you have to do to access data, while leaving you free to concentrate on the rest of your web site. There are many resources available that dig much deeper into what is possible, but hopefully this section has given you enough information to make a start and explained what the benefits and possibilities are.

MVC

As web site development continues to evolve, new and exciting ways to do things continually appear. One of the most recent (and most exciting) developments is the Model-View-Controller architectural pattern for web sites. This is not a new pattern — in fact the concept is at least 30 years old. However, it hasn't been used in web sites for very long, and (more importantly in the context of this chapter) has only been integrated with the .NET Framework with .NET 4. The version included in .NET 4 is ASP.NET MVC 2, a name that alludes to the fact that ASP.NET MVC has been around for a little while, although it was a separate download before .NET 4.

Before looking at the ASP.NET-specific implementation of MVC, though, it's worth taking a step back to describe what MVC actually means, and why it is useful. In this section you will look at:

➤ What MVC is

➤ What ASP.NET MVC is

➤ How to build and customize ASP.NET MVC-based web sites

What Is MVC?

MVC is a way of programming that involves breaking your code into three distinct parts: models, views, and controllers. This is not a web-specific idea, and can be applied to any system that involves user interaction. The definition of these terms is as follows:

- **Model** — A *model* refers to code that represents the data or state of an application. Note that this doesn't include data storage, which if included is the job of, for example, a database. However, it does encapsulate all manipulation of data, including business logic such as validation rules. It also includes the code necessary to interact with the underlying data store, if one exists.
- **View** — A *view* is the user interface that exposes the model to the user and allows the user to perform operations on the model. There is not necessarily a one-to-one relationship between views and models; a given model may be visualized through multiple views. Any changes to models should be reflected through changes in any associated views.
- **Controller** — *Controllers* are responsible for mediating between models and views. When the user performs an action on a view, the controller responds to the action and, if necessary, forwards the action on to the model by interacting with it directly.

The relationship between these three parts are shown in Figure 42-8.

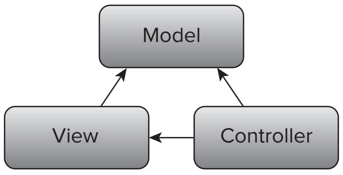

FIGURE 42-8

The controller has access to both the view and the model, as it must mediate between them. The view must render information from and reflect changes in the model, so it also requires access to the model.

There are numerous advantages to programming in this way. First, and most obviously, it provides a clean separation of functionality between distinct units of an application. These may even be developed independently, assuming that well-defined contracts exist between the parts. This means that MVC applications are perfect in situations where a large team of developers works on a project simultaneously.

Another advantage that follows on from this is that unit testing becomes much easier, as each part can be unit tested independently when required. Applications with user interfaces are notoriously difficult to test, as it is often difficult or impossible to design tests that precisely mimic what a user will do, and automation of a user interface can be a major challenge. Since MVC defines exactly what actions a user may perform via controllers, you can be sure that if those controllers are tested adequately you won't run into any surprises. After all, the view can only interact with the controller in the same way as any other client code can interact with the controller, including test code.

The main disadvantage of MVC is that there is an increase in complexity and, potentially, more code to be written. For small-scale applications, this may not be desirable, and it certainly will increase development time. It may also make it more difficult to make use of all the features provided by the overarching technology being used for the application. For example, when this technology is used with ASP.NET, as you will see, event-based user interaction and view state are not usable.

What Is ASP.NET MVC?

ASP.NET MVC applies the principles of MVC to the ASP.NET development environment. This means that ASP.NET pages and controls are used as views, .NET classes are used for controllers, and a data framework such as LINQ to SQL or the ADO.NET Entity Framework is used for the model.

You could, if you wanted, stop reading right now and start writing MVC web sites using ASP.NET. However, what is particularly exciting with .NET 4 is that a full implementation of the MVC pattern is included for you, with plenty of supporting classes that handle a lot of the plumbing (to connect things) and scaffolding (to reduce repetitive or boilerplate code) for you. This is the ASP.NET MVC 2 Framework.

The best way to see what is on offer here is to dive straight in and build an application (or inspect the version in the downloadable code for this chapter).

A Simple ASP.NET MVC Application

In this section, you will build an ASP.NET MVC application using the `MagicShop.mdf` database introduced earlier in this chapter. Along the way, you will walk through the code responsible for models, views, and controllers and see how it all fits together, before adding some additional customizations.

Creating the Application

To get started, create a new project in Visual Studio via the File ➪ New ➪ Project . . . menu item. Select the ASP.NET MVC 2 Web Application template, call the project PCSMVCMagicShop, and save it in the `C:\ProCSharp\Chapter42` directory. You will be prompted as to whether to create a unit test application at the same time, but for now deselect that option (unit testing is beyond the scope of this chapter).

Note that there is no template for ASP.NET MVC if you use the File ➪ New ➪ Web Site ... menu item. ASP.NET MVC applications must be web applications, *not web sites, as they require sites to be fully compiled before deployment in order to work. This is because of the interconnectedness of the modules that make up an ASP.NET MVC application and the way in which views are dynamically generated.*

Inspecting the Application

When the wizard has completed, you will notice that a fair number of directories and files have been created for you. These are described in the following table.

ITEM	DESCRIPTION
Content directory	This directory, like the Content directory for a dynamic data web site, is intended for images and other miscellaneous resources that are used by the application. Initially, it contains the CSS file used by the web application, `Site.css`.
Controllers directory	This directory contains the controller classes used by the site. The template includes two controllers to get you started, `HomeController` and `AccountController`.
Models directory	This directory, initially empty, is where you should put your models. For example, you could add LINQ to SQL classes, ADO.NET Entity Framework classes, or whatever custom classes you see fit here.
Scripts directory	This directory contains any script files, such as JavaScript files, used by the application. You will find a fair amount of JavaScript files here by default, including those required for the Microsoft jquery and AJAX libraries.
Views directory	This directory contains the views for the application, which are ASP.NET Web Forms and user controls. Each controller has its own views subdirectory, so you will see content in Home and Account directories by default. You will also see a Shared directory that includes general purpose views and master pages, including `Site.Master`, which is the default master page for the site. There is also a `Web.config` file in this directory, which is configured to prevent direct access to the view files.
Global.asax	The `Global.asax` file (and its code - behind file) included in the application root sets up routing as described earlier in this chapter. ASP.NET MVC defines extension methods on the `RouteCollection` class to make it easier to add routes in the way it requires.
Web.config	This configuration file references all of the additional resources required by ASP.NET MVC, including the required assemblies. It also configures the HTTP handler that is used to dynamically generate views according to the routing path requested, and (due to the project template) configures forms-based

At this point, you can run the application and see what's there. There's a perfectly functional home page with an About page and a registration/log on system. However, it's easier to learn about how everything works if you work through modifying what is there.

Adding a Model

The order in which you add model, view, and controller code will vary according to what you want to achieve. Typically, though, you will start with a model, particularly if you want to access data in a database. By starting with a model, you then have access to strongly typed model classes from the outset, and the ASP .NET MVC wizards will be able to use the model type information to automatically generate a lot of the scaffolding code you require.

In this example, you will use the `MagicShop.mdf` database introduced earlier in the chapter. Because the sample code is a web application rather than a web site, you cannot simply copy this file to the App_Data directory. Instead, you must add it to the App_Data directory by right-clicking on the directory and selecting the Add ➪ Existing Item . . . menu item, then browsing to the database file and clicking Add. Or, if you prefer, you can build a database in place through Visual Studio, connect to a different database, or select an entirely different data source.

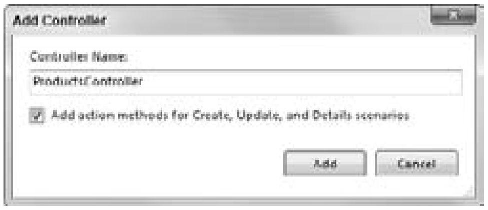
Once you have a data source in place, you can add a model using whatever technique you prefer. This includes using LINQ to SQL classes, an ADO.NET Entity Data Model, or custom classes that you design from scratch. Whichever method you use, you should place the code in the Models folder of the application. For simplicity, add an ADO.NET Entity Data Model with the name `MagicShop` by right-clicking on the Models directory and selecting the Add ➪ New Item . . . menu item. This template is located in the Data templates section. Since a data source exists, most of the default settings in the wizard will already be configured for you, so all you have to do is to select the tables to model (all of them).

After adding your model code, you must build the solution before proceeding in order to make the subsequent wizards aware of your new code.

Adding a Controller

To add a controller for your new model, you use the ASP .NET MVC Add Controller Wizard. You access this wizard by right-clicking on the Controllers folder and selecting the Add New Controller menu item.

Add a controller for the products in the MagicShop database with the name ProductsController, as shown in Figure 42-9, ensuring that the check box is checked as shown.



Add Controller
Controller Name:
ProductsController
Add action methods for Create, Update, and Details scenarios
Add
Cancel

FIGURE 42-9

The controller that is added contains several methods, each of which returns an `ActionResult`. These methods encapsulate operations that users (or other code) can perform, and each is exposed through a URL through routing (see the section "URL Operation Routing" for more details). The methods added by the wizard are shown in the following table.

METHOD	DESCRIPTION
`Index()`	This is the default operation for the controller, which views will use if no other method is specified; for example, when a view is first displayed. For the products controller, you want this to display a list of products.
`Create()`	There are two methods added for creating new items. The first, which takes no parameters, is used when a request to add a new item is triggered, perhaps with an "Add new item" link. The second is responsible for actually adding an item.
`Details()`	This method is responsible for displaying a detail view of a single item.
`Edit()`	The two edit methods are similar to the two create methods. The first takes a single ID value and will trigger editing for a specific, existing item. The second takes an ID and a second parameter that specifies the values to change.

Note that none of the methods that are added for you are implemented. Implementation is your responsibility, and you will see how this is done in subsequent sections.

Adding an Index Operation

The simplest controller method to implement is the `Index()` method. All this method needs to do is to return a view based on a collection of items. This requires a reference to the model in the code, and code to obtain and return the view, as follows:

```
using PCSMVCMagicShop.Models;

namespace PCSMVCMagicShop.Controllers
{
   public class ProductsController : Controller
   {
      private MagicShopEntities entities = new MagicShopEntities();

      public ActionResult Index()
      {
         return View(entities.Products.ToList());
      }

      ...
   }
}
```

code snippet PCSMVCMagicShop/Controllers/ProductsController.cs

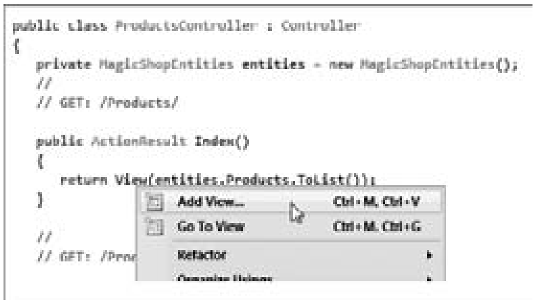
What this code is doing is instructing the ASP.NET MVC framework to construct a view for a collection of `Product` items, or, more specifically, for an `IEnumerable<Product>` instance. In order for this to work, you have to create a suitable view.

Adding a Products View

Luckily, adding a view isn't nearly as tricky as it might sound. In fact, ASP.NET MVC includes a wizard that is capable of creating many simple views for you.

To use this wizard, you right-click on the method that returns the view and select Add View from the context menu, as shown in Figure 42-10.

This brings up the Add View Wizard, which you should customize for the view you want to add. In this case, you can leave the View name with the default value of Index, but you should select a strongly typed view for the data model class type, and change the View content to List, as shown in Figure 42-11.

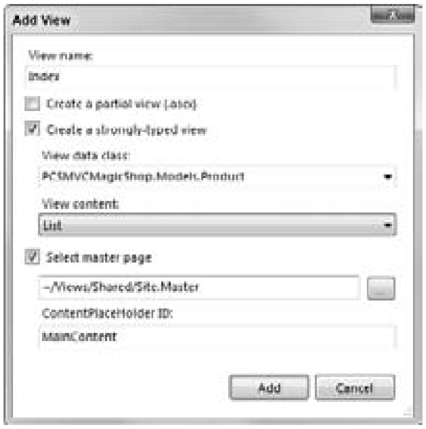


```
public class ProductsController : Controller
{
   private MagicShopEntities entities = new MagicShopEntities();
   //
   // GET: /Products/

   public ActionResult Index()
   {
      return View(entities.Products.ToList());
   }

   //
   // GET: /Prod
```

FIGURE 42-10



Add View

View name:
Index

[ ] Create a partial view (.ascx)

[✓] Create a strongly-typed view

View data class:
PCSMVCMagicShop.Models.Product

View content:
List

[✓] Select master page

~/Views/Shared/Site.Master

ContentPlaceHolder ID:
MainContent

FIGURE 42-11

This wizard adds a new folder to the Views folder called Products and a Web Form called `Index.aspx`. The code added to the view is as follows:

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site.Master"
  Inherits="System.Web.Mvc.ViewPage<IEnumerable<PCSMVCMagicShop.Models.Product>>" %>

<asp:Content ID="Content1" ContentPlaceHolderID="TitleContent" runat="server">
  Index
</asp:Content>
<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">
  <h2>
    Index</h2>
  <table>
    <tr>
      <th>
      </th>
      <th>
        ProductId
      </th>
      <th>
        Name
      </th>
      <th>
        Description
      </th>
      <th>
        Cost
      </th>
    </tr>
    <% foreach (var item in Model)
       { %>
    <tr>
      <td>
        <%= Html.ActionLink("Edit", "Edit", new { id=item.ProductId }) %>
        |
        <%= Html.ActionLink("Details", "Details", new { id=item.ProductId })%>
      </td>
      <td>
        <%= Html.Encode(item.ProductId) %>
      </td>
      <td>
        <%= Html.Encode(item.Name) %>
      </td>
      <td>
        <%= Html.Encode(item.Description) %>
      </td>
      <td>
        <%= Html.Encode(String.Format("{0:F}", item.Cost)) %>
      </td>
    </tr>
    <% } %>
  </table>
  <p>
    <%= Html.ActionLink("Create New", "Create") %>
  </p>
</asp:Content>
```

code snippet PCSMVCMagicShop/Views/Products/Index.aspx

There is no code-behind file for this view; instead, it inherits the ASP.NET MVC generic base class `ViewPage<>`, located in the `System.Web.Mvc` namespace. The generic parameter used is, as you might have guessed, `IEnumerable<Product>`.

This code is fairly self-explanatory, but some features are worthy of mention. First, note that the Web Form uses the site master page, and that the content regions are populated for you. Next, notice that the ASP.NET MVC framework has used the model type information to intelligently populate the view according to the properties available, including a looping structure to output information for multiple items. Finally, note that several helper methods are used to output model information and to add action links. An action link is a link that calls a controller method by navigating to an appropriate URL (more on this in the "URL Operation Routing" section).

You are free to edit this view as you see fit. For example, in this application you don't really need to expose the `ProductId` values, so you can remove the following sections:

```
<th>
  ProductId
</th>
```

and:

```
<td>
  <%= Html.Encode(item.ProductId) %>
</td>
```

Don't worry, this won't break anything.

Testing View Products Functionality

Now it's time to test that things are working. Build the application and run it (enabling debugging when prompted). You haven't yet added any code to provide a link to the new view, but that's not a problem as all of the plumbing is in place. When you see the home page, manually edit the URL by adding `Products` to the end and navigate to the page. The display should be updated as shown in Figure 42-12.

Create New

FIGURE 42-12

Our list view is now implemented, with a minimum of effort.

Note that none of the links provided are yet active. If you try to click on the first Details link, for example, the page will navigate to `http://localhost:59360/Products/Details/1` and receive the following error message:

```
The view 'Details' or its master was not found. The following locations were searched:
~/Views/Products/Details.aspx
~/Views/Products/Details.ascx
~/Views/Shared/Details.aspx
~/Views/Shared/Details.ascx
```

What is happening here is that the view exposes a URL that maps to the `Details()` method in `ProductsController`, which you haven't yet configured. You can put a breakpoint in this method and refresh the page to confirm this if you like. This method currently returns an `ActionResult` using a call to `View()` with no parameters, which has no associated view defined, hence the error.

Customizing ASP.NET MVC Applications

You now have a functioning ASP.NET MVC application, although you certainly wouldn't call it "fully" functioning. At the moment, you have created a simple list view for products, but as you saw at the end of the previous section, there are other views required in order to make things work properly. Also, navigating to a list of products by manually entering a URL is hardly a good way to navigate through a web site, so that needs fixing, too.

In this section, you will look in a little more detail at how URLs are mapped to controller operations, and then modify the PCSMVCMagicShop web application to add additional functionality for the Products page.

URL Operation Routing

Earlier, it was noted that the `Global.asax` file in your application configures routing. The contents of the code-behind for this file are as follows:

```
public class MvcApplication : System.Web.HttpApplication
{
   public static void RegisterRoutes(RouteCollection routes)
   {
      routes.IgnoreRoute("{resource}.axd/{*pathInfo}");

      routes.MapRoute(
          "Default",                                              // Route name
          "{controller}/{action}/{id}",                           // URL with parameters
          new { controller = "Home", action = "Index", id = "" }  // Parameter defaults
      );
   }

   protected void Application_Start()
   {
      RegisterRoutes(RouteTable.Routes);
   }
}
```

code snippet PCSMVCMagicShop/Global.asax.cs

Much of this should look familiar from the "Routing" section at the start of this chapter. The `IgnoreRoute()` and `MapRoute()` methods are extension methods that ASP.NET MVC defines for you to make it easier to customize routes.

You can see a single default route defined that takes the form `{controller}/{action}/{id}`. There are also default values provided for the three route parameters `controller`, `action`, and `id` of `Home`, `Index`, as well as an empty string. For the `/Products` route you entered to get to the products list, these parameters were set to `Products`, `Index`, and an empty string.

At this point, hopefully, things should click into place. Prior to testing you added a controller called `ProductsController`, which had a method called `Index()`, which at the time was described as being the default controller method. Now you can deduce what actually happened when you entered the URL:

1. The routing system interpreted the URL entered and assigned values to `controller`, `action`, and `id` as noted above.
2. ASP.NET MVC searched for — and found — a controller for Products (note that the URL didn't need to be `/ProductsController`, the `Controller` suffix is added automatically).
3. ASP.NET MVC searched for — and, again, found — an action called `Index`, which is the `Index()` method in `ProductsController`.
4. When calling `Index()`, ASP.NET MVC searched for — and, you guessed it, found — a view in the Products view folder capable of displaying a collection of `Product` objects.
5. ASP.NET rendered the view.

Similarly, when you subsequently attempted to view the details for an item, the appropriate method (`Details()`) was located after interpreting the URL route `/Products/Details/1`. The final parameter here was passed to the `Details()` method as an argument, although at this point things fell to pieces a bit as that method is not yet implemented and no view was available.

This routing behavior, and the way that URLs are mapped directly to controller methods, is central to understanding ASP.NET MVC. It means that you have a direct route from a given URL into your code, and what you do in that code is, of course, entirely up to you. The "simple" operations, such as listing products and so on, are therefore just the start of what is possible; you can write any action you can conceive of in the same way.

However, you must also consider other implications of this. You are in effect exposing your code, and the parameters passed to your code, directly to users. This means that defensive coding is essential, as who knows what parameters your methods might receive from people typing URLs manually.

Action Links

Now that you know how URLs are mapped to actions, it's worth looking at how to include links in your application. You could just hard-code a link in your site, for example, the following to get to the Products page you added:

```
<asp:HyperLink runat="server" NavigateUrl="~/Products">Products</asp:HyperLink>
```

However, this link makes assumptions about the site's structure that aren't necessarily permanent. If at some point you were to change the routing specification this link would break.

Earlier in the chapter, you saw how the ASP.NET Routing system allows links to be dynamically generated according to routing parameters. Similarly, ASP.NET MVC allows links to be generated according to the controller, action, and additional values you want to use, as well as the text you want to display. This is achieved through the `Html.ActionLink()` extension method, which has a number of overloads, depending on what you want to achieve.

For example, if you look in the `Site.Master` master page file in the Views\Shared folder, you will see the following code that defines the menu for the site:

```
<div id="menucontainer">
  <ul id="menu">
    <li><%= Html.ActionLink("Home", "Index", "Home")%></li>
    <li><%= Html.ActionLink("About", "About", "Home")%></li>
  </ul>
</div>
```

code snippet PCSMVCMagicShop/Views/Shared/Site.Master

The overload used here has three string parameters, `linkText`, `actionName`, and `controllerName`. The first parameter specifies the text to display, and the other two specify the action and controller to use. The first of the calls in the previous code snippet, for example, maps to the `Index()` method in the `HomeController` controller class.

When rendered with the default routing settings, these `ActionLink()` calls output the following HTML:

```
<div id="menucontainer">
  <ul id="menu">
    <li><a href="/">Home</a></li>
    <li><a href="/Home/About">About</a></li>
  </ul>
</div>
```

Given what you know about how the URLs map to controller methods, and how the defaults are set up for routing in `Global.asax`, this makes perfect sense. And the beauty is, you don't have to work these links out for yourself or rewrite them if routing changes.

To add a link to the product list page in the same way, add the following code to master page:

```
<div id="menucontainer">
  <ul id="menu">
    <li><%= Html.ActionLink("Home", "Index", "Home")%></li>
    <li><%= Html.ActionLink("About", "About", "Home")%></li>
    <li><%= Html.ActionLink("Products", "Index", "Products")%></li>
  </ul>
</div>
```

code snippet PCSMVCMagicShop/Views/Shared/Site.Master

The various overloads of `ActionLink()` enable you to do other things, such as pass parameters to a controller method. For example, in the product list view you created, the edit item link is rendered with the following code:

```
<%= Html.ActionLink("Edit", "Edit", new { id=item.ProductId }) %>
```

code snippet PCSMVCMagicShop/Views/Products/Index.aspx

This overload uses `linkText`, `actionName`, and `routeValues` parameters (the controller name defaults to the current controller). In this case, a single route value of `id` is used, which maps to the `id` parameter of the `Edit` method in `ProductsController`. This call renders links, as shown in the following example HTML:

```
<a href="/Products/Edit/1">Edit</a>
```

Viewing Items with Details()

The `Details()` action method in `ProductsController` is requested when a user clicks the Details link in the application. This results in the method being executed with the product ID passed as a parameter. All you need to do is to locate the requested product and, if it exists, return a new view, as follows:

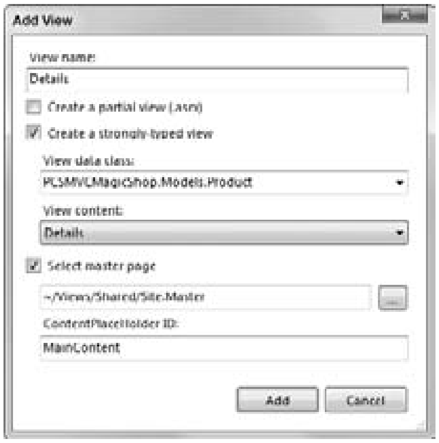
```
public ActionResult Details(int id)
{
   var product = (from e in entities.Products
                  where e.ProductId == id
                  select e).FirstOrDefault();

   if (product != null)
   {
      return View(product);
   }
   else
   {
      return RedirectToAction("Index");
   }
}
```

The `RedirectToAction()` method is used if no product is located and does exactly what its name suggests — it redirects the user to another view, in this case the Index view.

To add the new view, right-click on the `Details()` method and, as before, click the Add View . . . menu item. This time, create a strongly typed view for the `Product` class with Details view content, as shown in Figure 42-13.

Now when you run the application, you will be able to navigate to the products list through the Products menu item added in the previous section and view the details for any item, as shown in Figure 42-14.



View name: Details

FIGURE 42-14

If you manually edit the URL to an ID for a nonexistent product, you will be redirected to the product listing.

Adding Items with Create()

There are two actions associated with creating new items, which are currently defined in code as follows:

```
public ActionResult Create()
{
   return View();
}
```

```
[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Create(FormCollection collection)
{
   try
   {
      // TODO: Add insert logic here

      return RedirectToAction("Index");
   }
   catch
   {
      return View();
   }
}
```

code snippet PCSMVCMagicShop/Controllers/ProductsController.cs

The first of these, which has no parameters, simply redirects to the create view, which you can add in the same way as other views (remembering the View content value to Create in the Add View Wizard). The second is used to actually create a new item in the data source, and you have to implement it yourself.

Note that the second `Create()` overload includes an `AcceptVerbs` attribute. This restricts the HTTP verb used to `POST`, which makes sense as you will typically want to submit more information when creating an item than you could reasonably include in a URL for a `GET` request.

The view that you created for the first `Create()` method includes the following auto-generated code:

```
<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">
  <h2>
    Create</h2>
  <%= Html.ValidationSummary(
    "Create was unsuccessful. Please correct the errors and try again.") %>
  <% using (Html.BeginForm())
     {%>
  <fieldset>
    <legend>Fields</legend>
    <p>
      <label for="ProductId">
        ProductId:</label>
      <%= Html.TextBox("ProductId") %>
      <%= Html.ValidationMessage("ProductId", "*") %>
    </p>
    <p>
      <label for="Name">
        Name:</label>
      <%= Html.TextBox("Name") %>
      <%= Html.ValidationMessage("Name", "*") %>
    </p>
    <p>
      <label for="Description">
        Description:</label>
      <%= Html.TextBox("Description") %>
      <%= Html.ValidationMessage("Description", "*") %>
    </p>
    <p>
      <label for="Cost">
        Cost:</label>
      <%= Html.TextBox("Cost") %>
      <%= Html.ValidationMessage("Cost", "*") %>
    </p>
```

```
        <p>
          <input type="submit" value="Create" />
        </p>
      </fieldset>
      <% } %>
      <div>
        <%=Html.ActionLink("Back to List", "Index") %>
      </div>
    </asp:Content>
```

code snippet PCSMVCMagicShop/Views/Products/Create.aspx

Several helper methods are included here to create and edit the form, and again you can see how the data model has been interrogated to extract information for the fields to use and the validation required. The form itself is contained in the following code block:

```
using (Html.BeginForm())
{
   ...
}
```

This helper method creates a form that is submitted using a standard HTML `<input type="submit" />` control, which results in the form values being passed to the action method. You then have access to these values so that you can add a new item.

You can delete the following section of code to remove the text box for the product ID, since this is auto-generated:

```
        <p>
          <label for="ProductId">
            ProductId:</label>
          <%= Html.TextBox("ProductId") %>
          <%= Html.ValidationMessage("ProductId", "*") %>
        </p>
```

The code required to add an item is as follows:

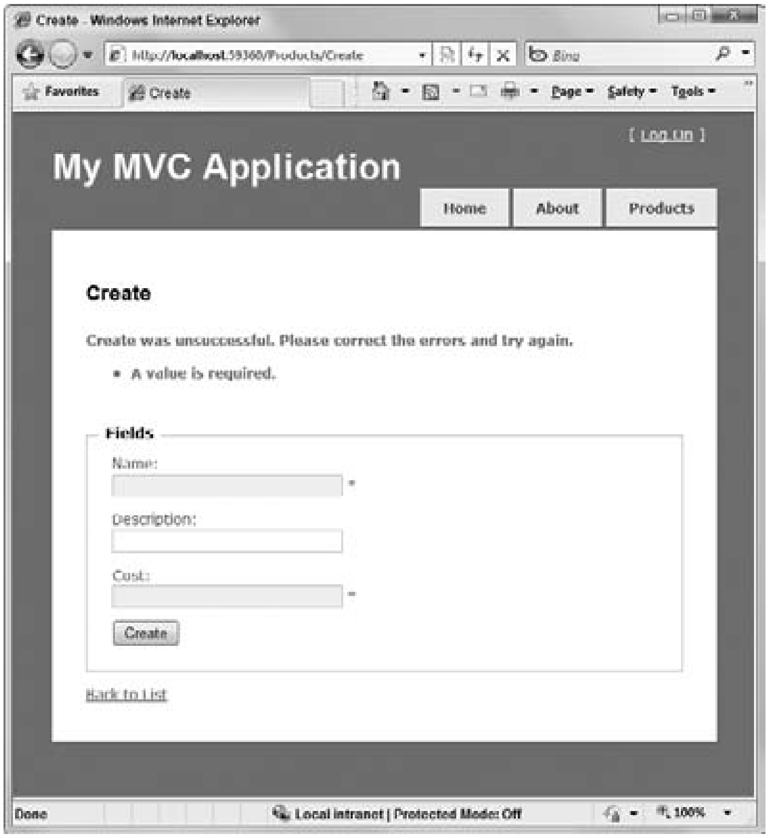
```
[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Create([Bind(Exclude = "ProductId")] Product productToCreate)
{
   try
   {
      if (!ModelState.IsValid)
      {
         return View();
      }

      entities.AddToProducts(productToCreate);
      entities.SaveChanges();
      return RedirectToAction("Index");
   }
   catch
   {
      return View();
   }
}
```

code snippet PCSMVCMagicShop/Controllers/ProductsController.cs

There are several points to note about this code. First, note that you can change the method signature to accept a strongly-typed `Product` value. This is easier than working through a collection of form values, but to facilitate it you need to exclude the `ProductId` field, since it won't be passed. The `Bind` attribute achieves this.

Next, note that a property called `ModelState.IsValid` is used to check that the model passed to the method is valid, and if not the method simply returns the create view with no parameters. If this happens, the validation summary and validation errors will be displayed, as shown in Figure 42-15.



Create

Create was unsuccessful. Please correct the errors and try again.

- A value is required.

Name:

Description:

Cost:

FIGURE 42-15

If there are no errors, the new item is added through the ADO.NET Entity Framework-defined `AddToProducts()` method, and the page redirects to the list view as follows:

```
                entities.AddToProducts(productToCreate);
                entities.SaveChanges();
                return RedirectToAction("Index");
```

An important point to note here is that the validation can be controlled through data annotations, introduced earlier in the chapter. Most of the default validation comes automatically from the constraints on data in the database, but you may want to modify this behavior. For example, you could limit the number of characters for a product name with the following two classes:

```
using System.ComponentModel.DataAnnotations;

namespace PCSMVCMagicShop.Models
{
   [MetadataType(typeof(ProductMetadata))]
   public partial class Product
   {
   }
}
```

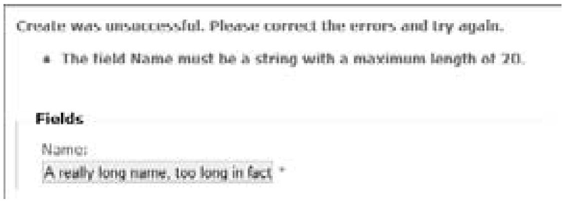
code snippet PCSMVCMagicShop/Models/Product.cs

```
using System.ComponentModel.DataAnnotations;

namespace PCSMVCMagicShop.Models
{
   public class ProductMetadata
   {
      [StringLength(20)]
      public object Name { get; set; }
   }
}
```

code snippet PCSMVCMagicShop/Models/ProductMetadata.cs

This will validate the data, as shown in Figure 42-16.



Create was unsuccessful. Please correct the errors and try again.

- The field Name must be a string with a maximum length of 20.

FIGURE 42-16

Obviously the code you need to use in the controller comes down to the model you are using, and this option may not always be available, but it can be very useful in the right circumstances.

You will also probably want to edit the view created to provide more meaningful text, but the skeleton created is suitable for most needs. In this example, you'd probably want to change the form's title and validation messages, as well as providing a bit more space for the item description.

Editing Items with Edit()

Editing items uses very similar code to creating new items. Rather than working through how to do this, let's just take a look at the code in the controller:

```
public ActionResult Edit(int id)
{
   var productToEdit = (from p in entities.Products
                        where p.ProductId == id
                        select p).First();

   return View(productToEdit);
}

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Edit(Product productToEdit)
{
   try
   {
      var originalProduct = (from p in entities.Products
                             where p.ProductId == productToEdit.ProductId
                             select p).First();

      if (!ModelState.IsValid)
      {
         return View(originalProduct);
      }

      entities.ApplyCurrentValues(originalProduct.EntityKey.EntitySetName,
                                  productToEdit);
      entities.SaveChanges();

      return RedirectToAction("Index");

   }
```

```
            catch
            {
               return View();
            }
        }
```

code snippet PCSMVCMagicShop/Controllers/ProductsController.cs

This time, both `Edit()` method overloads need implementing. The first obtains a `Product` item from an ID value, and the second updates an item, using standard ADO.NET Entity Framework code.

Note that this time you require the product ID in the second `Create()` overload, so you can't just remove the auto-generated HTML for the `ProductId` field in the edit view as you did in the details and create views. Instead, to prevent it from being edited, you can include it as a hidden field as follows:

```
<fieldset>
  <legend>Fields</legend>
  <%= Html.Hidden("ProductId", Model.ProductId) %>
```

code snippet PCSMVCMagicShop/Views/Products/Edit.aspx

This ensures that it will be passed to the action method correctly.

Further Development

As with dynamic data web sites, this chapter has only included a brief introduction to ASP.NET MVC. There is plenty more that is worth looking into, including:

- Adding your own actions
- Custom action return types
- Unit testing controllers
- Custom HTML helper methods

And much more. If you are interested in learning more, your first point of call should be the ASP.NET MVC web site at `http://asp.net/mvc`, which contains tutorials, samples, and everything you need to dig deeper into this exciting new technology. There are also plenty of other great resources on the internet, including Scott Guthrie's blog at `http://weblogs.asp.net/scottgu/`. Scott has also written a great book for Wrox, *Professional ASP.NET MVC 1.0* (ISBN: 0470384611), with fellow expert ASP.NET MVC authors Rob Conery, Scott Hanselman, and Phil Haack. While this only covers version 1.0 of ASP.NET MVC, it is well worth a look, and I expect an updated version for ASP.NET MVC 2 before too long.

SUMMARY

In this chapter, you have completed your grand tour of ASP.NET by looking at some of the latest additions to the language and tools built on the framework that make it such an exciting way to develop for the web.

You started by looking at how routing can make friendly URLs much easier to implement, and how to control that routing to tweak URL mapping in exactly the way you want.

Next, you saw how to create dynamic data web sites that provide seamless integration of your data with a powerful front-end ASP.NET UI. This technology provides so much code for you by default that at times it feels like your web sites write themselves. You saw how two different data access methodologies, LINQ to SQL and the ADO.NET Entity Framework, are both supported by dynamic data sites, and how to customize scaffolding to make sites work just the way you want.

Finally, you explored the latest (and perhaps greatest) web technology to make use of ASP.NET, the ASP .NET MVC 2 framework. You saw how this provides you with a robust structure to work with, ideal for large-scale applications that require proper unit testing. You saw how easy it is to provide advanced capabilities with the minimum of effort, and how the logical structure and separation of functionality that this framework provides makes code easy to understand and easy to maintain.

In the next chapter, you'll look at Windows Communication Foundation, which enables you to make remote calls across application boundaries in a flexible, secure way. This underpins a lot of web development, as you will often want to pull in data from disparate sources for your web applications rather than including in-place databases as you have been doing in this chapter.

PART VI Communication

43

Windows Communication Foundation

WHAT'S IN THIS CHAPTER?

- WCF overview
- A simple service and client
- Service, Operation, Data, and Message Contracts
- Implementing a Service
- Using Binding for Communication
- Different Hosting Options for Services
- Creating Clients with a Service Reference and Programmatically
- Duplex communication

Previous to .NET 3.0, several communication technologies were required in a single enterprise solution. For platform-independent communication, ASP.NET Web services were used. For more advanced Web services — technologies such as reliability, platform-independent security, and atomic transactions — Web Services Enhancements added a complexity layer to ASP.NET Web services. If the communication needed to be faster, and both the client and service were .NET applications, .NET Remoting was the technology of choice. .NET Enterprise Services with its automatic transaction support, by default, used the DCOM protocol, which was even faster than .NET Remoting. DCOM was also the only protocol to allow the passing of transactions. All of these technologies have different programming models that require many skills from the developer.

.NET Framework 3.0 introduced a new communication technology that includes all the features from these predecessors and combines them into one programming model: Windows Communication Foundation (WCF).

WCF OVERVIEW

WCF combines the functionality from ASP.NET Web services, .NET Remoting, Message Queuing, and Enterprise Services. What you get from WCF is:

- **Hosting for components and services** — Just as you can use custom hosts with .NET Remoting and Web Service Enhancements (WSE), you can host a WCF service in the ASP.NET runtime, a Windows service, a COM+ process, or just a Windows Forms application for peer-to-peer computing.
- **Declarative behavior** — Instead of the requirement to derive from a base class (this requirement exists with .NET Remoting and Enterprise Services), attributes can be used to define the services. This is similar to Web services developed with ASP.NET.
- **Communication channels** — Although NET Remoting is very flexible for changing the communication channel, WCF is a good alternative because it offers the same flexibility. WCF offers multiple channels to communicate using HTTP, TCP, or an IPC channel. Custom channels using different transport protocols can be created as well.
- **Security infrastructure** — For implementing platform-independent Web services, a standardized security environment must be used. The proposed standards are implemented with WSE 3.0, and this continues with WCF.
- **Extensibility** — .NET Remoting has a rich extensibility story. It is not only possible to create custom channels, formatters, and proxies, but also to inject functionality inside the message flow on the client and on the server. WCF offers similar extensibilities; however, here the extensions are created by using SOAP headers.
- **Support of previous technologies** — Instead of rewriting a distributed solution completely to use WCF, WCF can be integrated with existing technologies. WCF offers a channel that can communicate with serviced components using DCOM. Web services that have been developed with ASP.NET can be integrated with WCF as well.

The final goal is to send and receive messages between a client and a service across processes or different systems, across a local network, or across the Internet. This should be done, if required, in a platform-independent way and as fast as possible. From a distant view, the service offers an endpoint that is described by a contract, binding, and an address. The contract defines the operations offered by the service, binding gives information about the protocol and encoding, and the address is the location of the service. The client needs a compatible endpoint to access the service.

Figure 43-1 shows the components that participate with a WCF communication.

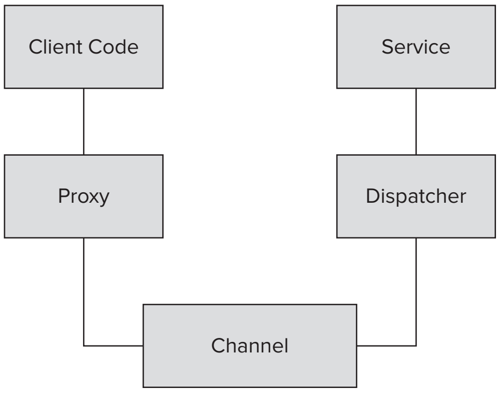


FIGURE 43-1

The client invokes a method on the proxy. The proxy offers methods as defined by the service but converts the method call to a message and transfers the message to the channel. The channel has a client-side part and a server-side part that communicate across a networking protocol. From the channel, the message is passed to the dispatcher, which converts the message to a method call that is invoked with the service.

WCF supports several communication protocols. For platform-independent communication, Web services standards are supported. For communication between .NET applications, faster communication protocols with less overhead can be used.

The following sections look at the functionality of core services used for platform-independent communication:

- SOAP — a platform-independent protocol that is the foundation of several Web service specifications to support security, transactions, reliability
- WSDL (Web Services Description Language) — offers metadata to describe a service

- REST (Representational State Transfer) — used with RESTful web services to communicate across HTTP
- JSON (JavaScript Object Notation) — allows easy use from within JavaScript clients.

SOAP

For platform-independent communication, the SOAP protocol can be used and is directly supported from WCF. SOAP originally was shorthand for Simple Object Access Protocol (SOAP), but since SOAP 1.2 this is no longer the case. SOAP no longer is an object access protocol, because, instead, messages are sent that can be defined by an XML schema.

A service receives a SOAP message from a client and returns a SOAP response message. A SOAP message consists of an envelope, which contains a header and a body:

```
<s:Envelope xmlns:a="http://www.w3.org/2005/08/addressing"
    xmlns:s="http://www.w3.org/2003/05/soap-envelope">
  <s:Header>
  </s:Header>
  <s:Body>
    <ReserveRoom xmlns="http://www.wrox.com/ProCSharp/2010">
      <roomReservation
          xmlns:d4p1="http://schemas.datacontract.org/2009/10/Wrox.ProCSharp.WCF"
          xmlns:i="http://www.w3.org/2001/XMLSchema-instance">
        <d4p1:RoomName>Hawelka</d4p1:RoomName>
        <d4p1:StartDate>2010-06-21T08:00:00</d4p1:StartDate>
        <d4p1:EndDate>2010-06-21T14:00:00</d4p1:EndDate>
        <d4p1:Contact>Georg Danzer</d4p1:Contact>
        <d4p1:Event>White Horses</d4p1:Event>
      </roomReservation>
    </ReserveRoom>
  </s:Body>
</s:Envelope>
```

The header is optional and can contain information about addressing, security, and transactions. The body contains the message data.

WSDL

A Web Services Description Language (WSDL) document describes the operations and messages of the service. WSDL defines metadata of the service that can be used to create a proxy for the client application.

The WSDL contains this information:

- **Types** for the messages that are described using an XML schema.
- **Messages** that are sent to and from the service. Parts of the messages are the types that are defined with an XML schema.
- **Port types** map to service contracts and list operations that are defined with the service contract. Operations contain messages; for example, an input and an output message as used with a request and response sequence.
- **Binding** information that contains the operations listed with the port types and that defines the SOAP variant used.
- **Service** information that maps port types to endpoint addresses.

REST

WCF also offers communication by using REST. This is not really a protocol but defines several principles for using services to access resources. A RESTful web service is a simple service based on the HTTP protocol and REST principles. The principles are defined by three categories: a service can be accessed with a simple URI, supports MIME types, and uses different HTTP methods. With the support of MIME types, different data formats can be returned from the service such as plain XML, JSON, or AtomPub. The `GET` method of a HTTP request returns data from the service. Other methods that are used are `PUT`, `POST`, and `DELETE`. The `PUT` method is used to make an update on the service side, `POST` creates a new resource, and `DELETE` deletes a resource.

REST allows the sending of smaller requests to services than is possible with SOAP. If transactions, secure messages, (secure communication is still possible, for example. via HTTPS), and the reliability that is offered by SOAP are not needed, a REST-architected service can reduce overhead.

With the REST architecture, the service is always stateless, and the response from the service can be cached.

JSON

Instead of sending SOAP messages, accessing services from JavaScript can best be done by using JSON. .NET includes a data contract serializer to create objects with the JSON notation.

JSON has less overhead than SOAP because it is not XML but is optimized for JavaScript clients. This makes it extremely useful from Ajax clients. Ajax is discussed in Chapter 41, "ASP.NET Features." JSON does not provide the reliability, security, and transaction features that can be sent with the SOAP header, but these are features usually not needed by JavaScript clients.

SIMPLE SERVICE AND CLIENT

Before going into the details of WCF, let's start with a simple service. The service is used to reserve meeting rooms.

For a backing store of room reservations, a simple SQL Server database with the table `RoomReservations` is used. You can download the database from `www.wrox.com` together with the sample code of this chapter.

Create an empty solution with the name `RoomReservation`, and add a new Component Library project with the name `RoomReservationData` to the solution. The first project that is implemented contains just the code to access the database. Because the ADO.NET Entity Framework makes the database access code much simpler, this .NET 4 technology is used here.

Add a new item, ADO.NET Entity Data Model, and name it `RoomReservationModel.edmx`. After selecting the `RoomReservations` database, select the `RoomReservations` table to create an entity data model. After its creation, you can see the `RoomReservation` entity in the Designer, as shown in figure 43-2.

This designer creates an entity class, `RoomReservation`, which contains properties for every column of the table, and the class `RoomReservationsEneities`. `RoomReservationsEntities` connects to the database and registers with the entity classes to be notified of all changes.

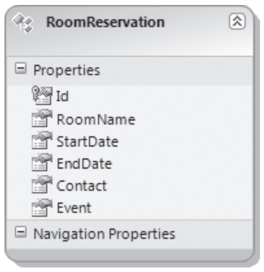

FIGURE 43-2

To read and write data to and from the database using the ADO.NET Entity Framework, add the class `RoomReservationData`. The method `ReserveRoom()` writes a room reservation to the database. The method `GetReservations()` returns an array of room reservations from a specified date range.

```
using System;
using System.Collections.Generic;
using System.Linq;

namespace Wrox.ProCSharp.WCF
{
    public class RoomReservationData
    {
        public void ReserveRoom(RoomReservation roomReservation)
        {
            using (var data = new RoomReservationsEntities())
            {
                data.RoomReservations.AddObject(roomReservation);
                data.SaveChanges();
            }
        }

        public RoomReservation[] GetReservations(DateTime fromDate,
                                                 DateTime toDate)
        {
            using (var data = new RoomReservationsEntities())
            {
                return (from r in data.RoomReservations
                        where r.StartDate > fromDate && r.EndDate < toDate
                        select r).ToArray();
            }
        }
    }
}
```

code snippet RoomReservationData/RoomReservationData.cs

Now start creating the service.

Service Contract

Add a new project of type WCF Service Library to the solution, and name the project `RoomReservationService`. Rename the generated files `IService1.cs` to `IRoomService.cs` and `Service1.cs` to `RoomReservationService.cs`, and change the namespace within the generated files to `Wrox.ProCSharp.WCF.Service`. The assembly `RoomReservationData` needs to be referenced to have the entity types and the `RoomReservationData` class available.

The operations offered by the service can be defined by an interface. The interface `IRoomService` defines the methods `ReserveRoom` and `GetRoomReservations`. The service contract is defined with the attribute `ServiceContract`. The operations defined by the service have the attribute `OperationContract` applied.

```
using System;
using System.ServiceModel;

namespace Wrox.ProCSharp.WCF
{
    [ServiceContract()]
    public interface IRoomService
    {
        [OperationContract]
        bool ReserveRoom(RoomReservation roomReservation);
        [OperationContract]
        RoomReservation[] GetRoomReservations(DateTime fromDate, DateTime toDate);
    }
}
```

code snippet RoomReservationService/IRoomService.cs

Service Implementation

The service class `RoomReservationService` implements the interface `IRoomService`. The service is implemented just by invoking the appropriate methods of the `RoomReservationData` class:

```
using System;
using System.Linq;

namespace Wrox.ProCSharp.WCF
{
    public class RoomReservationService : IRoomService
    {
        public bool ReserveRoom(RoomReservation roomReservation)
        {
            var data = new RoomReservationData();
            data.ReserveRoom(roomReservation);
            return true;
        }

        public RoomReservation[] GetRoomReservations(DateTime fromDate, DateTime toDate)
        {
            var data = new RoomReservationData();
            return data.GetReservations(fromDate, toDate);
        }
    }
}
```

code snippet RoomReservationService/RoomReservationService.cs

WCF Service Host and WCF Test Client

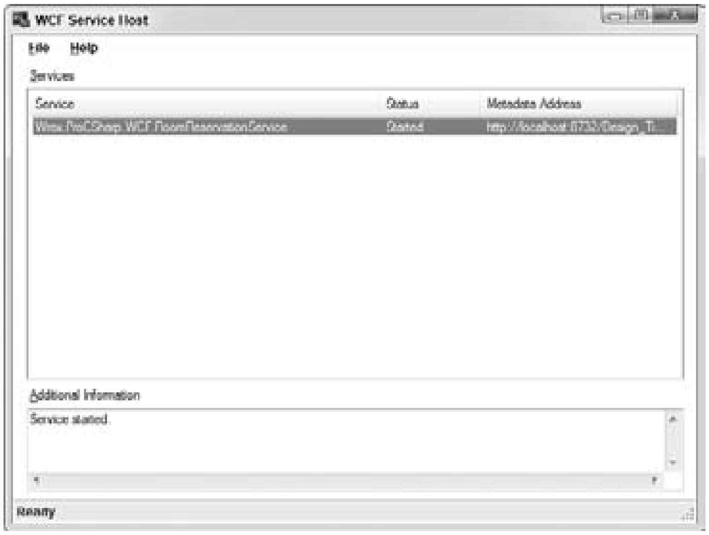
The WCF Service Library project template creates an application configuration file named `App.config` that you need to adapt to the new class and interface names. The `service` element references the service type `RoomReservationService`, including the namespace; the contract interface needs to be defined with the `endpoint` element.

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <system.web>
    <compilation debug="true" />
  </system.web>
  <!-- When deploying the service library project, the content of the config file must be added
  to the host's app.config file. System.Configuration does not support config files for
  libraries. -->
  <system.serviceModel>
    <services>
      <service name="Wrox.ProCSharp.WCF.RoomReservationService">
        <host>
          <baseAddresses>
            <add baseAddress =
                "http://localhost:8732/Design_Time_Addresses/RoomReservationService/Service1/"
            />
          </baseAddresses>
        </host>
        <!-- Service Endpoints -->
        <!-- Unless fully qualified, address is relative to base address supplied above -->
        <endpoint address ="" binding="wsHttpBinding"
                  contract="Wrox.ProCSharp.WCF.IRoomService">
          <!--
              Upon deployment, the following identity element should be removed or replaced to
              reflect the identity under which the deployed service runs.  If removed, WCF will
              infer an appropriate identity automatically.
          -->
          <identity>
            <dns value="localhost"/>
          </identity>
        </endpoint>
        <!-- Metadata Endpoints -->
        <!-- The Metadata Exchange endpoint is used by the service to describe itself to
             clients. -->
        <!-- This endpoint does not use a secure binding and should be secured or removed
             before deployment -->
        <endpoint address="mex" binding="mexHttpBinding" contract="IMetadataExchange"/>
      </service>
    </services>
    <behaviors>
      <serviceBehaviors>
        <behavior>
          <!-- To avoid disclosing metadata information,
          set the value below to false and remove the metadata endpoint above before
          deployment -->
          <serviceMetadata httpGetEnabled="True"/>
          <!-- To receive exception details in faults for debugging purposes,
          set the value below to true.  Set to false before deployment
          to avoid disclosing exception information -->
          <serviceDebug includeExceptionDetailInFaults="False" />
        </behavior>
      </serviceBehaviors>
    </behaviors>
  </system.serviceModel>
</configuration>
```

code snippet RoomReservationService/App.config

The service address `http://localhost:8732/Design_Time_Addresses` *has an access control list (ACL) associated with it that allows the interactive user to create a listener port. By default, a non-administrative user is not allowed to open ports in listening mode. You can view the ACLs with the command-line utility* `netsh http show urlacl`, *and add new entries with* `netsh http add urlacl url=http://+:8080/MyURI user=someUser`.

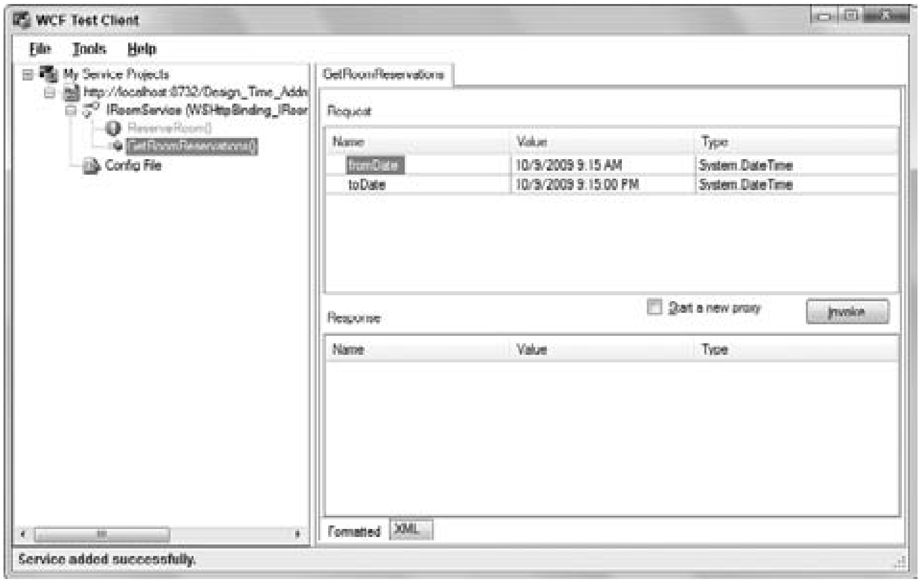
Starting this library from Visual Studio 2010 starts the WCF Service Host, which appears as an icon in the notification area of the taskbar. Clicking this icon opens the WCF Service Host window (see Figure 43-3), where you can see the status of the service. The project properties of a WCF library application include the tab WCF options, where you can select whether the WCF service host should be started when running a project from the same solution. By default, this option is turned on. Also, with the Debug configuration of the project properties, you will find the command-line argument `/client: "WcfTestClient.exe"` defined. With this option, the WCF Service host starts the WCF Test Client (see Figure 43-4), which you can use to test the application. When you double-click an operation, input fields appear on the right side of the application that you can fill to send data to the service. When you click the XML tab, you can see the SOAP messages that have been sent and received.



Service	Status	Metadata Address
Wrox.ProCSharp.WCF.RoomReservationService	Started	http://localhost:8732/Design_Ti...

Service started.

FIGURE 43-3



Name	Value	Type
fromDate	10/9/2009 9:15 AM	System.DateTime
toDate	10/9/2009 9:15:00 PM	System.DateTime

Name	Value	Type

Service added successfully.

FIGURE 43-4

Custom Service Host

WCF allows services to run in any host. You can create a Windows Forms or Windows Presentation Foundation (WPF) application for peer-to-peer services, or you can create a Windows service, or host the service with Windows Activation Services (WAS). A console application is also good to demonstrate a simple host.

With the service host, you must reference the library `RoomReservationService`. The service is started by instantiating and opening an object of type `ServiceHost`. This class is defined in the namespace `System.ServiceModel`. The `RoomReservationService` class that implements the service is defined in the constructor. Invoking the `Open()` method starts the listener channel of the service — the service is ready to listen for requests. The `Close()` method stops the channel.

```
using System;
using System.ServiceModel;

namespace Wrox.ProCSharp.WCF
{
    class Program
    {
        internal static ServiceHost myServiceHost = null;

        internal static void StartService()
        {
            myServiceHost = new ServiceHost(typeof(RoomReservationService));
            myServiceHost.Open();
        }

        internal static void StopService()
        {
            if (myServiceHost.State != CommunicationState.Closed)
                myServiceHost.Close();
        }

        static void Main()
        {
            StartService();

            Console.WriteLine("Server is running. Press return to exit");
            Console.ReadLine();

            StopService();
        }
    }
}
```

code snippet RoomReservationServiceHost/Program.cs

For the WCF configuration, you need to copy the application configuration file that was created with the service library to the host application. You can edit this configuration file with the WCF Service Configuration Editor (see Figure 43-5).

Using the custom service host, you can deselect the WCF option to start the WCF Service Host in the project settings of the WCF library.

FIGURE 43-5

WCF Client

For the client, WCF is flexible again in what application type can be used. The client can be a simple console application as well. However, for reserving rooms, create a WPF application with controls, as shown in Figure 43-6.

Because the service offers a MEX endpoint with the binding `mexHttpBinding`, and metadata access is enabled with the behavior configuration, you can add a service reference from Visual Studio. When you add a service reference, the dialog shown in Figure 43-7 pops up. When you click the Discover button, you can find services within the same solution.

Enter the link to the service, and set the service reference name to `RoomReservationService`. The service reference name defines the namespace of the generated proxy class.

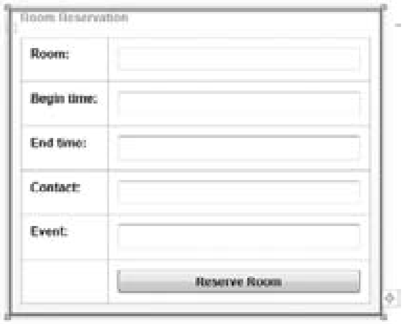

FIGURE 43-6

- GetRoomReservations
- ReserveRoom

1 service(s) found at address 'http://localhost:8732/Design_Time_Addresses/RoomReservationService/Service1/mex'.

Namespace:
RoomReservationService

Advanced... | OK | Cancel

FIGURE 43-7

Adding a service reference adds references to the assemblies `System.Runtime.Serialization` and `System.ServiceModel` and a configuration file containing the binding information and the endpoint address to the service.

From the data contract the class `RoomReservation` is generated. This class contains all `[DataMember]` elements of the contract. The class `RoomServiceClient` is the proxy for the client that contains methods that are defined by the service contract. Using this client, you can send a room reservation to the running service.

```
private void OnReserveRoom(object sender, RoutedEventArgs e)
{
   var reservation = new RoomReservation()
   {
      RoomName = textRoom.Text,
      Event = textEvent.Text,
      Contact = textContact.Text,
      StartDate = DateTime.Parse(textStartTime.Text),
      EndDate = DateTime.Parse(textEndTime.Text)
   };

   var client = new RoomServiceClient();
   bool reserved = client.ReserveRoom(reservation);
   client.Close();
   if (reserved)
       MessageBox.Show("reservation ok");
}
```

code snippet RoomReservationClient/MainWindow.xaml.cs

By running both the service and the client, you can add room reservations to the database. With the settings of the `RoomReservation` solution, you can configure multiple startup projects, which should be `RoomReservationClient` and `RoomReservationHost` in this case.

Diagnostics

When running a client and service application, it can be very helpful to know what's happening behind the scenes. For this, WCF makes use of a trace source that just needs to be configured. You can configure tracing using the Service Configuration Editor, selecting Diagnostics, and enabling Tracing and Message Logging. Setting the trace level of the trace sources to Verbose produces very detailed information. This configuration change adds trace sources and listeners to the application configuration file as shown here:

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <system.diagnostics>
    <sources>
      <source name="System.ServiceModel.MessageLogging" switchValue="Verbose,ActivityTracing">
        <listeners>
          <add type="System.Diagnostics.DefaultTraceListener" name="Default">
            <filter type="" />
          </add>
          <add name="ServiceModelMessageLoggingListener">
            <filter type="" />
          </add>
        </listeners>
      </source>
      <source name="System.ServiceModel" switchValue="Verbose,ActivityTracing"
        propagateActivity="true">
        <listeners>
          <add type="System.Diagnostics.DefaultTraceListener" name="Default">
            <filter type="" />
          </add>
          <add name="ServiceModelTraceListener">
            <filter type="" />
          </add>
        </listeners>
      </source>
    </sources>
    <sharedListeners>
      <add initializeData="c:\code\wcf\roomreservation\roomreservationhost\app_messages.svclog"
        type="System.Diagnostics.XmlWriterTraceListener, System, Version=4.0.0.0,
              Culture=neutral, PublicKeyToken=b77a5c561934e089"
        name="ServiceModelMessageLoggingListener" traceOutputOptions="Timestamp">
        <filter type="" />
      </add>
      <add initializeData="c:\code\wcf\roomreservation\roomreservationhost\app_tracelog.svclog"
        type="System.Diagnostics.XmlWriterTraceListener, System, Version=4.0.0.0,
              Culture=neutral, PublicKeyToken=b77a5c561934e089"
        name="ServiceModelTraceListener" traceOutputOptions="Timestamp">
        <filter type="" />
      </add>
    </sharedListeners>
    <trace autoflush="true" />
  </system.diagnostics>
  <!-- -->
```

code snippet RoomReservationHost/App.config

The implementation of the WCF classes uses the trace sources named `System.ServiceModel` *and* `System.ServiceModel.MessageLogging` *for writing trace messages. You can read more about tracing and configuring trace sources and listeners in Chapter 19, "Instrumentation."*

When you start the application, the trace files soon get large with verbose trace settings. To analyze the information from the XML log file, the .NET SDK includes the Service Trace Viewer tool, `svctraceviewer.exe`. Figure 43-8 shows the view from this tool after selecting the trace and message log files. With the default configuration, you can see several messages exchanged; many of them are related to security. Depending on your security needs, you can choose other configuration options.

FIGURE 43-8

The following sections discuss the details and different options of WCF.

CONTRACTS

A contract defines what functionality a service offers and what functionality can be used by the client. The contract can be completely independent of the implementation of the service.

The contracts defined by WCF can be grouped into three different contract types: data, service, and message. The contracts can be specified by using .NET attributes:

- **Data contract** — The data contract defines the data received by and returned from the service. The classes used for sending and receiving messages have data contract attributes associated with them.
- **Service contract** — The service contract is used to define the WSDL that describes the service. This contract is defined with interfaces or classes.
- **Message contract** — If complete control over the SOAP message is needed, a message contract can specify what data should go into the SOAP header and what belongs in the SOAP body.

The following sections explore these contract types further and discuss versioning issues that should be thought about when defining the contracts.

Data Contract

With the data contract, CLR types are mapped to XML schemas. The data contract is different from other .NET serialization mechanisms: with runtime serialization, all fields are serialized (including private fields); with XML serialization, only the public fields and properties are serialized. The data contract requires explicit marking of the fields that should be serialized with the `DataMember` attribute. This attribute can be used regardless of whether the field is private or public, or if it is applied to a property.

```
[DataContract(Namespace="http://www.thinktecture.com/SampleServices/2010"]
public class RoomReservation
{
   [DataMember] public string Room { get; set; }
   [DataMember] public DateTime StartDate { get; set; }
   [DataMember] public DateTime EndDate { get; set; }
   [DataMember] public string ContactName { get; set; }
   [DataMember] public string EventName { get; set; }
}
```

To be platform-independent, and provide the option to change data with new versions without breaking older clients and services, using data contracts is the best way to define which data should be sent. However, you can also use XML serialization and runtime serialization. XML serialization is the mechanism used by ASP.NET Web services; .NET Remoting uses runtime serialization.

With the attribute `DataMember`, you can specify the properties described in the following table.

DATAMEMBER PROPERTY	DESCRIPTION
`Name`	By default, the serialized element has the same name as the field or property where the `[DataMember]` attribute is applied. You can change the name with the `Name` property.
`Order`	The `Order` property defines the serialization order of the data members.
`IsRequired`	With the `IsRequired` property, you can specify that the element must be received with serialization. This property can be used for versioning. If you add members to an existing contract, the contract is not broken because, by default, the fields are optional (`IsRequired=false`). You can break an existing contract by setting `IsRequired` to true.
`EmitDefaultValue`	The property `EmitDefaultValue` defines whether the member should be serialized if it has the default value. If `EmitDefaultValue` is set to true, the member is not serialized if it has the default value for the type.

Versioning

When you create a new version of a data contract, pay attention to what kind of change it is and act accordingly if old and new clients and old and new services should be supported simultaneously.

When defining a contract, you should add XML namespace information with the `Namespace` property of the `DataContractAttribute`. This namespace should be changed if a new version of the data contract is created that breaks compatibility. If just optional members are added, the contract is not broken — this is a compatible change. Old clients can still send a message to the new service because the additional data is not needed. New clients can send messages to an old service because the old service just ignores the additional data.

Removing fields or adding required fields breaks the contract. Here, you should also change the XML namespace. The name of the namespace can include the year and the month, for example, `http://thinktecture.com/SampleServices/2009/10`. Every time a breaking change is done, the namespace is changed; for example, by changing the year and month to the actual value.

Service Contract

The service contract defines the operations the service can perform. The attribute `ServiceContract` is used with interfaces or classes to define a service contract. The methods that are offered by the service have the attribute `OperationContract` applied, as you can see with the interface `IRoomService`:

```
[ServiceContract]
public interface IRoomService
{
   [OperationContract]
   bool ReserveRoom(RoomReservation roomReservation);
}
```

The possible properties that you can set with the `ServiceContract` attribute are described in the following table.

SERVICECONTRACT PROPERTY	DESCRIPTION
`ConfigurationName`	This property defines the name of the service configuration in a configuration file.
`CallbackContract`	When the service is used for duplex messaging, the property `CallbackContract` defines the contract that is implemented in the client.
`Name`	The `Name` property defines the name for the `<portType>` element in the WSDL.
`Namespace`	The `Namespace` property defines the XML namespace for the `<portType>` element in the WSDL.
`SessionMode`	With the `SessionMode` property, you can define whether sessions are required for calling operations of this contract. The possible values `Allowed`, `NotAllowed`, and `Required` are defined with the `SessionMode` enumeration.
`ProtectionLevel`	The `ProtectionLevel` property defines whether the binding must support protecting the communication. Possible values defined by the `ProtectionLevel` enumeration are `None`, `Sign`, and `EncryptAndSign`.

With the `OperationContract`, you can specify properties, as shown in the following table.

OPERATIONCONTRACT PROPERTY	DESCRIPTION
Action	WCF uses the Action of the SOAP request to map it to the appropriate method. The default value for the Action is a combination of the contract XML namespace, the name of the contract, and the name of the operation. If the message is a response message, Response is added to the Action string. You can override the Action value by specifying the Action property. If you assign the value "*", the service operation handles all messages.
ReplyAction	Whereas Action sets the Action name of the incoming SOAP request, ReplyAction sets the Action name of the reply message.
AsyncPattern	If the operation is implemented by using an asynchronous pattern, set the AsyncPattern property to true. The async pattern is discussed in Chapter 20, "Threads, Tasks, and Synchronization."
IsInitiating IsTerminating	If the contract consists of a sequence of operations, the initiating operation should have the IsInitiating property assigned to it; the last operation of the sequence needs the IsTerminating property assigned. The initiating operation starts a new session; the server closes the session with the terminating operation.
IsOneWay	With the IsOneWay property set, the client does not wait for a reply message. Callers of a one-way operation have no direct way to detect a failure after sending the request message.
Name	The default name of the operation is the name of the method the operation contract is assigned to. You can change the name of the operation by applying the Name property.
ProtectionLevel	With the ProtectionLevel property, you define whether the message should be signed or encrypted and signed.

With the service contract, you can also define the requirements that the service has from the transport with the attribute [DeliveryRequirements]. The property RequireOrderedDelivery defines that the messages sent must arrive in the same order. With the property QueuedDeliveryRequirements, you can define that the message should be sent in a disconnected mode, for example, by using Message Queuing (covered in Chapter 46).

Message Contract

A message contract is used if complete control over the SOAP message is needed. With the message contract, you can specify what part of the message should go into the SOAP header and what belongs in the SOAP body. The following example shows a message contract for the class ProcessPersonRequestMessage. The message contract is specified with the attribute MessageContract. The header and body of the SOAP message are specified with the attributes MessageHeader and MessageBodyMember. By specifying the Position property, you can define the element order within the body. You can also specify the protection level for header and body fields.

```
[MessageContract]
public class ProcessPersonRequestMessage
{
   [MessageHeader]
   public int employeeId;

   [MessageBodyMember(Position=0)]
   public Person person;
}
```

The class `ProcessPersonRequestMessage` is used with the service contract that is defined with the interface `IProcessPerson`:

```
[ServiceContract]
public interface IProcessPerson
{
   [OperationContract]
   public PersonResponseMessage ProcessPerson(
         ProcessPersonRequestMessage message);
}
```

Another contract that is important in regard to WCF services is the fault contract. This contract is discussed in the next section with Error Handling.

SERVICE IMPLEMENTATION

The implementation of the service can be marked with the attribute `ServiceBehavior`, as shown with the class `RoomReservationService`:

```
[ServiceBehavior]
public class RoomReservationService: IRoomService
{
   public bool ReserveRoom(RoomReservation roomReservation)
   {
   // implementation
   }
}
```

The attribute `ServiceBehavior` is used to describe behavior as is offered by WCF services to intercept the code for required functionality, as shown in the following table.

SERVICEBEHAVIOR PROPERTY	DESCRIPTION
`TransactionAutoCompleteOnSessionClose`	When the current session is finished without error, the transaction is automatically committed. This is similar to the `AutoComplete` attribute, which is discussed with Enterprise Services in Chapter 51 (this is a downloadable chapter).
`TransactionIsolationLevel`	To define the isolation level of the transaction within the service, the property `TransactionIsolationLevel` can be set to one value of the `IsolationLevel` enumeration. You can read information about transaction information levels in Chapter 23, “System.Transactions.”
`ReleaseServiceInstanceOnTransactionComplete`	When the transaction is finished, the instance of the service is recycled.
`AutomaticSessionShutdown`	If the session should not be closed when the client closes the connection, you can set the property `AutomaticSessionShutdown` to `false`. By default, the session is closed.
`InstanceContextMode`	With the property `InstanceContextMode`, you can define whether stateful or stateless objects should be used. The default setting is `InstanceContextMode.PerCall` to create a new object with every method call. Other possible settings are `PerSession` and `Single`. With both of these settings, stateful objects are used. However, with `PerSession` a new object is created for every client. `Single` allows the same object to be shared with multiple clients.

SERVICEBEHAVIOR PROPERTY	DESCRIPTION
`ConcurrencyMode`	Because stateful objects can be used by multiple clients (or multiple threads of a single client), you must pay attention to concurrency issues with such object types. If the property `ConcurrencyMode` is set to `Multiple`, multiple threads can access the object, and you must deal with synchronization. If you set the option to `Single`, only one thread accesses the object at a time. Here, you don't have to do synchronization; however, scalability problems can occur with a higher number of clients. The value `Reentrant` means that only a thread coming back from a callout might access the object. For stateless objects, this setting has no meaning, because new objects are instantiated with every method call and thus no state is shared.
`UseSynchronizationContext`	With Windows Forms and WPF, members of controls can be invoked only from the creator thread. If the service is hosted in a Windows application, and the service methods invoke control members, set the `UseSynchronizationContext` to `true`. This way, the service runs in a thread defined by the `SynchronizationContext`.
`IncludeExceptionDetailInFaults`	With .NET, errors show up as exceptions. SOAP defines that a SOAP fault is returned to the client in case the server has a problem. For security reasons, it's not a good idea to return details of server-side exceptions to the client. Thus, by default, exceptions are converted to unknown faults. To return specific faults, throw an exception of type `FaultException`. For debugging purposes, it can be helpful to return the real exception information. This is the case when changing the setting of `IncludeExceptionDetailIn` Faults to true. Here a `FaultException<TDetail>` is thrown where the original exception contains the detail information.
`MaxItemsInObjectGraph`	With the property `MaxItemsInObjectGraph`, you can limit the number of objects that are serialized. The default limitation might be too low if you serialize a tree of objects.
`ValidateMustUnderstand`	The property `ValidateMustUnderstand` set to true means that the SOAP headers must be understood (which is the default).

To demonstrate a service behavior, the interface `IStateService` defines a service contract with two operations to set and get state. With a stateful service contract, a session is needed. That's why the `SessionMode` property of the service contract is set to `SessionMode.Required`. The service contract also defines methods to initiate and close the session by applying the `IsInitiating` and `IsTerminating` properties to the operation contract:

```
[ServiceContract(SessionMode=SessionMode.Required)]
public interface IStateService
{
   [OperationContract(IsInitiating=true)]
   void Init(int i);

   [OperationContract]
   void SetState(int i);

   [OperationContract]
   int GetState();
```

```
      [OperationContract(IsTerminating=true)]
      void Close();
   }
```

code snippet StateServiceSample/IStateService.cs

The service contract is implemented by the class `StateService`. The service implementation defines the `InstanceContextMode.PerSession` to keep state with the instance:

```
   [ServiceBehavior(InstanceContextMode=InstanceContextMode.PerSession)]
   public class StateService: IStateService
   {
      int i = 0;

      public void Init(int i)
      {
         this.i = i;
      }

      public void SetState(int i)
      {
         this.i = i;
      }

      public int GetState()
      {
         return i;
      }

      public void Close()
      {
      }
   }
```

code snippet StateServiceSample/StateService.cs

Now the binding to the address and protocol must be defined. Here, the `basicHttpBinding` is assigned to the endpoint of the service:

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <system.serviceModel>
    <services>
      <service behaviorConfiguration="StateServiceSample.Service1Behavior"
        name="Wrox.ProCSharp.WCF.StateService">
        <endpoint address="" binding="basicHttpBinding"
            bindingConfiguration=""
            contract="Wrox.ProCSharp.WCF.IStateService">
        </endpoint>
        <endpoint address="mex" binding="mexHttpBinding"
            contract="IMetadataExchange" />
        <host>
          <baseAddresses>
             <add baseAddress="http://localhost:8731/Design_Time_Addresses/
                                  StateServiceSample/Service1/" />
          </baseAddresses>
        </host>
      </service>
    </services>
    <behaviors>
      <serviceBehaviors>
        <behavior name="StateServiceSample.Service1Behavior">
          <serviceMetadata httpGetEnabled="True"/>
          <serviceDebug includeExceptionDetailInFaults="False" />
        </behavior>
      </serviceBehaviors>
    </behaviors>
  </system.serviceModel>
</configuration>
```

code snippet StateServiceSample/app.config

If you start the service host with the defined configuration, an exception of type `InvalidOperationException` is thrown. The error message with the exception gives this error message: "Contract requires Session, but Binding '`BasicHttpBinding`' doesn't support it or isn't configured properly to support it."

Not all bindings support all services. Because the service contract requires a session with the attribute `[ServiceContract(SessionMode=SessionMode.Required)]`, the host fails because the configured binding does not support sessions.

As soon as you change the configuration to a binding that supports sessions (for example, the `wsHttpBinding`), the server starts successfully:

```
          <endpoint address="" binding="wsHttpBinding"
              bindingConfiguration=""
              contract="Wrox.ProCSharp.WCF.IStateService">
         </endpoint>
```

code snippet StateServiceSample/app.config

Creating a Client Programmatically

Now a client application can be created. In the previous example, the client application was created by adding a service reference. Instead of adding a service reference, you can directly access the assembly containing the contract interface and use the `ChannelFactory<TChannel>` class to instantiate the channel to connect to the service.

The constructor of the class `ChannelFactory<TChannel>` accepts the binding configuration and endpoint address. The binding must be compatible with the binding defined with the service host, and the address defined with the `EndpointAddress` class references the URI of the running service.

The `CreateChannel()` method creates a channel to connect to the service. Then, you can invoke methods of the service, and you can see that the service instance holds state until the `Close()` method that has the `IsTerminating` operation behavior assigned is invoked:

```
using System;
using System.ServiceModel;

namespace Wrox.ProCSharp.WCF
{
   class Program
   {
      static void Main()
      {
         var binding = new WSHttpBinding();
         var address = new EndpointAddress("http://localhost:8731/" +
               "Design_Time_Addresses/StateServiceSample/Service1/");

         var factory = new ChannelFactory<IStateService>(binding, address);

         IStateService channel = factory.CreateChannel();
         channel.Init(1);
         Console.WriteLine(channel.GetState());
         channel.SetState(2);
```

```
            Console.WriteLine(channel.GetState());
            channel.Close();

            factory.Close();
         }
      }
   }
```

code snippet StateClient/program.cs

With the implementation of the service, you can apply the properties in the following table to the service methods, with the attribute `OperationBehavior`.

OPERATIONBEHAVIOR PROPERTY	DESCRIPTION
`AutoDisposeParameters`	By default, all disposable parameters are automatically disposed. If the parameters should not be disposed, you can set the property `AutoDisposeParameters` to false. Then the sender is responsible for disposing the parameters.
`Impersonation`	With the `Impersonation` property, the caller can be impersonated and the method runs with the identity of the caller.
`ReleaseInstanceMode`	The `InstanceContextMode` defines the lifetime of the object instance with the service behavior setting. With the operation behavior setting, you can override the setting based on the operation. The `ReleaseInstanceMode` defines an instance release mode with the enumeration `ReleaseInstanceMode`. The value `None` uses the instance context mode setting. With the values `BeforeCall`, `AfterCall`, and `BeforeAndAfterCall` you can define recycle times with the operation.
`TransactionScopeRequired`	With the property `TransactionScopeRequired`, you can specify if a transaction is required with the operation. If a transaction is required, and the caller already flows a transaction, the same transaction is used. If the caller doesn't flow a transaction, a new transaction is created.
`TransactionAutoComplete`	The `TransactionAutoComplete` property specifies whether the transaction should complete automatically. If the `TransactionAutoComplete` property is set to true, the transaction is aborted if an exception is thrown. The transaction is committed if it is the root transaction and no exception is thrown.

Error Handling

By default, the detailed exception information that occurs in the service is not returned to the client application. The reason for this behavior is security. You wouldn't want to give detailed exception information to a third party by using your service. Instead, the exception should be logged on the service (which you can do with tracing and event logging), and an error with useful information should be returned to the caller.

You can return SOAP faults by throwing a `FaultException`. Throwing a `FaultException` creates an untyped SOAP fault. The preferred way of returning errors is to generate a strongly typed SOAP fault.

The information that should be passed with a strongly typed SOAP fault is defined with a data contract, as shown with the `StateFault` class:

```
[DataContract]
public class StateFault
{
   [DataMember]
```

```
        public int BadState { get; set; }
    }
```

code snippet StateServiceSample/IStateService.cs

The type of the SOAP fault must be defined by using the `FaultContractAttribute` with the operation contract:

```
[FaultContract(typeof(StateFault))]
[OperationContract]
void SetState(int i);
```

With the implementation, a `FaultException<TDetail>` is thrown. With the constructor, you can assign a new `TDetail` object, which is a `StateFault` in the example. In addition, error information within a `FaultReason` can be assigned to the constructor. `FaultReason` supports error information in multiple languages.

```
public void SetState(int i)
{
   if (i == -1)
   {
      FaultReasonText[] text = new FaultReasonText[2];
      text[0] = new FaultReasonText("Sample Error",
            new CultureInfo("en"));
      text[1] = new FaultReasonText("Beispiel Fehler",
            new CultureInfo("de"));
      FaultReason reason = new FaultReason(text);

      throw new FaultException<StateFault>(
         new StateFault() { BadState = i }, reason);
   }
   else
   {
      this.i = i;
   }
}
```

code snippet StateServiceSample/StateService.cs

With the client application, exceptions of type `FaultException<StateFault>` can be caught. The reason for the exception is defined by the `Message` property; the `StateFault` is accessed with the `Detail` property:

```
try
{
   channel.SetState(-1);
}
catch (FaultException<StateFault> ex)
{
   Console.WriteLine(ex.Message);
   StateFault detail = ex.Detail;
   Console.WriteLine(detail.BadState);
}
```

code snippet StateServiceClient/Program.cs

In addition to catching the strongly typed SOAP faults, the client application can also catch exceptions of the base class of `FaultException<Detail>`: `FaultException` and `CommunicationException`. By catching `CommunicationException`, you can also catch other exceptions related to the WCF communication.

BINDING

A binding describes how a service wants to communicate. With binding, you can specify the following features:

- Transport protocol
- Security
- Encoding format
- Transaction flow
- Reliability
- Shape change
- Transport upgrade

A binding is composed of multiple binding elements that describe all binding requirements. You can create a custom binding or use one of the predefined bindings that are shown in the following table.

STANDARD BINDING	DESCRIPTION
`BasicHttpBinding`	`BasicHttpBinding` is the binding for the broadest interoperability, the first-generation Web services. Transport protocols used are HTTP or HTTPS; security is available only from the transport protocol.
`WSHttpBinding`	`WSHttpBinding` is the binding for the next-generation Web services, platforms that implement SOAP extensions for security, reliability, and transactions. The transports used are HTTP or HTTPS; for security the WS-Security specification is implemented; transactions are supported, as has been described, with the WS-Coordination, WS-AtomicTransaction, and WS-BusinessActivity specifications; reliable messaging is supported with an implementation of WS-ReliableMessaging. WS-Profile also supports MTOM (Message Transmission Optimization Protocol) encoding for sending attachments. You can find specifications for the WS-* standards at `http://www.oasis-open.org`.
`WS2007HttpBinding`	`WS2007HttpBinding` derives from the base class `WSHttpBinding` and supports security, reliability, and transaction specifications defined by OASIS (Organization for the Advancement of Structured Information Standards).
`WSHttpContextBinding`	`WSHttpContextBinding` derives from the base class `WSHttpBinding` and adds support for a context without using cookies. This binding adds a `ContextBindingElement` to exchange context information.
`WebHttpBinding`	This binding is used for services that are exposed through HTTP requests instead of SOAP requests. This is useful for scripting clients — for example, ASP.NET AJAX.
`WSFederationHttpBinding`	`WSFederationHttpBinding` is a secure and interoperable binding that supports sharing identities across multiple systems for authentication and authorization.
`WSDualHttpBinding`	The binding `WSDualHttpBinding`, in contrast to `WSHttpBinding`, supports duplex messaging.
`NetTcpBinding`	All standard bindings prefixed with the name `Net` use a binary encoding used for communication between .NET applications. This encoding is faster than the text encoding with WSxxx bindings. The binding `NetTcpBinding` uses the TCP/IP protocol.
`NetTcpContextBinding`	Similar to `WSHttpContextBinding`, `NetTcpContextBinding` adds a `ContextBindingElement` to exchange context with the SOAP header.
`NetPeerTcpBinding`	`NetPeerTcpBinding` provides a binding for peer-to-peer communication.

STANDARD BINDING	DESCRIPTION
`NetNamedPipeBinding`	`NetNamedPipeBinding` is optimized for communication between different processes on the same system.
`NetMsmqBinding`	The binding `NetMsmqBinding` brings queued communication to WCF. Here, the messages are sent to the message queue.
`MsmqIntegrationBinding`	`MsmqIntegrationBinding` is the binding for existing applications that uses message queuing. In contrast, the binding `NetMsmqBinding` requires WCF applications both on the client and server.
`CustomBinding`	With a `CustomBinding` the transport protocol and security requirements can be completely customized.

Depending on the binding, different features are supported. The bindings starting with `WS` are platform-independent, supporting Web services specifications. Bindings that start with the name `Net` use binary formatting for high-performance communication between .NET applications. Other features are support of sessions, reliable sessions, transactions, and duplex communication; the following table lists the bindings supporting these features.

FEATURE	BINDING
Sessions	`WSHttpBinding`, `WSDualHttpBinding`, `WsFederationHttpBinding`, `NetTcpBinding`, `NetNamedPipeBinding`
Reliable Sessions	`WSHttpBinding`, `WSDualHttpBinding`, `WsFederationHttpBinding`, `NetTcpBinding`
Transactions	`WSHttpBinding`, `WSDualHttpBinding`, `WSFederationHttpBinding`, `NetTcpBinding`, `NetNamedPipeBinding`, `NetMsmqBinding`, `MsmqIntegrationBinding`
Duplex Communication	`WsDualHttpBinding`, `NetTcpBinding`, `NetNamedPipeBinding`, `NetPeerTcpBinding`

Along with defining the binding, the service must define an endpoint. The endpoint is dependent on the contract, the address of the service, and the binding. In the following code sample, a `ServiceHost` object is instantiated, and the address `http://localhost:8080/RoomReservation`, a `WsHttpBinding` instance, and the contract are added to an endpoint of the service:

```
static ServiceHost host;

static void StartService()
{
   var baseAddress = new Uri("http://localhost:8080/RoomReservation");
   host = new ServiceHost(
      typeof(RoomReservationService));

   var binding1 = new WSHttpBinding();
   host.AddServiceEndpoint(typeof(IRoomService), binding1, baseAddress);
   host.Open();
}
```

In addition to defining the binding programmatically, you can define it with the application configuration file. The configuration for WCF is placed inside the element `<system.serviceModel>`. The `<service>` element defines the services offered. Similarly, as you've seen in the code, the service needs an endpoint, and the endpoint contains address, binding, and contract information. The default binding configuration of `wsHttpBinding` is modified with the `bindingConfiguration` XML attribute that references the binding configuration `wsHttpConfig1`. This is the binding configuration you can find inside the `<bindings>` section, which is used to change the `wsHttpBinding` configuration to enable `reliableSession`.

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <system.serviceModel>
    <services>
      <service name="Wrox.ProCSharp.WCF.RoomReservationService">
        <endpoint address=" http://localhost:8080/RoomReservation"
            contract="Wrox.ProCSharp.WCF.IRoomService"
            binding="wsHttpBinding" bindingConfiguration="wsHttpBinding" />
      </service>
    </services>
    <bindings>
      <wsHttpBinding>
        <binding name="wsHttpBinding">
          <reliableSession enabled="true" />
        </binding>
      </wsHttpBinding>
    </bindings>
  </system.serviceModel>
</configuration>
```

HOSTING

WCF is very flexible when you are choosing a host to run the service. The host can be a Windows service, a COM+ application, WAS (Windows Activation Services) or IIS, a Windows application, or just a simple console application. When creating a custom host with Windows Forms or WPF, you can easily create a peer-to-peer solution.

Custom Hosting

Let's start with a custom host. The sample code shows hosting of a service within a console application; however, in other custom host types, such as Windows services or Windows applications, you can program the service in the same way.

In the `Main()` method, a `ServiceHost` instance is created. After the `ServiceHost` instance is created, the application configuration file is read to define the bindings. You can also define the bindings programmatically, as shown earlier. Next, the `Open()` method of the `ServiceHost` class is invoked, so the service accepts client calls. With a console application, you need to be careful not to close the main thread until the service should be closed. Here, the user is asked to "press return" to exit the service. When the user does this, the `Close()` method is called to actually end the service:

```
using System;
using System.ServiceModel;

public class Program
{
   public static void Main()
   {
      using (var serviceHost = new ServiceHost())
      {
         serviceHost.Open();

         Console.WriteLine("The service started. Press return to exit");
         Console.ReadLine();

         serviceHost.Close();
      }
   }
}
```

To abort the service host, you can invoke the `Abort()` method of the `ServiceHost` class. To get the current state of the service, the `State` property returns a value defined by the `CommunicationState` enumeration. Possible values are `Created`, `Opening`, `Opened`, `Closing`, `Closed`, and `Faulted`.

WAS Hosting

With WAS (Windows Activation Services) hosting, you get the features from the WAS worker process such as automatic activation of the service, health monitoring, and process recycling.

To use WAS hosting, you just need to create a web site and a `.svc` file with the `ServiceHost` declaration that includes the language and the name of the service class. The code shown here is using the class `Service1`. In addition, you must specify the file that contains the service class. This class is implemented in the same way that you saw earlier when defining a WCF service library.

```
<%@ServiceHost language="C#" Service="Service1" CodeBehind="Service1.svc.cs" %>
```

If you use a WCF service library that should be available from WAS hosting, you can create a `.svc` file that just contains a reference to the class:

```
<%@ ServiceHost Service="Wrox.ProCSharp.WCF.Services.RoomReservationService" %>
```

Since the introduction of Windows Vista and Windows Server 2008, WAS allows defining .NET TCP and Message Queue bindings. If you are using the previous edition, IIS 6 or IIS 5.1, which is available with Windows Server 2003 and Windows XP, activation from a `.svc` file can be done only with an HTTP binding.

Preconfigured Host Classes

To reduce the configuration necessities, WCF also offers some hosting classes with preconfigured bindings. One example is located in the assembly `System.ServiceModel.Web` in the namespace `System.ServiceModel.Web` with the class `WebServiceHost`. This class creates a default endpoint for HTTP and HTTPS base addresses if a default endpoint is not configured with the `WebHttpBinding`. Also, this class adds the `WebHttpBehavior` if another behavior is not defined. With this behavior, simple HTTP `GET` and `POST`, `PUT`, `DELETE` (with the `WebInvoke` attribute) operations can be done without additional setup.

```
Uri baseAddress = new Uri("http://localhost:8000/RoomReservation");
var host = new WebServiceHost(typeof(RoomReservationService), baseAddress);
host.Open();

Console.WriteLine("service running");
Console.WriteLine("Press return to exit...");
Console.ReadLine();

if (host.State == CommunicationState.Opened)
    host.Close();
```

code snippet RoomReservationWebServiceHost/Program.cs

To use a simple HTTP `GET` request to receive the reservations, the method `GetRoomReservation` needs a `WebGet` attribute to map the method parameters to the input from the `GET` request. In the following code, a `UriTemplate` is defined that requires `Reservations` to be added to the base address followed by `From` and `To` parameters. The `From` and `To` parameters in turn are mapped to the `fromDate` and `toDate` variables.

```
[WebGet(UriTemplate="Reservations?From={fromDate}&To={toDate}")]
public RoomReservation[] GetRoomReservations(DateTime fromDate, DateTime toDate)
{
    var data = new RoomReservationData();
    return data.GetReservations(fromDate, toDate);
}
```

code snippet RoomReservationService/RoomReservationService.cs

Now the service can be invoked with a simple request as shown. All the reservations for the specified time frame are returned.

```
http://localhost:8000/RoomReservation/Reservations?From=2010/1/1&To=2010/8/1
```

CLIENTS

A client application needs a proxy to access a service. There are three ways to create a proxy for the client:

- **Visual Studio Add Service Reference** — This utility creates a proxy class from the metadata of the service.
- **ServiceModel Metadata Utility tool (Svcutil.exe)** — You can create a proxy class with the `Svcutil` utility. This utility reads metadata from the service to create the proxy class.
- **ChannelFactory class** — This class is used by the proxy generated from `Svcutil`; however, it can also be used to create a proxy programmatically.

Adding a service reference from Visual Studio requires accessing a WSDL document. The WSDL document is created by a MEX endpoint that needs to be configured with the service. With the following configuration, the endpoint with the relative address `mex` uses the `mexHttpBinding` and implements the contract `IMetadataExchange`. To access the metadata with an HTTP `GET` request, the `behaviorConfiguration MexServiceBehavior` is configured.

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <system.serviceModel>
    <services>
      <service behaviorConfiguration=" MexServiceBehavior "
        name="Wrox.ProCSharp.WCF.RoomReservationService">
        <endpoint address="Test" binding="wsHttpBinding"
            contract="Wrox.ProCSharp.WCF.IRoomService" />
        <endpoint address="mex" binding="mexHttpBinding"
            contract="IMetadataExchange" />
        <host>
          <baseAddresses>
            <add baseAddress=
                "http://localhost:8732/Design_Time_Addresses/RoomReservationService/" />
          <baseAddresses>
        </host>
      </service>
    </services>
    <behaviors>
      <serviceBehaviors>
        <behavior name="MexServiceBehavior">
          <! — To avoid disclosing metadata information,
          set the value below to false and remove the metadata endpoint above
          before deployment — >
          <serviceMetadata httpGetEnabled="True"/>
        </behavior>
      </serviceBehaviors>
    </behaviors>
  </system.serviceModel>
</configuration>
```

Similar to the Add service reference from Visual Studio, the `Svcutil` utility needs metadata to create the proxy class. The `Svcutil` utility can create a proxy from the MEX metadata endpoint, the metadata of the assembly, or WSDL and XSD documentation:

```
svcutil http://localhost:8080/RoomReservation?wsdl /language:C# /out:proxy.cs
svcutil CourseRegistration.dll
svcutil CourseRegistration.wsdl CourseRegistration.xsd
```

After the proxy class is generated, it just needs to be instantiated from the client code, the methods need to be called, and finally the `Close()` method must be invoked:

```
var client = new RoomServiceClient();
client.RegisterForCourse(roomReservation);
client.Close();
```

The generated proxy class derives from the base class `ClientBase<TChannel>` that wraps the `ChannelFactory<TChannel>` class. Instead of using a generated proxy class, you can use the `ChannelFactory<TChannel>` class directly. The constructor requires the binding and endpoint address; next, you can create the channel and invoke methods as defined by the service contract. Finally, the factory must be closed:

```
var binding = new WsHttpBinding();
var address = new EndpointAddress("http://localhost:8080/RoomService");

var factory = new ChannelFactory<IStateService>(binding, address);

IRoomService channel = factory.CreateChannel();
channel.ReserveRoom(roomReservation);

//.
factory.Close();
```

The `ChannelFactory<TChannel>` class has several properties and methods, as shown in the following table.

CHANNELFACTORY MEMBERS	DESCRIPTION
`Credentials`	`Credentials` is a read-only property to access the `ClientCredentials` object that is assigned to the channel for authentication with the service. The credentials can be set with the endpoint.
`Endpoint`	`Endpoint` is a read-only property to access the `ServiceEndpoint` that is associated with the channel. The endpoint can be assigned in the constructor.
`State`	The `State` property is of type `CommunicationState` and returns the current state of the channel. `CommunicationState` is an enumeration with the values `Created`, `Opening`, `Opened`, `Closing`, `Closed`, and `Faulted`.
`Open()`	The `Open()` method is used to open the channel.
`Close()`	The `Close()` method closes the channel.
`Opening Opened Closing Closed Faulted`	You can assign event handlers to get informed about state changes of the channel. Events are fired before and after the channel is opened, before and after the channel is closed, and in case of a fault.

DUPLEX COMMUNICATION

The next sample application shows how a duplex communication can be done between the client and the service. The client starts the connection to the service. After the client connects to the service, the service can call back into the client.

For duplex communication, a contract must be specified that is implemented in the client. Here the contract for the client is defined by the interface `IMyMessageCallback`. The method implemented by the client is `OnCallback()`. The operation has the operation contract setting `IsOneWay=true` applied. This way, the service doesn't wait until the method is successfully invoked on the client. By default, the service instance can be invoked from only one thread (see the `ConcurrencyMode` property of the service behavior, which is, by default, set to `ConcurrencyMode.Single`).

If the service implementation now does a callback to the client and waits to get an answer from the client, the thread getting the reply from the client must wait until it gets a lock to the service object. Because the service object is already locked by the request to the client, a deadlock occurs. WCF detects the deadlock and throws an exception. To avoid this situation, you can change the `ConcurrencyMode` property to the value `Multiple` or `Reentrant`. With the setting `Multiple`, multiple threads can access the instance concurrently. Here, you must implement locking on your own. With the setting `Reentrant`, the service instance stays single-threaded, but allows answers from callback requests to reenter the context. Instead of changing the concurrency mode, you can specify the `IsOneWay` property with the operation contract. This way, the caller does not wait for a reply. Of course, this setting is possible only if return values are not expected.

The contract of the service is defined by the interface `IMyMessage`. The callback contract is mapped to the service contract with the `CallbackContract` property of the service contract definition:

```
public interface IMyMessageCallback
{
   [OperationContract(IsOneWay=true)]
   void OnCallback(string message);
}

[ServiceContract(CallbackContract=typeof(IMyMessageCallback))]
public interface IMyMessage
{
   [OperationContract]
   void MessageToServer(string message);
}
```

code snippet MessageService/IMyMessage.cs

The class `MessageService` implements the service contract `IMyMessage`. The service writes the message from the client to the console. To access the callback contract, you can use the `OperationContext` class. `OperationContext.Current` returns the `OperationContext` that is associated with the current request from the client. With the `OperationContext`, you can access session information, message headers and properties, and, in the case of a duplex communication, the callback channel. The generic method `GetCallbackChannel()` returns the channel to the client instance. This channel can then be used to send a message to the client by invoking the method `OnCallback()`, which is defined with the callback interface `IMyMessageCallback`. To demonstrate that it is also possible to use the callback channel from the service independently of the completion of the method, a new thread that receives the callback channel is created. The new thread sends messages to the client by using the callback channel.

```
public class MessageService: IMyMessage
{
   public void MessageToServer(string message)
   {
      Console.WriteLine("message from the client: {0}", message);
      IMyMessageCallback callback =
            OperationContext.Current.
```

```
                GetCallbackChannel<IMyMessageCallback>();

         callback.OnCallback("message from the server");

         new Thread(ThreadCallback).Start(callback);
      }

      private void ThreadCallback(object callback)
      {
         IMyMessageCallback messageCallback = callback as IMyMessageCallback;
         for (int i = 0; i < 10; i++)
         {
            messageCallback.OnCallback("message " + i.ToString());
            Thread.Sleep(1000);
         }
      }
   }
```

code snippet MessageService/MessageService.cs

Hosting the service is the same as it was with the previous samples, so it is not shown here. However, for duplex communication, you must configure a binding that supports a duplex channel. One of the bindings supporting a duplex channel is `wsDualHttpBinding`, which is configured in the application's configuration file:

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <system.serviceModel>
    <services>
      <service name="Wrox.ProCSharp.WCF.MessageService">
        <endpoint contract="Wrox.ProCSharp.WCF.IMyMessage"
            binding="wsDualHttpBinding"/>
        <host>
          <baseAddresses>
            <add baseAddress="http://localhost:8732/Service1" />
          </baseAddresses>
        </host>
      </service>
    </services>
  </system.serviceModel>
</configuration>
```

code snippet MessageService/app.config

With the client application, the callback contract must be implemented as shown here with the class `ClientCallback` that implements the interface `IMyMessageCallback`:

```
class ClientCallback: IMyMessageCallback
{
   public void OnCallback(string message)
   {
      Console.WriteLine("message from the server: {0}", message);
   }
}
```

code snippet MessageClient/Program.cs

With a duplex channel, you cannot use the `ChannelFactory` to initiate the connection to the service as was done previously. To create a duplex channel, you can use the `DuplexChannelFactory` class. This class has a constructor with one more parameter in addition to the binding and address configuration. This parameter specifies an `InstanceContext` that wraps one instance of the `ClientCallback` class. When passing this instance to the factory, the service can invoke the object across the channel. The client just needs to keep the connection open. If the connection is closed, the service cannot send messages across it.

```
var binding = new WSDualHttpBinding();
var address = new EndpointAddress("http://localhost:8732/Service1");

ClientCallback clientCallback = new ClientCallback();
InstanceContext context = new InstanceContext(clientCallback);

DuplexChannelFactory<IMyMessage> factory =
   new DuplexChannelFactory<IMyMessage>(context, binding, address);

IMyMessage messageChannel = factory.CreateChannel();

messageChannel.MessageToServer("From the client");
```

Duplex communication is achieved by starting the service host and the client application.

SUMMARY

In this chapter, you learned how to use Windows Communication Foundation for communication between a client and a server. WCF is platform-independent like ASP.NET Web services, but it offers features similar to .NET Remoting, Enterprise Services, and Message Queuing.

WCF has a heavy focus on contracts to make it easier to isolate developing clients and services, and to support platform independence. It defines three different contract types: service contracts, data contracts, and message contracts. You can use several attributes to define the behavior of the service and its operations.

You saw how to create clients from the metadata offered by the service and also by using the .NET interface contract. You learned the features of different binding options. WCF offers not only bindings for platform independence but also bindings for fast communication between .NET applications. You've seen how to create custom hosts and also make use of the WAS host. You saw how duplex communication is achieved by defining a callback interface, applying a service contract, and implementing a callback contract in the client application.

The next few chapters continue with WCF features. In Chapter 44 you learn about Windows Workflow Foundation and how WCF is used to communicate with workflow instances. Chapter 46 explains how disconnected Message Queuing features can be used with WCF bindings. Chapter 47 is about the syndication features of WCF. And in Chapter 51 (available as a download), you learn how to integrate Enterprise Services with WCF.

44 Windows Workflow Foundation 4

WHAT'S IN THIS CHAPTER?

- ➤ The different types of workflows that can be created
- ➤ A description of some of the built-in activities
- ➤ How to create custom activities
- ➤ Overview of a workflow

This chapter presents an overview of the Windows Workflow Foundation 4 (referred to as Workflow 4 throughout the rest of this chapter), which provides a model to define and execute processes using a set of building blocks called *activities*. WF provides a Designer that, by default, is hosted within Visual Studio, and that allows you to drag and drop activities from the toolbox onto the design surface to create a workflow template.

This template can then be executed in a number of different ways, which we explain throughout the chapter. As a workflow executes, it may need to access the outside world, and there are a couple of methods that are typically used that allow you to do this. In addition, a workflow may need to save and restore its state, for example, when a long wait is needed.

A workflow is constructed from a number of activities, and these activities are executed at runtime. An activity might send an e-mail, update a row in a database, or execute a transaction on a back-end system. There are a number of built-in activities that can be used for general-purpose work, and you can also create your own custom activities and plug these into the workflow as necessary.

With Visual Studio 2010, there are now effectively two versions of Workflow — the 3.*x* version, which shipped with the .NET Framework 3, and version 4, which ships with the .NET Framework 4. This chapter concentrates on the latest version of Workflow — for details of the previous version see Chapter 57, "Windows Workflow Foundation 3.0," which is available online.

While there is broad feature parity between the versions, there are many subtle differences. If you are using Workflow for the first time, we urge you to use the latest version; however, if you have already used version 3.*x*, there are some tips in Chapter 57 to assist you in moving to Workflow 4.

We begin with the canonical example that everyone uses when faced with a new technology — Hello World.

HELLO WORLD

Visual Studio 2010 contains built-in support for creating workflow projects for both the 3.*x* and version 4 of the frameworks, and when you open the New Project dialog you will see a list of workflow project types, as shown in Figure 44-1.

FIGURE 44-1

Ensure that you select .NET Framework 4 from the version combo box, and then choose Workflow Console Application from the available templates. This will construct a simple console application that includes a workflow template and also a main program, which executes this template.

Next, drag a `WriteLine` activity from the toolbox onto the design surface so that you have a workflow that looks like the one shown in Figure 44-2.

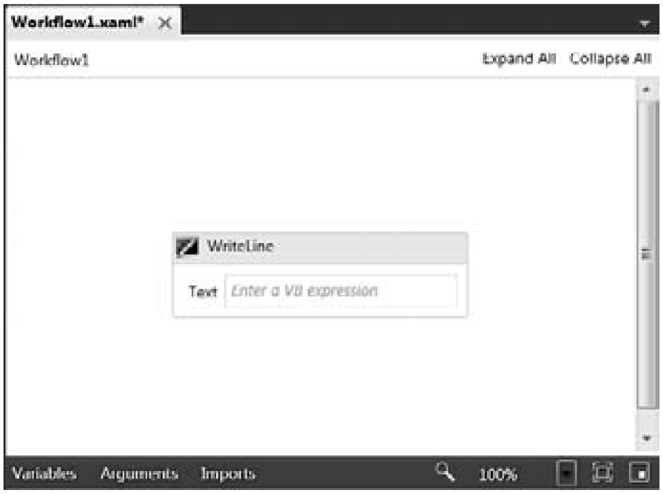

FIGURE 44-2

The WriteLine activity includes a Text property that you can set either on the design surface itself by simply entering text inline, or by displaying the property grid. Later in this chapter, we show you how to define your custom activities to use this same behavior.

The Text property is not just a simple string — it's actually defined as an argument type that can use an expression as its source. Expressions are evaluated at runtime to yield a result, and it is this textual result that is used as the input to the WriteLine activity. To enter a simple text expression, you must use double quotation marks — so if you are following along with this in Visual Studio, type "Hello World" into the Text property. If you omit the quotation marks, you will receive a compiler error, as without quotation marks this is not a legal expression.

If you build and run the program, you will see the output text on the console. When the program executes, an instance of the workflow is created in the Main method, which uses a static method of the WorkflowInvoker class to execute the instance. The code for this example is available in the 01_HelloWorld solution.

The WorkflowInvoker class is new to Workflow 4, and it lets you synchronously invoke a workflow. There are two other methods of workflow execution that execute workflows asynchronously, which you'll see later in this chapter. Synchronous execution was possible in Workflow 3.*x* but was somewhat more difficult to set up, and there was a lot more overhead.

The synchronous nature of WorkflowInvoker makes it ideal for running short-lived workflows in response to some UI action — you could use a workflow here to enable or disable some elements of the UI. While it was possible to do this in Workflow 3.*x*, it was also more difficult to synchronously execute a given workflow instance.

ACTIVITIES

Everything in a workflow is an activity, including the workflow itself. The workflow is a specific type of activity that typically allows other activities to be defined within it — this is known as a composite activity, and you'll see other composite activities later in this chapter. An activity is just a class that ultimately derives from the abstract Activity class.

The class hierarchy is somewhat deeper than that defined for Workflow 3.*x*, and the main classes are defined in Figure 44-3.

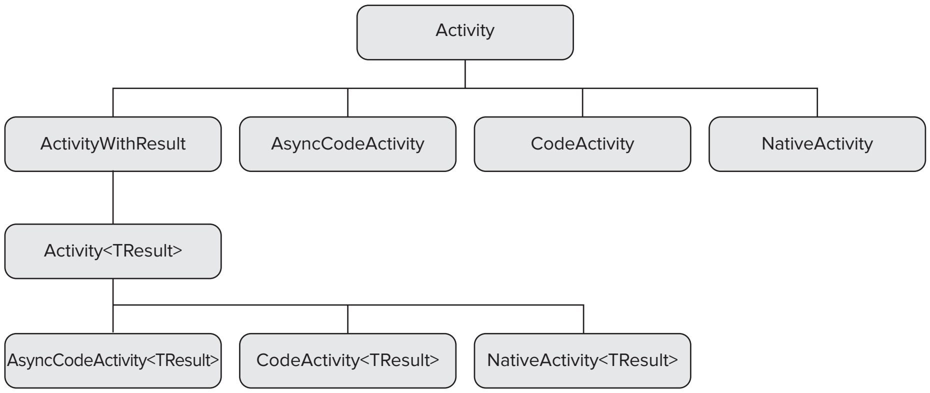

FIGURE 44-3

The Activity class is the root for all workflow activities and typically you will derive custom activities from the second tier. To create a simple activity like the WriteLine activity previously mentioned, you would derive from CodeActivity, as this class has just enough functionality for your write line clone to function. Activities that execute and return some form of a result should derive from the `ActivityWithResult` class — and note that it is preferable to use the generic `Activity<TResult>` class here as that provides a strongly typed `Result` property.

Deciding which base class to derive from can be the main battle when constructing custom activities, and we show you examples in this chapter to assist with choosing the right base class.

In order for an activity to do something, it will typically override the `Execute()` method, which has a number of different signatures depending on the base class chosen. These signatures are shown in the following table.

BASE CLASS	EXECUTE METHOD

`AsyncCodeActivity`	`IAsyncResult BeginExecute(AsyncCodeActivityContext, AsyncCallback, object)`
	`void EndExecute(AsyncCodeActivityContext, IAsyncResult)`

`CodeActivity`	`void Execute (CodeActivityContext)`
`NativeActivity`	`void Execute (NativeActivityContext)`

`AsyncCodeActivity<TResult>`	`IAsyncResult BeginExecute(AsyncCodeActivityContext, AsyncCallback, object)`
	`TResult EndExecute(AsyncCodeActivityContext, IAsyncResult)`

`CodeActivity<TResult>`	`TResult Execute (CodeActivityContext)`
`NativeActivity<TResult>`	`void Execute (NativeActivityContext)`

Here you may notice that the parameter(s) passed into the `Execute` methods differ in that there are type-specific execution context parameters used. In Workflow 3.*x*, there was a single class used (the `ActivityExecutionContext`); however, in Workflow 4 we use different contexts for different classes of activity.

The main difference is that the `CodeActivityContext` (and by derivation the `AsyncCodeActivityContext`) has a limited set of functionality compared with the `NativeActivityContext`. This means that activities deriving from `CodeActivity` and `AsyncCodeActivity` can do far less with their container. As an example, the `WriteLine` activity presented earlier only needs to write to the console. Therefore, it doesn't need access to its runtime environment. A more complex activity might need to schedule other child activities or communicate with other systems, in which case you would need to derive from `NativeActivity` in order to access the full runtime. We revisit this topic when you create your own custom activities.

Numerous standard activities are provided with WF, and the following sections provide examples of some of these together with scenarios in which you might use these activities. Workflow 4 uses three main assemblies: `System.Activities.dll`, `System.Activities.Core.Presentation.dll`, an `System.Activities.Presentation.dll`.

If Activity

As its name implies, this activity acts like an `If-Else` statement in C#.

When you drop an `If` onto the design surface, you will see an activity, as displayed in Figure 44-4. The `If` is a composite activity that contains two child activities that are dropped into the Then and Else portions of the screen.

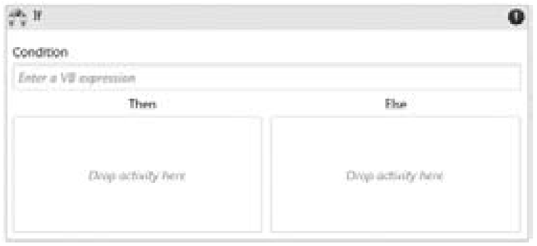

FIGURE 44-4

The If activity shown in Figure 44-4 also includes a glyph indicating that the Condition property needs to be defined. This condition is evaluated when the activity is executed; if it returns True, the Then branch will execute, otherwise the Else branch will be called.

The Condition property is an expression that evaluates to a Boolean value, so you can include any expression here that is valid.

Workflow 4 includes an expression engine that uses Visual Basic syntax. This might seem strange to a C# programmer, as VB is significantly different from C#. Unfortunately, that is the way it is at the moment, so to use the built-in activities you'll have to learn enough VB to get by. Just remember to be extremely verbose and leave off any semicolons and you'll be OK.

An expression can reference any variables defined in the workflow and also access many static classes available in the .NET framework. So you could, for example, define an expression based on the Environment.Is64BitOperatingSystem value, if that was crucial to some part of your workflow. Naturally, you can define arguments that are passed into the workflow and that can then be evaluated by an expression inside an If activity. We'll cover arguments and variables later in the chapter.

InvokeMethod Activity

This is one of the most useful activities in the box, as it allows you to execute code that already exists and effectively wrap that code within the execution semantics of a workflow.

It's typical to have a lot of preexisting code, and this activity allows you to call that code directly from within a workflow.

There are two ways that you can use InvokeMethod to call code; which method you use depends on whether you wish to call a static method or an instance method. If you're calling a static method, you need to define the TargetType and the MethodName parameters. However if you're calling an instance method, then the TargetObject and MethodName properties are used, and in this instance the TargetObject could be created inline, or it could be a variable defined somewhere within the workflow itself. The example code in the 02_ParallelExecution sample shows both modes of using the InvokeMethod activity.

If you need to pass arguments to the method you're invoking, you can define these using the Parameters collection. The order of the parameters in the collection must match the order of the parameters to the method. In addition, there is a Result property that is set to the return value of the function call. You can bind this to a variable within the workflow in order to use the value as appropriate.

Parallel Activity

The Parallel activity is rather poorly named because, at first sight, you might think that on a multiprocessor machine this activity would schedule its children in true parallel; however, that isn't the case apart from some special circumstances.

After you drop a Parallel activity onto the design surface, you can then drop in other subordinate activities, as shown in Figure 44-5.

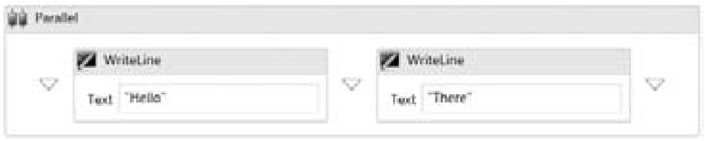

FIGURE 44-5

These child activities can be singular activities, as in Figure 44-5, or they can form a composite activity, such as a Sequence or another Parallel activity.

At runtime, the `Parallel` activity schedules each immediate child for execution. The underlying runtime execution engine will then schedule these children in a FIFO (first in, first out) manner, thereby providing the illusion of parallel execution; however, they run only on a single thread.

To include true parallel execution, the activities you drop into the `Parallel` activity must be derived from the `AsyncCodeActivity` class. The sample code in `02_ParallelExecution` includes an example that shows how to asynchronously process code within two branches of a `Parallel` activity. Figure 44-6 shows the use of two `InvokeMethod` activities within a `Parallel` activity.

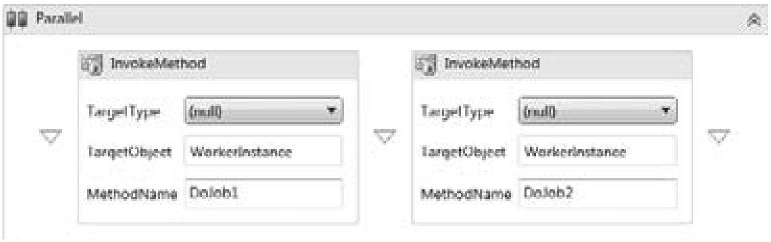

FIGURE 44-6

The `InvokeMethod` activities used here call two simple methods, `DoJob1` and `DoJob2`, which sleep for two and three seconds, respectively. In order to run these methods asynchronously, there is one final change that is needed. The `InvokeMethod` activity has a `Boolean RunAsynchronously` property that defaults to `False`. Setting this in the UI to `True` then calls the target method asynchronously, thereby allowing the `Parallel` activity to execute more than one activity at the same time. With a uni-processor machine, two threads will execute, giving the illusion of simultaneous execution; however, on a multiprocessor machine, these threads may well be scheduled on different cores, thereby providing true parallel execution. If you are creating your own activities, it is worthwhile creating these as asynchronous activities, as then the end user can get the benefits of true parallel execution.

Delay Activity

Business processes often need to wait for a period before completing. Consider using a workflow for expense approval. Your workflow might send an e-mail to your immediate manager asking him or her to approve your expense claim. The workflow then enters a waiting state where it waits for approval (or, horror of horrors, rejection); but it would also be nice to define a timeout so that if no response is returned within, say, one day, the expense claim is then routed to the next manager up the chain of command.

The `Delay` activity can form part of this scenario (the other part is the `Pick` activity defined in the next section). Its job is to wait for a predefined time before continuing execution of the workflow.

The `Delay` activity contains a `Duration` property, which can be set to a discrete `TimeSpan` value, but, as it is defined as an expression, this value could be linked to a variable within the workflow or computed from some other values as required.

When a workflow is executed, it enters an `Idle` state in which it runs a `Delay` activity. Workflows that are idle are candidates for persistence — this is where the workflow instance data is stored within a persistent medium (such as a SQL Server database), and the workflow itself can then be unloaded from memory. This conserves system resources, as only running workflows need to be in memory at any given time. Any workflows that are delayed will be persisted to disk.

Pick Activity

A common programming construct is to wait for one of a set of possible events — one example of this is the `WaitAny` method of the `WaitHandle` class in the `System.Threading` namespace. The `Pick` activity is the way to do this in a workflow because it can define any number of branches, and each branch can wait for a trigger action to occur before running. Once a trigger has been fired, the other activities within that branch execute.

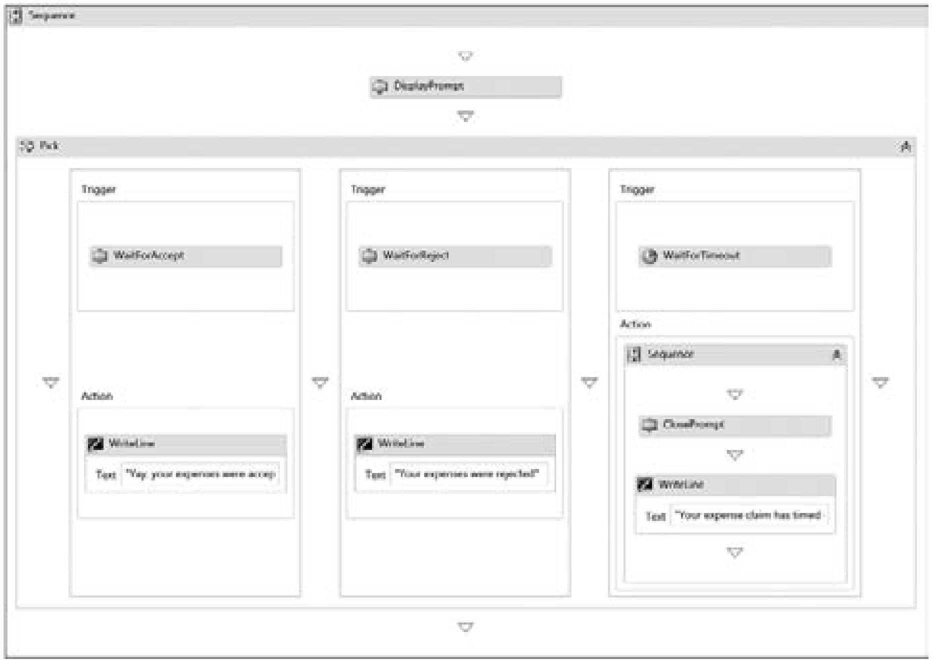
As a concrete example, consider the expense claims procedure outlined in the previous section. Here, we'll have a `Pick` activity with three branches — one to deal with accepted claims, one to deal with rejected claims, and a third to deal with a timeout.

The example is available in the `03_PickDemo` code in the download. This contains a sample workflow consisting of a `Pick` activity and three branches. When it is run, you are prompted to accept or reject the claim. If 10 seconds or more elapses, it'll close this prompt and run the delay branch instead.

In the example, the `DisplayPrompt` activity is used as the first activity in the workflow. This calls a method defined on an interface that would prompt the manager for approval or rejection. Because this functionality is defined as an interface, the prompt could be an e-mail, an IM message, or any other manner of notifying your manager that an expense claim needs to be processed. The workflow then executes the `Pick`, which awaits input from this external interface (either an approval or a rejection) and also waits on a delay.

When the pick executes, it effectively queues a wait on the first activity in each branch, and when one event is triggered, this cancels all other waiting events and then processes the rest of the branch where the event was raised. So, in the instance where the expense report is approved, the `WaitForAccept` activity completes and then the next action is to write out a confirmation message. If, however, your manager rejects the claim, the `WaitForReject` activity completes, and in the example this then outputs a rejection message.

Lastly, if neither the `WaitForAccept` nor `WaitForReject` activities completes, the `WaitForTimeout` ultimately completes after its delay expires, and the expense report could then be routed to another manager — potentially looking up that person in Active Directory. In the example, a dialog is displayed to the user when the `DisplayPrompt` activity is executed, so if the delay executes, you also need to close the dialog, which is the purpose of the activity named `ClosePrompt` in Figure 44-7.



Text "Yay, your expenses were accep

Text "Your expenses were rejected"

Text "Your expense claim has timed

FIGURE 44-7

Some concepts used in that example have not been covered yet — such as how to write custom activities or waiting on external events; however, we cover these topics later in the chapter.

CUSTOM ACTIVITIES

So far, you have used activities that are defined within the `System.Activities` namespace. In this section, you learn how to create custom activities and extend these activities to provide a good user experience at both design time and runtime.

To begin, you create a `DebugWrite` activity that can be used to output a line of text to the console in debug builds. Although this is a trivial example, it will be expanded to show the full gamut of options available for custom activities using this example. When creating custom activities, you can simply construct a class within a workflow project; however, it is preferable to construct your custom activities inside a separate assembly, because the Visual Studio design-time environment (and specifically workflow projects) will load activities from your assemblies and can lock the assembly that you are trying to update. For this reason, you should create a simple class library project to construct your custom activities within. The code for this example is available in the `04_CustomActivities` project.

A simple activity, such as the `DebugWrite` activity, will be derived directly from the `CodeActivity` base class. The following code shows a constructed activity class and defines a `Message` property that is displayed when the activity is executed:

```
using System;
using System.Activities;
using System.Diagnostics;

namespace Activities
{
    public class DebugWrite : CodeActivity
    {
        [Description("The message output to the debug stream")]
        public InArgument<string> Message { get; set; }

        protected override void Execute(CodeActivityContext context)
        {
            Debug.WriteLine(Message.Get(context));
        }
    }
}
```

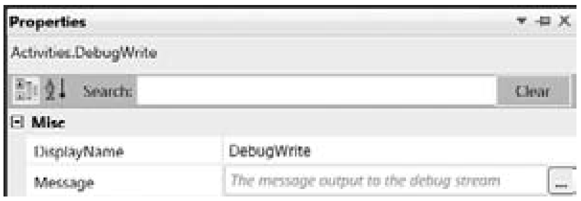
code download 04_CustomActivities

When a `CodeActivity` is scheduled for execution, its `Execute` method is called — this is where the activity actually needs to do something.

In the example, we have defined the `Message` property, which looks like a regular .NET property; however, its usage inside the `Execute` method may be unfamiliar. One of the many changes made in Workflow 4 is where state data is stored. Within Workflow 3.*x*, it was common to use standard .NET properties and store activity data within the activity itself. The problem with that method was that this storage was effectively opaque to the workflow runtime engine, and so in order to persist a workflow, it was necessary to perform binary persistence on all constructed activities in order to faithfully restore their data.

With Workflow 4, all data is stored outside of the individual activities — so the model here is that in order to get the value of an argument, you ask the context for the value, and in order to set the value of an argument, you provide the new value to the context. In this way, the workflow engine can track changes to state as the workflow executes and potentially stores only the changes between persistence points rather than the entire workflow data.

The [Description] attribute defined on the Message property is used within the property grid in Visual Studio to provide extra information about the property, as shown in Figure 44-8.



Properties
Activities.DebugWrite
Search: Clear
Misc
DisplayName	DebugWrite
Message	The message output to the debug stream

FIGURE 44-8

As it stands, the activity is perfectly usable; however, there are several areas that should be addressed to make this more user-friendly. As you have seen with activities such as the Pick earlier in the chapter, an activity may have some mandatory properties that, when not defined, produce an error glyph on the design surface. To get the same behavior from your activity, you need to extend the code.

Activity Validation

When an activity is placed on the design surface, the Designer will look in two places for validation information. The simplest form of validation is to add a [RequiredArgument] attribute to the argument property. If the argument is not defined, the exclamation mark glyph is shown to the right of the activity name, as in Figure 44-9.

FIGURE 44-9

If you hover over the glyph, a tooltip is displayed that states "Value for a required activity argument 'Message' was not supplied." This is a compilation error, so you need to define a value for this argument before you can execute your application.

In the case where there are multiple properties that may be related, you can override the CacheMetadata method to add on some extra validation code. This method is called prior to the activity being executed; within it you can check that mandatory arguments are defined and optionally add extra metadata to the passed argument. You can also add extra validation errors (or warnings) by calling one of the AddValidationError overrides on the CodeActivityMetadata object passed to the CacheMetadata method.

Now that you have completed the activity validation, the next thing to do is to change the rendering behavior of the activity, as the current Designer experience is provided for you, and it could stand to be made more interesting.

Designers

When an activity is rendered onscreen, it is typical to associate a designer with the activity. The job of the designer is to provide the on-screen representation of that activity, and in Workflow 4 this representation is done in XAML. If you haven't used XAML before we recommend looking at Chapter 35, "Core WPF," before continuing.

The design-time experience for an activity is typically created in a separate assembly from the activity itself, as this design experience is unnecessary at runtime. Visual Studio includes an Activity Designer Library project type that is an ideal starting point, as when you create a project using this template you're provided with a default activity designer that you can then alter as appropriate.

Within the XAML for your designer, you can provide anything you wish — including animations, if you so desire. Less is usually more when it comes to user interfaces, and we suggest looking at the preexisting activities in order to get a feel for what is appropriate.

First, we'll create a simple designer and associate this with the DebugWrite activity. The code that follows shows the template created for you when you add an activity designer to your project (or when you construct a new activity designer library project). Again, this code is available in the 04_CustomActivities solution.

```
<sap:ActivityDesigner x:Class="Activities.Presentation.DebugWriteDesigner"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
    xmlns:sap="clr-namespace:System.Activities.Presentation;
               assembly=System.Activities.Presentation"
    xmlns:sapv="clr-namespace:System.Activities.Presentation.View;
                assembly=System.Activities.Presentation">
  <Grid>

  </Grid>
</sap:ActivityDesigner>
```

code download 04_CustomActivities

The XAML created simply constructs a grid and also includes some imported namespaces, which may be needed by your activity. Obviously, there is little content within the template, so to begin we add in a label and a text box that will be used to define the message.

```
<Grid>
    <Grid.ColumnDefinitions>
        <ColumnDefinition Width="Auto"/>
        <ColumnDefinition Width="*"/>
    </Grid.ColumnDefinitions>
    <TextBlock Text="Message" Margin="0,0,5,0"/>
    <TextBox Text="{Binding Path=ModelItem.Message, Mode=TwoWay}"
        Grid.Column="1"/>
</Grid>
```

The XAML here constructs a binding between the `Message` property of the activity and the text box. Within the designer XAML, you can always reference the activity being designed by using the `ModelItem` reference.

In order to associate the designer defined above with the `DebugWrite` activity, you also need to alter the activity and add on a `Designer` attribute (you can also implement the `IRegisterMetadata` interface but we don't cover that further in this chapter).

```
[Designer("Activities.Presentation.DebugWriteDesigner, Activities.Presentation")]
public class DebugWrite : CodeActivity
{
    ...
}
```

Here, we've used the `[Designer]` attribute to define the link between the designer and the activity. It's good practice to use the string version of this attribute, as that ensures that there is no reference to the design assembly within the activity assembly.

Now when you use an instance of the `DebugWrite` activity within Visual Studio, you'll see something like Figure 44-10.

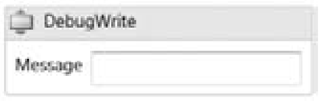


FIGURE 44-10

The problem with this, however, is the `Message` property — it's not showing the value defined within the property grid, and if you try to set a value by typing it into the text box, you'll receive an exception. The reason is that you're trying to bind a simple text value to an `InArgument<string>` type, and in order to do that, you need to use another couple of built-in classes that come with Workflow 4 — the `ExpressionTextBox` and the `ArgumentToExpressionConverter`. The full XAML for the designer is now as follows. We have added boldface to the lines that have been added or modified.

```
<sap:ActivityDesigner x:Class="Activities.Presentation.DebugWriteDesigner"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
    xmlns:sap="clr-namespace:System.Activities.Presentation;
        assembly=System.Activities.Presentation"
    xmlns:sapv="clr-namespace:System.Activities.Presentation.View;
        assembly=System.Activities.Presentation"
    xmlns:sadc="clr-namespace:System.Activities.Presentation.Converters;
```

```
            assembly=System.Activities.Presentation"
        >
        <sap:ActivityDesigner.Resources>
            <sadc:ArgumentToExpressionConverter x:Key="argConverter"/>
        </sap:ActivityDesigner.Resources>
        <Grid>
            <Grid.ColumnDefinitions>
                <ColumnDefinition Width="Auto"/>
                <ColumnDefinition Width="*"/>
            </Grid.ColumnDefinitions>
            <TextBlock Text="Message" Margin="0,0,5,0" />
            <sapv:ExpressionTextBox Grid.Column="1"
                Expression="{Binding Path=ModelItem.Message, Mode=TwoWay,
                             Converter={StaticResource argConverter},
                             ConverterParameter=In}"
                OwnerActivity="{Binding ModelItem}"/>
        </Grid>
    </sap:ActivityDesigner>
```

code download 04_CustomActivitiesFirst

We have included a new namespace in the file — the `System.Activities.Presentation.View`. This includes the converter used to convert between an expression onscreen and the `Message` property of the activity — this is the `ArgumentToExpressionConverter`, which has been added to the resources of the XAML file.

Then we replaced the standard `TextBox` control with an `ExpressionTextBox`. This control is used to permit the user to enter expressions as well as simple text, so the `DebugWrite` activity could include an expression combining many values from the running workflow, rather than just a simple text string. With those changes in place, the activity behaves much more like the built-in activities.

Custom Composite Activities

A common requirement with activities is to create a composite activity — that is, an activity that contains other child activities. You have already seen examples, such as the `Pick` activity and the `Parallel` activity. The execution of a composite activity is entirely up to the programmer — you could, for example, have a random activity that only schedules one of its children, or an activity that bypasses some children based on the current day of the week. The simplest execution pattern would be to execute all children, but as the developer you can decide how child activities are executed and also when your activity is complete.

The first type of composite activity we create is a “retry” activity. It is quite common to try an operation, and if it fails, retry it a number of times before having it fail. The pseudo-code for this activity is as follows:

```
int iterationCount = 0;
bool looping = true;
while ( looping )
{
  try
  {
    // Execute the activity here
    looping = false;
  }
  catch (Exception ex)
  {
    iterationCount += 1;
    if ( iterationCount >= maxRetries )
      rethrow;
  }
}
```

What we would like to do is replicate the preceding code as an activity and insert the activity we wish to execute where the comment is placed. You might consider doing this all within the `Execute` method of a custom activity. However, there is another way — you can code the whole lot using other activities. What we need to do is create a custom activity that contains a “hole” into which the end user can place the activity that will be retried, and then a maximum retry count property. The code that follows shows how this can be done.

```
public class Retry : Activity
{
    public Activity Body { get; set; }

    [RequiredArgument]
    public InArgument<int> NumberOfRetries { get; set; }

    public Retry()
    {
        Variable<int> iterationCount =
            new Variable<int> ( "iterationCount", 0 );
        Variable<bool> looping = new Variable<bool> ( "looping", true );

        this.Implementation = () =>
        {
            return new While
            {
                Variables = { iterationCount, looping },
                Condition = new VariableValue<bool>
                    { Variable = looping },
                Body = new TryCatch
                {
                    Try = new Sequence
                    {
                        Activities =
                        {
                            this.Body,
                            new Assign
                            {
                                To = new OutArgument<bool> ( looping ),
                                Value = new InArgument<bool>
                                    { Expression = false }
                            }
                        }
                    },
                    Catches =
                    {
                        new Catch<Exception>
                        {
                            Action = new ActivityAction<Exception>
                            {
                                Handler = new Sequence
                                {
                                    Activities =
                                    {
                                        new Assign
                                        {
                                            To = new OutArgument<int>
                                                (iterationCount) ,
                                            Value = new InArgument<int>
                                  (ctx => iterationCount.Get(ctx) + 1)
                                        },
                                        new If
                                        {
                                            Condition = new InArgument<bool>
                                                (env=>iterationCount.Get(env)
                                                          >= NumberOfRetries.Get(env)),
                                                   Then = new Rethrow()
                                               }
                                           }
                                       }
                                   }
                               }
                           }
                       }
                   };
               };
           }
       }
```

code download 04_CustomActivities

Phew!

First, we've defined a `Body` property of type `Activity` — this will be the activity that is executed within the retry loop. Then we've defined the `RetryCount` property, which is used to define the number of times the operation will be tried.

This custom activity derives directly from the `Activity` class and provides the implementation as a function. When a workflow is executed that contains this activity, it will effectively execute the function, which provides a runtime execution path similar to the pseudo-code defined earlier. Within the constructor, we create the local variables used by the activity and then construct a set of activities that matches the pseudo-code. The code for this example is also available in the `04_CustomActivities` solution.

From the preceding, you'll also be able to infer that we can create workflows without XAML — there is no design experience (that is, you can't drag and drop activities to generate code); however, if code is what you prefer, then there's no reason not to use it instead of XAML.

Now that you have the custom composite activity, you'll also need to define a designer. What's needed here is an activity that has a placeholder into which you can drop another activity. If you look at other standard activities, there are several that exhibit a similar behavior, such as the `If` and `Pick` activities. Ideally, you would like the activity to work in a similar manner to the built-in activities, so it's time to look at their implementations.

If you use Reflector to poke around inside the workflow libraries, you'll find a distinct lack of any designer XAML. This is because it's been compiled into the assemblies as a set of resources. You can use Reflector to look at these resources, but first you need to download the BAML viewer add-on. This decompiles the binary BAML format and produces text, so you can use it to view the XAML used by the standard activities. To find the BAML viewer, search for "Reflector BAML viewer" online, and you'll soon find it.

When you have the add-in loaded in Reflector, load up the `System.Activities.Presentation` assembly, and then click the BAML Viewer item on the Tools menu. This will then present you with a list of all the BAML resources in the currently loaded assemblies, and you can then look at an appropriate sample in order to see some sample XAML.

I used this method to learn about the XAML that was used for the built-in activities, and this helped me to construct the example for the Retry activity shown in Figure 44-11.

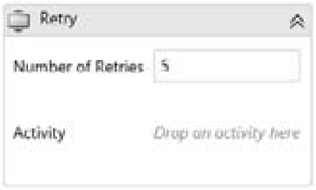

FIGURE 44-11

The key to this activity is the `WorkflowItemPresenter` class, which is used in the XAML to define the placeholder for the child activity. This is defined as follows:

```
<sap:WorkflowItemPresenter IsDefaultContainer="True"
     AllowedItemType="{x:Type sa:Activity}"
     HintText="Drop an activity here" MinWidth="100" MinHeight="60"
     Item="{Binding Path=ModelItem.Body, Mode=TwoWay}"
     Grid.Column="1" Grid.Row="1" Margin="2">
```

This control is bound to the `Body` property of the `Retry` activity, and the `HintText` defines the help text shown when no child activity has been added to the control. The XAML also includes some styles that are used to show the expanded or contracted version of the designer — this ensures that the activity works the same way as the built-in activities. All of the code and XAML for this example is available in the `04_CustomActivities` solution.

WORKFLOWS

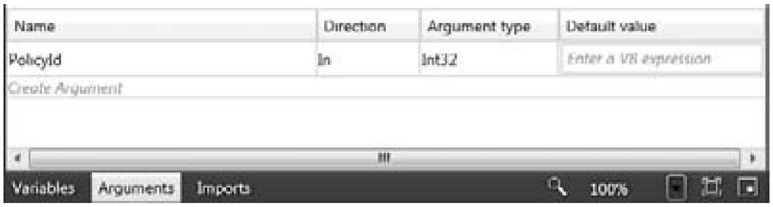
Up to this point, the chapter has concentrated on activities but has not discussed workflows. A workflow is simply a list of activities, and indeed a workflow itself is just another type of activity. Using this model simplifies the runtime engine, because the engine just needs to know how to execute one type of object — that being anything derived from the `Activity` class.

You've already seen the `WorkflowExecutor` class, which can be used to execute a workflow, but as mentioned at the time, this is only one of the ways that a workflow can be executed. There are three different options for executing workflows, and each has different capabilities. Before getting into the other methods of executing workflows, we must delve into arguments and variables.

Arguments and Variables

A workflow can be considered a program, and one of the facets of any programming language is the ability to create variables, and pass arguments into and out of that program. Naturally, Workflow 4 supports both constructs, and in this section we show you how you can define both arguments and variables.

To begin with, let's assume that the workflow is processing an insurance policy, so a likely argument to pass to the workflow would be the policy ID. In order to define an argument to a workflow, you need to go into the Designer and click on the Arguments button on the bottom left. This brings up a list of arguments defined for the workflow, as shown in Figure 44-12, and here you can also add your own.



Name	Direction	Argument type	Default value
PolicyId	In	Int32	Enter a VB expression
Create Argument			

FIGURE 44-12

To define an argument, you need to specify the Name, Direction (which can be `In`, `Out`, or `InOut`) and the data type for that argument. You can optionally specify a default value, which will be used if the argument is not provided.

The direction of the argument is used to define whether the argument is expected as an input to the workflow, as an output from the workflow, or in the case of the `InOut` direction, as both an input and output.

In the first section of this chapter, we described using the `WorkflowInvoker` class to execute a workflow. There are several overrides of the `Invoke` method that can be used to pass arguments into the workflow. They are passed as a dictionary of name/value pairs, where the name must match the argument's name exactly — this match is case sensitive. The code below is used to pass a `PolicyId` value into a workflow — the code for this example is available in the `05_ArgsAndVars` solution.

```
Dictionary<string, object> parms = new Dictionary<string, object>();
parms.Add("PolicyId", 123);

WorkflowInvoker.Invoke(new PolicyFlow(), parms);
```

code download 05_ArgsAndVars

This will then invoke the workflow and pass the `PolicyId` from the dictionary to the named parameter. If you supply a name in the dictionary for which an argument does not exist, then an `ArgumentException` will be thrown. Conversely, if you don't supply the value for an `In` argument, no exception is thrown. we feel that this is the wrong way around — we would expect an argument exception to be thrown for any `In` arguments that were not defined and would prefer no exception to be thrown if we passed in too many arguments.

When a workflow completes, you may wish to retrieve output arguments. In order to do this, there is a specific override of the `WorkflowInvoker.Invoke` method that returns a dictionary. This dictionary will contain just the `Out` or `InOut` arguments.

Within the workflow, you may then wish to define variables. This wasn't easy to do in XAML workflows in Workflow 3.*x*, however in Workflow 4 this has been addressed and you can easily define parameters in the XAML.

As in any programming language, workflow variables have the notion of scope. You can define "globally" scoped variables by defining them on the root activity of the workflow. These variables are available by all activities within the workflow, and their lifetime is tied to that of the workflow.

You can also define variables on individual activities, and in this case these variables are only available to the activity that the variable is defined on and also children of that activity. Once an activity has completed, its variables go out of scope and are no longer accessible.

WorkflowApplication

While `WorkflowInvoker` is a useful class for synchronous execution of workflows, you might need to have long-running workflows that may persist to a database and need to be rehydrated at some point in the future. If that's the case then you might wish to use the `WorkflowApplication` class.

The `WorkflowApplication` class is similar to the `WorkflowRuntime` class that existed in Workflow 3 in that it allows you to run a workflow and also respond to events that occur on that workflow instance. Probably the simplest program you can write to use the `WorkflowApplication` class is shown here:

```
WorkflowApplication app = new WorkflowApplication(new Workflow1());

ManualResetEvent finished = new ManualResetEvent(false);

app.Completed = (completedArgs) => { finished.Set(); };

app.Run();

finished.WaitOne();
```

code download 06_WorkflowApplication

This constructs a workflow application instance and then hooks up to the `Completed` delegate of that instance in order to set a manual reset event. The `Run` method is called to start the workflow execution, and lastly the code waits for the event to be triggered.

This shows one of the main differences between `WorkflowExecutor` and `WorkflowApplication` — the latter is asynchronous. When you call `Run`, the system uses a thread pool thread to execute the workflow rather than the calling thread. Thus, you need some form of synchronization in order to ensure that the application hosting the workflow doesn't exit before the workflow completes.

A typical long-running workflow may have many periods when it is dormant — the execution behavior for most workflows can best be described as periods of episodic execution. There is typically some work done at the start of the workflow, then it waits on some input or a delay, and once this input has been received it processes up to the next wait state.

So, when a workflow is dormant it would be ideal to unload it from memory and only reload it when an event triggers the workflow to continue. In order to do this, we need to add an `InstanceStore` object to the `WorkflowApplication` and also make some other minor alterations to the preceding code. There is one implementation of the abstract `InstanceStore` class in the framework — the `SqlWorkflowInstanceStore`. In order to use this class, you first need a database, and the scripts for this can be found by default in the `C:\Windows\Microsoft.NET\Framework\v4.0.21006\SQL\en` directory. Note that the version number is subject to change.

You'll find a number of SQL files in this directory, but the two you need are `SqlWorkflowInstanceStoreSchema.sql` and `SqlWorkflowInstanceStoreLogic.sql`. You can run these against an existing database or create an entirely new database as appropriate, and you can use a full SQL server installation or a SQL Express installation.

Once you have a database, you need to make some alterations to the hosting code. First, you need to construct an instance of the `SqlWorkflowInstanceStore` and then add this to the workflow application:

```
SqlWorkflowInstanceStore store = new SqlWorkflowInstanceStore
  (ConfigurationManager.ConnectionStrings["db"].ConnectionString);

AutoResetEvent finished = new AutoResetEvent(false);

WorkflowApplication app = new WorkflowApplication(new Workflow1());
app.Completed = (e) => { finished.Set(); };
app.PersistableIdle = (e) => { return PersistableIdleAction.Unload; };
app.InstanceStore = store;

app.Run();

finished.WaitOne();
```

code download 06_WorkflowApplication

The emboldened lines are those added to the previous example. You'll also notice that we've added an event handler to the `PersistableIdle` delegate on the workflow application. When a workflow executes, it runs as many activities as it can, until there is no more work to do. At that point, it transitions to an `Idle` state, and an idle workflow is a candidate for persistence. The `PersistableIdle` delegate is used to determine what should happen to an idle workflow. The default is to do nothing; however, you can also specify `PersistableIdleAction.Persist`, which will take a copy of the workflow and store that in the database but still leave the workflow in memory, or you can specify `PersistableIdleAction.Unload`, which will persist and then unload the workflow.

It is also possible to request persistence of a workflow by using the `Persist` activity, and indeed as a custom activity writer you can also request persistence if you have derived from `NativeActivity` by calling the `RequestPersist` method of the `NativeActivityContext`.

We now have a problem — we have the ability to unload a workflow from memory and store it in the persistence store, but as yet we've not described how to go about retrieving it from the store and getting it to execute again.

Bookmarks

The traditional use of a bookmark is to mark a page in a book, so you can resume reading from the same point. In the context of a workflow, a bookmark specifies a place where you would like to resume running that workflow, and bookmarks are typically used when you're waiting for external input.

As an example, you might be writing an application that deals with insurance quotes. An end user might go online to produce a quotation, and as you can imagine, there would be a workflow associated with that quotation. The quotation might only be valid for 30 days, so you would like to invalidate the quote after that point. Similarly, you might request proof of a no claims discount, and cancel the policy if that proof didn't arrive within a specified time. This workflow then has a number of periods of execution, and other times when it is dormant and could be unloaded from memory. Before being unloaded, however, it is necessary to define a point in the workflow where processing can be resumed, and this is where bookmarks are used.

To define a bookmark, you need a custom activity that derives from `NativeActivity`. You can then create a bookmark within the `Execute` method, and when the bookmark has been resumed your code will continue. The example activity below defines a simplistic `Task` activity that creates a bookmark, and on resumption at the point of that bookmark, the activity completes.

```
public class Task : NativeActivity<Boolean>
{
    [RequiredArgument]
    public InArgument<string> TaskName { get; set; }

    protected override bool CanInduceIdle
    {
        get { return true; }
    }

    protected override void Execute(NativeActivityContext context)
    {
        context.CreateBookmark(TaskName.Get(context),
            new BookmarkCallback(OnTaskComplete));
    }

    private void OnTaskComplete(NativeActivityContext context,
        Bookmark bookmark, object state)
    {
        bool taskOK = Convert.ToBoolean(state);

        this.Result.Set(context, taskOK);
    }
}
```

code download 06_WorkflowApplication

The call to `CreateBookmark` passes the name of the bookmark and also a callback function. This callback will be executed when the bookmark is resumed. The callback itself is passed an arbitrary object, which in this case is a `Boolean`, as we've decided that each task should report success or failure, and we can then use this to decide on the next steps in the workflow. There's nothing to stop you from passing any object into the workflow — it could be a complex type with many fields.

So that's the activity written — we now need to alter the hosting code so as to resume at the point of the bookmarks. But there's another problem — how does the hosting code know that a workflow has created a bookmark? If it's the host's responsibility to resume from the bookmark, it needs to know that one exists.

The `Task` we've created above really needs to do some more work — telling the outside world that a task has been created. In a production system, this would typically result in an entry being stored in a queue table, and this queue would be presented to the call center staff as a job list.

Communicating with the host is the subject of the next section, "Extensions."

Extensions

An extension is simply a class or interface that is added to the runtime context of a workflow application. In Workflow 3.*x* these were called Services, however that clashed with WCF Services, so these have been renamed *extensions* in Workflow 4.

You will typically define an interface for your extensions and then provide a runtime implementation of this interface. Your activities will simply call the interface, and this allows the implementation to change as necessary. A good example of an extension is something that sends an e-mail. You could create a `SendEmail` activity that would call the extension within its `Execute` method, and then you could define an SMTP based e-mail extension or an Exchange-based outlook extension to actually send the e-mail at runtime. Your activity wouldn't need to be changed to use any e-mail provider — you can just plug in a new one by altering the application configuration file.

For the task sample, we need an extension that will be notified when the `Task` activity is about to wait at its bookmark. This could write the name of the bookmark and other pertinent information into a database so that a task queue could then be presented to the user. We'll use the following interface to define this extension:

```
public interface ITaskExtension
{
    void ExecuteTask(string taskName);
}
```

The task activity can then be updated to notify the task extension that it's executing by modifying the `Execute` method as follows:

```
protected override void Execute(NativeActivityContext context)
{
    context.CreateBookmark(TaskName.Get(context),
        new BookmarkCallback(OnTaskComplete));
    context.GetExtension<ITaskExtension>().
        ExecuteTask(TaskName.Get(context));
}
```

The context object passed to the `Execute` method is queried for the `ITaskExtension` interface and then the code calls the `ExecuteTask` method. The `WorkflowApplication` maintains a collection of extensions, so you can create a class that implements this extension interface, which can then be used to maintain the list of tasks. You could then construct and execute a new workflow, and each task would then notify the extension when it was executed. Some other process might look at the task list and present this to the end user.

To keep things simple in the sample code, we've created just one workflow instance. This instance contains a `Task` activity followed by an `If`, which outputs a message according to whether the user accepts or rejects the task.

Putting It All Together

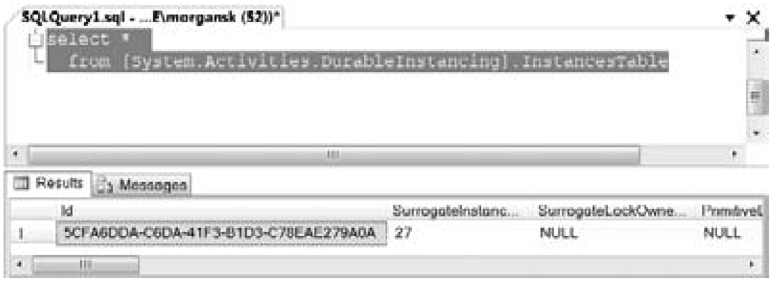
Now you can run, persist, and unload a workflow, and also deliver events into that workflow via bookmarks; the last part is reloading the workflow. When using `WorkflowApplication`, you can call `Load` and pass through the unique ID of the workflow. Every workflow has a unique ID that can be retrieved from the `WorkflowApplication` object by calling the `Id` property. So, in pseudo-code, our workflow-hosting application is as follows:

```
WorkflowApplication app = BuildApplication();
Guid id = app.Id;
app.Run();
// Wait for a while until a task is created, then reload the workflow
app = BuildApplication();
app.Load(id);
app.ResumeBookmark()
```

The sample code provided is a little more complex than the preceding, as it also includes an implementation of the `ITaskExtension` interface, but the code follows the earlier pattern. You may notice two calls to the `BuildApplication` method. This is one we've used in the code to construct a `WorkflowApplication` instance and to set up all required properties, such as the `InstanceStore` and the delegates for `Completed` and `PersistableIdle`. After the first call, we execute the `Run` method. This begins execution of a new instance of the workflow.

The second time the application is loaded is after a persistence point, so by that point the workflow has been unloaded, hence, the application instance is also essentially dead. We then construct a new `WorkflowApplication` instance, but instead of calling `Run`, we call the `Load` method, which uses the persistence provider to load up an existing instance from the database. This instance is then resumed by calling the `ResumeBookmark` function.

If you run the example, you'll see a prompt onscreen. While that prompt is there the workflow is persisted and unloaded, and you can check this by running SQL Server Management Studio and executing the command shown in Figure 44-13.



```
select *
  from [System.Activities.DurableInstancing].InstancesTable
```

	Id	SurrogateInstanc...	SurrogateLockOwne...	PrimitiveL
1	5CFA6DDA-C6DA-41F3-B1D3-C78EAE279A0A	27	NULL	NULL

FIGURE 44-13

Workflow instances are stored within the `InstancesTable` of the `System.Activities.DurableInstancing` schema. The entry shown in Figure 44-13 is the persisted instance of the workflow running on my machine.

When we continue the workflow it will eventually complete, and at that point the workflow will be deleted from the instances table, as there's an option on the instance store exposed as the `InstanceCompletionAction`, which by default is set to be `DeleteAll`. This ensures that any data stored in the database for a given workflow instance will be deleted once that workflow completes. This is a sensible default, as once a workflow completes you would normally not expect any data to hang around. You can change this option when you define the instance store by setting the instance completion action to `DeleteNothing`.

If you now continue running the test application and then retry the SQL command from Figure 44-13, you should notice that the workflow instance has been deleted.

WorkflowServiceHost

A long way back in this chapter we mentioned that there were three ways to host workflows — the last is by using the `WorkflowServiceHost` class which exposes a workflow through WCF. One of the major areas that Workflow is destined to be used for is as the back-end to WCF services. If you think about what a typical WCF service does, it's usually a bunch of related methods that are typically called in some sort of order. The main problem here is that you could call these methods in any order, and usually you need to define the ordering so that, for example, the order details are not uploaded before the order itself.

With Workflow you can easily expose WCF services that also have a notion of method ordering. The main classes you'll use here are the `Receive` and the `Send` activities. In the code for this example (which is available in the `07_WorkflowsAsServices` solution), the scenario used is an estate agent (a Realtor if you're in the United States) who wishes to upload information about a property to a web site.

The first call to the service will construct a new workflow instance, and this call will return a unique ID that is used in subsequent calls to the service. We'll then use this unique ID in subsequent calls, as this will identify which workflow instance on the server we wish to communicate with. Workflow uses a facility called "correlation" to map an incoming request to a workflow instance. Here, we're using message-based correlation to link a property of the incoming message with an existing workflow instance. The workflow we'll use for this example is outlined in Figure 44-14.

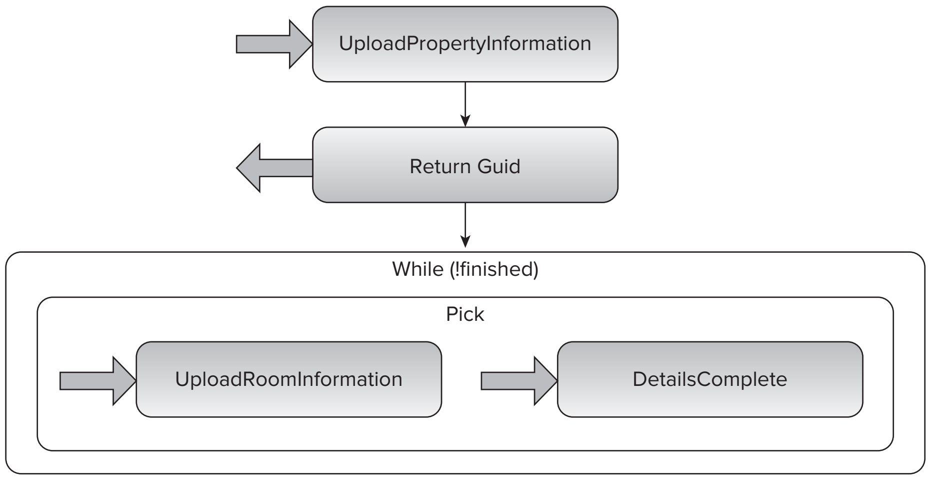


FIGURE 44-14

Defining the WorkflowServiceHost

The workflow begins in a `Receive` activity which defines the initial service operation of UploadPropertyInformation. The data received from the service call is stored within the workflow and a `Guid` is then returned to the caller by the `Send` activity. This `Guid` uniquely defines this workflow instance and is used when calling back to that instance in the other operations.

Once these initial two activities have completed, the workflow then runs a `While` activity within which there is a `Pick` activity with two branches. The first branch has a `Receive` activity with an operation named UploadRoomInformation and the second has a `Receive` activity with an operation named DetailsComplete.

The code shown in the following snippet is used to host the workflow. It makes use of the `WorkflowServiceHost` class, which is very similar to the `ServiceHost` class available with WCF.

```
string baseAddress = "http://localhost:8080/PropertyService";

using (WorkflowServiceHost host =
    new WorkflowServiceHost(GetPropertyWorkflow(), new Uri(baseAddress)))
{
    host.AddServiceEndpoint(XName.Get("IProperty", ns),
        new BasicHttpBinding(), baseAddress);

    ServiceMetadataBehavior smb = new ServiceMetadataBehavior();
    smb.HttpGetEnabled = true;
    host.Description.Behaviors.Add(smb);
    try
    {
        host.Open();

        Console.WriteLine("Service host is open for business...");
        Console.ReadLine();
    }
    finally
    {
        host.Close();
    }
}
```

code download 07_WorkflowsAsServices

Here, an instance of the WorkflowServiceHost class is constructed, and the workflow it exposes is provided by the GetPropertyWorkflow method call. You can use a code based workflow, as we have done with this example, or an XAML-based workflow. We then add an endpoint and specify a basic HTTP binding, and then enable metadata publishing so that a client can point svcutil.exe at this endpoint to download the service definition. Once that's done, it is simply a matter of calling Open on the service host class, and we're then ready to receive incoming calls.

Ensuring That a Workflow Can Be Created

The first activity within the workflow is a Receive, and it has been defined with the CanCreateInstance property set to True. This is important, as it notifies the host that, if a caller calls this operation, a new workflow instance will be constructed based on that call. What is happening under the covers is that the WorkflowServiceHost is probing the workflow definition looking for Receive activities, and it will construct a service contract based on these activities. It's also looking for any such activities with True set for CanCreateInstance, as then it knows what to do when it receives a message.

The sample code contains a client application that creates a new workflow instance by calling UploadPropertyInformation; it then uploads information about three rooms using the UploadRoomInformation operation, and finally it calls DetailsComplete. This sets the Finished flag used by the While activity, and this completes that workflow.

The workflow code is fairly complex, as there's a lot going on under the covers. Knowing how it works, though, is instructive, so we'll go through some of it here.

The first activity within the workflow is defined as follows:

```
Variable<string> address = new Variable<string>();
Variable<string> owner = new Variable<string>();
Variable<double> askingPrice = new Variable<double>();

// Initial receive - this kicks off the workflow
Receive receive = new Receive
{
    CanCreateInstance = true,
    OperationName = "UploadPropertyInformation",
    ServiceContractName = XName.Get("IProperty", ns),
    Content = new ReceiveParametersContent
    {
        Parameters =
        {
            {"address", new OutArgument<string>(address)},
            {"owner", new OutArgument<string>(owner)},
            {"askingPrice", new OutArgument<double>(askingPrice)}
        }
    }
};
```

This Receive has the CanCreateInstance flag set to true, and it defines both operation and service contract names. The ServiceContractName includes a namespace (in the example set to http://pro-csharp/) so as to uniquely identify this service. The Content property defines what is expected to be passed up from the client when the operation is called — in this instance we're passing up address, owner, and asking price values. The service operation is completely defined here by this code — and the metadata exported uses this code to construct the operation definition.

The arguments received from this operation are bound to variables defined by the workflow. This is how we pass arguments from the outside world into a workflow hosted by WCF.

Inside the workflow, we then create the unique ID that will be used when calling back to this workflow instance. In order to do this, we need to define a workflow variable and assign its value — in the code that follows, we've used an Assign activity to do this.

```
return new Sequence
{
    Variables = { propertyId, operationHandle, finished,
                  address, owner, askingPrice },
    Activities =
    {
        receive,
        new WriteLine { Text = "Assigning a unique ID" },
        new Assign<Guid>
        {
            To = new OutArgument<Guid> (propertyId),
            Value = new InArgument<Guid> (Guid.NewGuid())
        },
        new SendReply
        {
            Request = receive,
            Content = SendContent.Create
                (new InArgument<Guid> (env => propertyId.Get(env))),
            CorrelationInitializers =
            {
                new QueryCorrelationInitializer
                {
                    CorrelationHandle = operationHandle,
                    MessageQuerySet = extractGuid
                }
            }
        }
        // Other activities omitted for clarity
    }
};
```

Next, the `SendReply` activity is used to respond to the caller with the `Guid` defined by the workflow. This part is fairly complex.

The `SendReply` activity is linked to the initial `Receive` activity by setting its `Request` property to the receive activity instance. The return value of the operation is defined by the `Content` property. There are three types of responses that can be returned from an operation — a discrete value, such as a `Guid` used here, a set of parameters defined by a dictionary of name/value pairs, or a message type. The `SendContent` class is a helper that constructs the appropriate object for you.

The last part is the most complex. The `CorrelationInitializers` property is effectively used to extract a correlation token from the current message and use this in subsequent calls to the workflow to uniquely identify the workflow. The `MessageQuerySet` is used to do the extraction and is defined as shown below for this outgoing message. Once the query has been defined, it is then linked with a handle value. This handle is used by any other activity wishing to be part of the same correlation group.

```
MessageQuerySet extractGuid = new MessageQuerySet
{
    { "PropertyId",
      new XPathMessageQuery ( "sm:body()/ser:guid", messageContext ) }
};
```

This query uses XPath (otherwise known as voodoo magic) to extract data from the message being sent back to the client. Here, it is reading the `body` element and, within that, looking for the value of the `guid` element within the message.

Awaiting Events with Pick

So, we've constructed a new workflow instance and replied to the caller with a unique operation ID. The next part is to await further data from the client, which is done with two further `Receive` activities. The first of these corresponds to the `UploadRoomInformation` operation.

```
Variable<string> roomName = new Variable<string>();
Variable<double> width = new Variable<double>();
Variable<double> depth = new Variable<double>();

// Receive room information
Receive receiveRoomInfo = new Receive
{
    OperationName = "UploadRoomInformation",
    ServiceContractName = XName.Get("IProperty", ns),
    CorrelatesWith = operationHandle,
    CorrelatesOn = extractGuidFromUploadRoomInformation,
    Content = new ReceiveParametersContent
    {
        Parameters =
        {
            {"propertyId", new OutArgument<Guid>()},
            {"roomName", new OutArgument<string>(roomName)},
            {"width", new OutArgument<double>(width)},
            {"depth", new OutArgument<double>(depth)},
        }
    }
};
```

The variables initially defined are used to record the data passed from the client to the workflow. Again the `Receive` activity specifies both the `OperationName` and the `ServiceContractName` so that metadata can be generated for this operation. The `CorrelatesWith` value is critical here, as it links the different operations of the workflow together. In the `SendReply` activity, we created this handle so that we could reference it with these later operations. Without this handle, it would not be possible to work out which workflow instance an incoming message is for.

The `CorrelatesOn` property defines what is extracted from the incoming message in order to verify that the message is for this workflow instance. Again, a `MessageQuerySet` is used, which in this case extracts the unique ID from the incoming message:

```
MessageQuerySet extractGuidFromUploadRoomInformation =
  new MessageQuerySet
  {
    { "PropertyId",
      new XPathMessageQuery
      ( @"sm:body()/local:UploadRoomInformation/local:propertyId",
        messageContext ) }
  };
```

Here, the XPath is looking for the `propertyId` element within the `UploadRoomInformation` call.

The last part of this `Receive` defines what happens with the incoming parameters passed to the service operation. Here, I'm expecting the unique `propertyId`, a room name and dimensions. This data is extracted into variables, and in the example code we simply output it to the console. In a real application, you would obviously use this data to update a database or something similar.

The last `Receive` activity is used to await the `DetailsComplete` message from the client. It follows a similar pattern to the other receive activities in that it defines the service contract name and operation name, uses the same correlation handle as the initial `Send` and the `Receive` used for the `UploadRoomInformation` operation, and it uses a `MessageQuerySet` in order to retrieve the unique property ID from the incoming message.

With those activities in place, the rest of the workflow is a `While` loop that contains the `Pick` activity and its branches:

```
new While
{
    Condition = ExpressionServices.Convert<bool>
        (env => !finished.Get(env)),
    Body = new Pick
```

```
        {
            Branches =
            {
                new PickBranch
                {
                    Variables = { roomName, width, depth },
                    Trigger = receiveRoomInfo,
                    Action = new WriteLine { Text = "Room Info Received"},
                },
                new PickBranch
                {
                    Trigger = receiveDetailsComplete,
                    Action = new Sequence
                    {
                        Activities =
                        {
                            new Assign<bool>
                            {
                                To = new OutArgument<bool>(finished),
                                Value = new InArgument<bool>(true)
                            },
                            new WriteLine { Text = "Finished" }
                        }
                    }
                }
            }
        }
    }
```

Here, the `While` defines a `Condition` that evaluates the value of the `finished` variable. The `Condition` property is defined as an `Activity<bool>`, so the `ExpressionServices` helper class is used to convert the variable expression into an activity.

The `Pick` contains two branches, and the `Trigger` activity of each branch is what we are waiting for in order to execute the `Action` activity. Building workflows in code is somewhat long-winded; however, we believe it's easier to see what is going on when you are learning Workflow 4 than using XAML-based workflows. You might disagree!

Hosting the Designer

Often one wishes to save the best till last. We'd rather not break with tradition, so that's what we've done with this chapter. The Workflow Designer that is used within Visual Studio can also be hosted within your own application, allowing your end users to create their own workflows without a copy of Visual Studio in sight. This is, we believe, the best feature of Workflow 4 by far. Traditional application extension mechanisms always require some form of developer — either to write an extension DLL and plug it into the system somewhere, or by writing macros or scripts. Windows Workflow allows end users to customize an application simply by dragging and dropping activities onto a design surface.

Rehosting the designer in Workflow 3.*x* was not for the faint-hearted; however, in Workflow 4 it becomes almost trivial. The Designer itself is a WPF control, so we'll use a WPF project as the main application. The code for this example is available in the `08_DesignerRehosting` project.

The first thing we need to do is to include the workflow assemblies, and then we need to define the main window XAML. We always use the Model-View-ViewModel (MVVM) pattern when constructing WPF user interfaces, as it simplifies the coding and also ensures that we can drape different XAML over the same view model if necessary. The XAML for the main window is as follows:

```
<Window x:Class="HostApp.MainWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        Title="MainWindow">
        <Grid>
            <Grid.RowDefinitions>
                <RowDefinition Height="Auto"/>
                <RowDefinition Height="*"/>
            </Grid.RowDefinitions>
            <Menu IsMainMenu="True">
                <MenuItem Header="_File">
                    <MenuItem Header="_New" Command="{Binding New}"/>
                    <MenuItem Header="_Open" Command="{Binding Open}"/>
                    <MenuItem Header="_Save" Command="{Binding Save}"/>
                    <Separator/>
                    <MenuItem Header="_Exit" Command="{Binding Exit}"/>
                </MenuItem>
                <MenuItem Header="Workflow">
                    <MenuItem Header="_Run" Command="{Binding Run}"/>
                </MenuItem>
            </Menu>
            <Grid Grid.Row="1">
                <Grid.ColumnDefinitions>
                    <ColumnDefinition Width="*"/>
                    <ColumnDefinition Width="4*"/>
                    <ColumnDefinition Width="*"/>
                </Grid.ColumnDefinitions>
                <ContentControl Content="{Binding Toolbox}" />
                <ContentControl Content="{Binding DesignerView}"
                    Grid.Column="1"/>
                <ContentControl Content="{Binding PropertyInspectorView}"
                    Grid.Column="2"/>
            </Grid>
        </Grid>
    </Window>
```

code download 08_DesignerRehosting

It is a fairly simple layout with a main menu and then a grid that defines placeholders for the toolbox, designer, and property grid. You'll notice that everything is bound, including the commands.

The `ViewModel` we've created consists of properties for each of the main UI elements — those being the Toolbox, Designer, and Property Grid. In addition to these properties there are also properties for each command, such as New, Save, and Exit.

```
    public class ViewModel : BaseViewModel
    {
        public ViewModel()
        {
            // Ensure all designers are registered for inbuilt activities
            new DesignerMetadata().Register();
        }

        public void InitializeViewModel(Activity root)
        {
            _designer = new WorkflowDesigner();
            _designer.Load(root);

            this.OnPropertyChanged("DesignerView");
            this.OnPropertyChanged("PropertyInspectorView");
        }

        public UIElement DesignerView
        {
            get { return _designer.View; }
        }
        public UIElement ProperttInspectorView
        {
            get { return _designer.PropertyInspectorView; }
        }

        private WorkflowDesigner _designer;
    }
```

To begin, the `ViewModel` class derives from `BaseViewModel` — this base class is one that we use every time we construct a view model, as it provides an implementation of `INotifyPropertyChanged`. It comes from a set of snippets written by Josh Twist and available on `www.thejoyofcode.com`.

The constructor ensures that the metadata for all of the built-in activities is registered — without this call, none of the type specific designers will show up on the user interface. Within the `InitializeViewModel` method, we then construct an instance of the Workflow Designer and load an activity into it. The `WorkflowDesigner` class is curious in that once you've loaded one workflow into it, you cannot load another, so here we re-create this class whenever a new workflow is created.

The last thing that the `InitializeViewModel` method does is to call the property change notification function to indicate to the user interface that both the `DesignerView` and `PropertyInspectorView` are updated. As the UI is bound to these properties, they will be requeried and will load the new values from the new Workflow Designer instance.

The next part of the user interface that needs to be created is the toolbox. In Workflow 3.*x* you had to construct this control yourself; however, in Workflow 4 there is a `ToolboxControl`, which is trivially easy to use.

```
    public UIElement Toolbox
    {
        get
        {
            if (null == _toolbox)
            {
                _toolbox = new ToolboxControl();

                ToolboxCategory cat = new ToolboxCategory
                    ("Standard Activities");
                cat.Add(new ToolboxItemWrapper(typeof(Sequence),
                    "Sequence"));
                cat.Add(new ToolboxItemWrapper(typeof(Assign), "Assign"));
                _toolbox.Categories.Add(cat);

                ToolboxCategory custom = new ToolboxCategory
                    ("Custom Activities");
                custom.Add(new ToolboxItemWrapper(typeof(Message),
                    "MessageBox"));
                _toolbox.Categories.Add(custom);
            }

            return _toolbox;
        }
    }
```

Here, we construct the toolbox control, then add two toolbox items to the first category and one toolbox item to a second category. The `ToolboxItemWrapper` class is used to simplify the code needed to add a given activity to the toolbox.

With that code in place, we have a functioning application — well almost. All we need to do now is wire up the `ViewModel` with the XAML. This is done in the constructor for the main window.

```
    public MainWindow()
    {
        InitializeComponent();

        ViewModel vm = new ViewModel();
        vm.InitializeViewModel(new Sequence());

        this.DataContext = vm;
    }
```

Here, we construct the view model, and, by default, add in a `Sequence` activity so that something is displayed onscreen when the application runs. Figure 44-15 shows what the screen looks like if you run the application at this point.

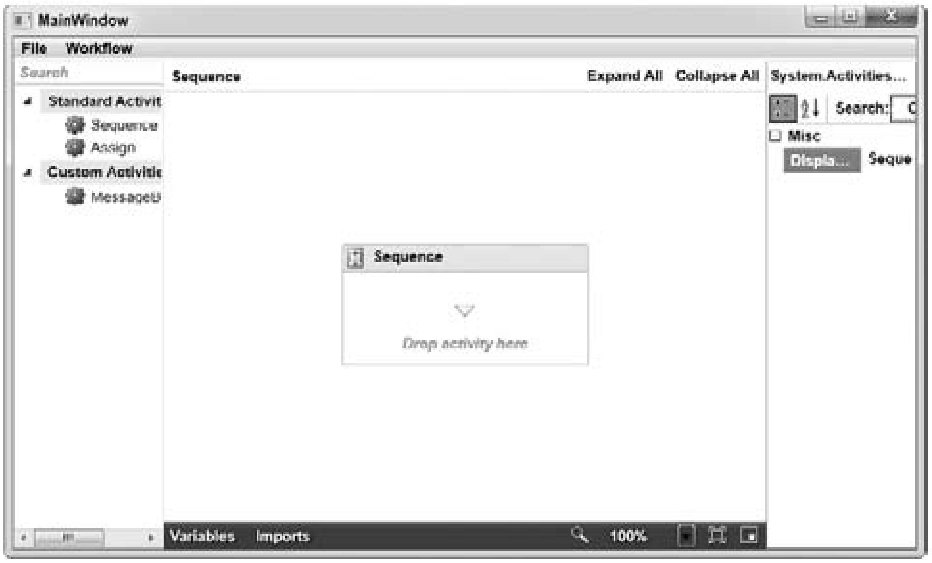

FIGURE 44-15

The only part missing now is some commands. We use a `DelegateCommand` class to write `ICommand`-based commands for WPF, as then we find the code in the view model is easy to understand. The commands are fairly trivial to implement, as is evident by the `New` command shown here:

```
    public ICommand New
    {
        get
        {
            return new DelegateCommand(unused =>
            {
                InitializeViewModel(new Sequence());
            });
        }
    }
```

This command is bound to the New menu item, so when that is clicked the delegate is executed, and in this instance that simply calls the `InitializeViewModel` method with a new `Sequence` activity. Because this method also raises the property change notification for the designer and the property grid, these are updated, too.

The `Open` command is a little more involved but not much:

```
    public ICommand Open
    {
        get
        {
            return new DelegateCommand(unused =>
            {
                OpenFileDialog ofn = new OpenFileDialog();
                ofn.Title = "Open Workflow";
                ofn.Filter = "Workflows (*.xaml)|*.xaml";
                ofn.CheckFileExists = true;
                ofn.CheckPathExists = true;

                if (true == ofn.ShowDialog())
                    InitializeViewModel(ofn.FileName);
            });
        }
    }
```

Here, we've used another override of `InitializeViewModel`, which in this instance takes a filename rather than an activity. We've not shown this code, but it is available in the code download. This command displays an `OpenFileDialog`, and when one is chosen it loads the workflow into the Designer. There is a corresponding `Save` command, which calls the `WorkflowDesigner.Save` method to store the workflow XAML on disk.

The last section of code in the view model is the Run command. It wouldn't be much good designing workflows without being able to execute them, so we've included this facility in the view model as well. It's fairly trivial — the Designer includes a `Text` property, which is the XAML representation of the activities within the workflow. All we need to do is convert this into an `Activity` and then execute that using the `WorkflowInvoker` class.

```
    public ICommand Run
    {
        get
        {
            return new DelegateCommand(unused =>
            {
                Activity root = _designer.Context.Services.
                    GetService<ModelService>().Root.
                    GetCurrentValue() as Activity;

                WorkflowInvoker.Invoke(root);
            },
            unused => { return !HasErrors; }
            );
        }
    }

    public bool HasErrors
    {
        get { return (0 != _errorCount); }
    }

    public void ShowValidationErrors(IList<ValidationErrorInfo> errors)
    {
        _errorCount = errors.Count;
        OnPropertyChanged("HasErrors");
    }

    private int _errorCount;
```

I have had to butcher the preceding code to fit it into the space on the page, as the first line of the delegate command that retrieves the root activity from the designer is long to say the least. All we then have to do is use the `WorkflowInvoker.Invoke` method to execute the workflow.

The command infrastructure within WPF includes a way to disable commands if they cannot be accessed, and that's the second Lambda function on the `DelegateCommand`. This function returns the value of `HasErrors`, a Boolean property that has been added to the view model. This property indicates whether any validation errors have been found within the workflow, as the view model implements the `IValidationErrorService`, which is notified whenever the valid state of the workflow changes.

You could extend the sample to expose this list of validation errors on the user interface as necessary — and you will probably want to add in some more activities to the toolbox, as you won't get far with just three activities.

SUMMARY

Windows Workflow will produce a radical change in the way that applications are constructed. You can now surface complex parts of an application as activities and permit users to alter the processing of the system simply by dragging and dropping activities into a workflow.

There is almost no application that you could not apply workflow to — from the simplest command-line tool to the most complex system containing many hundreds of modules. Where before you might have needed a developer to write an extension module for a system, it is now possible to provide a simple and extensible customization mechanism that almost anyone can use. As an application vendor, you would have provided the custom activities that interacted with your system, and you would also have provided the code in the application that called the workflow(s), but you can now leave it up to your customers to define what they want to happen when an event occurs in the application.

Workflow 3.*x* has now been largely superseded by Workflow 4, and if you are planning on using workflow for the first time, we would recommend starting this new version and bypassing Workflow 3.*x* entirely.

45 Peer-to-Peer Networking

WHAT'S IN THIS CHAPTER?

- An overview of P2P
- The Microsoft Windows Peer-to-Peer Networking platform, including PNRP and PNM
- Building P2P applications with the .NET Framework

Peer-to-peer networking, often referred to as P2P, is perhaps one of the most useful and yet misunderstood technologies to emerge in recent years. When people think of P2P they usually think of one thing: sharing music files, often illegally. This is because file-sharing applications such as BitTorrent have risen in popularity at a staggering rate, and these applications use P2P technology to work.

Although P2P is used in file-sharing applications, that doesn't mean it doesn't have other applications. Indeed, as you see in this chapter, P2P can be used for a vast array of applications, and is becoming more and more important in the interconnected world in which we live. You learn about this in the first part of this chapter, when you look at an overview of P2P technologies.

Microsoft has not been oblivious to the emergence of P2P, and has been developing its own tools and technologies to use it. You can use the Microsoft Windows Peer-to-Peer Networking platform as a communication framework for P2P applications. This platform includes the important components Peer Name Resolution Protocol (PNRP) and People Near Me (PNM). Also, version 3.5 of the .NET Framework introduced a new namespace, `System.Net.PeerToPeer`, and several new types and features that you can use to build P2P applications yourself with minimal effort.

PEER-TO-PEER NETWORKING OVERVIEW

Peer-to-peer networking is an alternative approach to network communication. To understand how P2P differs from the "standard" approach to network communication it is helpful to take a step backward and look at client-server communications. Client-server communications are ubiquitous in networked applications today.

Client-Server Architecture

Traditionally, you interact with applications over a network (including the Internet) using a client-server architecture. Web sites are a great example of this. When you look at a web site you send a request over the Internet to a web server, which then returns the information that you require. If you want to download a file, you do so directly from the web server.

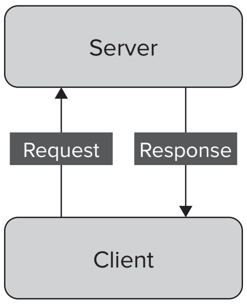

FIGURE 45-1

Similarly, desktop applications that include local or wide area network connectivity will typically connect to a single server, for example, a database server or a server that hosts other services.

This simple form of client-server architecture is illustrated in Figure 45-1.

There is nothing inherently wrong with the client-server architecture, and indeed in many cases it will be exactly what you want. However, there is a scalability problem. Figure 45-2 shows how the client-server architecture scales with additional clients.

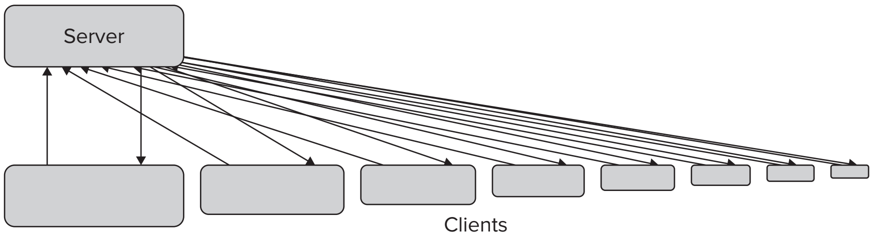

FIGURE 45-2

With every client that is added an increased load is placed on the server, which must communicate with each client. To return to the web site example, this increased communication load is how web sites collapse. When there is too much traffic the server simply becomes unresponsive.

There are of course scaling options that you can implement to mitigate this situation. You can *scale up* by increasing the power and resources available to the server, or you can *scale out* by adding additional servers. Scaling up is of course limited by the technology available and the cost of better hardware. Scaling out is potentially more flexible, but requires an additional infrastructure layer to ensure that clients either communicate with individual servers or maintain session state independent of the server with which they are communicating. Plenty of solutions are available for this, such as web or server farm products.

P2P Architecture

The peer-to-peer approach is completely different from either the scaling up or scaling out approach. With P2P, instead of focusing on and attempting to streamline the communication between the server and its clients, you instead look at ways in which clients can communicate with each other.

Say, for example, that the web site that clients are communicating with is www.wrox.com. In our imaginary scenario, Wrox has announced that a new version of this book is to be released on the wrox.com web site and will be free to download to anyone who wants it; however, it will be removed after one day. Before the book becomes available on the web site you might imagine that an awful lot of people will be looking at the web site and refreshing their browsers, waiting for the file to appear. When the file is available, everyone will try to download it at the same time, and more than likely the wrox.com web server will collapse under the strain.

You could use P2P technology to prevent this web server collapse. Instead of sending the file directly from the server to all the clients, you send the file to just a few clients. A few of the remaining clients then download the file from the clients that already have it, a few more clients download it from those second-level clients, and so on. In fact, this process is made even faster by splitting the file into chunks and dividing these chunks among clients, some of whom download it directly from the server, and some whom download chunks from other clients. This is how file-sharing technologies such as BitTorrent work, and is illustrated in Figure 45-3.

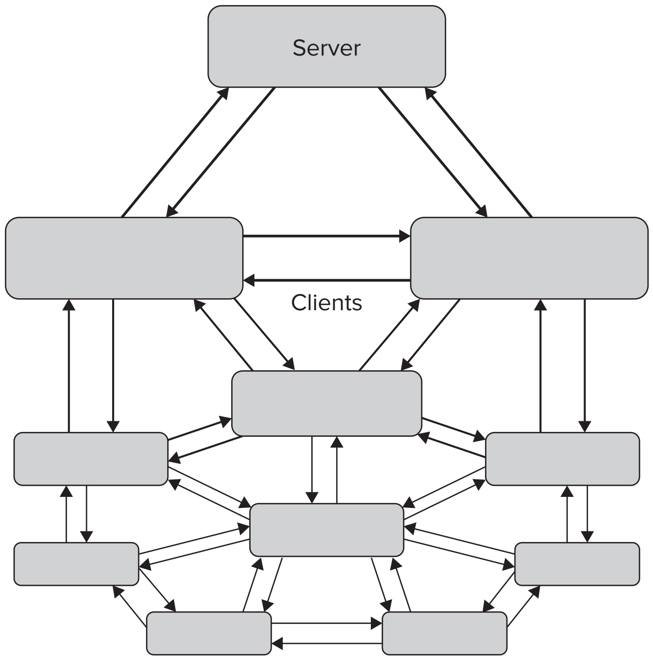

FIGURE 45-3

P2P Architectural Challenges

There are still problems to solve in the file-sharing architecture discussed here. For a start, how do clients detect that other clients exist, and how do they locate chunks of the file that other clients might have? Also, how can you ensure optimal communication between clients that may be separated by entire continents?

Every client participating in a P2P network application must be able to perform the following operations to overcome these problems:

- It must be able to *discover* other clients.
- It must be able to *connect* to other clients.
- It must be able to *communicate* with other clients.

The discovery problem has two obvious solutions. You can either keep a list of the clients on the server so clients can obtain this list and contact other clients (known as *peers*), or you can use an infrastructure (for example PNRP, covered in the next section) that enables clients to find each other directly. Most file-sharing systems use the "list on a server" solution by using servers known as *trackers*. Also, in file-sharing systems any client may act as a server as shown in Figure 45-3, by declaring that it has a file available and registering it with a tracker. In fact, a pure P2P network needs no servers at all, just peers.

The connection problem is a more subtle one, and concerns the overall structure of the networks used by a P2P application. If you have one group of clients, all of which can communicate with one another, the topology of the connections between these clients can become extremely complex. You can often improve performance by having more than one group of clients, each of which consists of connections between clients in that group, but not to clients in other groups. If you can make these groups locale-based you will get an additional performance boost, because clients can communicate with each other with fewer hops between networked computers.

Communication is perhaps a problem of lesser importance, because communication protocols such as TCP/IP are well established and can be reused here. There is, however, scope for improvement in both high-level technologies (for example, you can use WCF services and therefore all the functionality that WCF offers) and low-level protocols (such as multicast protocols to send data to multiple endpoints simultaneously).

Discovery, connection, and communication are central to any P2P implementation. The implementation you look at in this chapter is to use the `System.Net.PeerToPeer` types with PNM for discovery and PNRP for connection. As you see in subsequent sections, these technologies cover all three of these operations.

P2P Terminology

In the previous sections you were introduced to the concept of a *peer*, which is how clients are referred to in a P2P network. The word "client" makes no sense in a P2P network because there is not necessarily a server to be a client of.

Groups of peers that are connected to each other are known by the interchangeable terms *meshes*, *clouds*, or *graphs*. A given group can be said to be *well-connected* if at least one of the following statements applies:

- ➤ There is a connection path between every pair of peers, so that every peer can connect to any other peer as required.
- ➤ There are a relatively small number of connections to traverse between any pair of peers.
- ➤ Removing a peer will not prevent other peers from connecting to each other.

Note that this does not mean that every peer must be able to connect to every other peer directly. In fact, if you analyze a network mathematically you will find that peers need to connect only to a relatively small number of other peers for these conditions to be met.

Another P2P concept to be aware of is *flooding*. Flooding is the way in which a single piece of data may be propagated through a network to all peers, or of querying other nodes in a network to locate a specific piece of data. In unstructured P2P networks this is a fairly random process of contacting nearest neighbor peers, which in turn contact their nearest neighbors, and so on until every peer in the network is contacted. It is also possible to create structured P2P networks such that there are well-defined pathways for queries and data flow among peers.

P2P Solutions

When you have an infrastructure for P2P you can start to develop not just improved versions of client-server applications, but entirely new applications. P2P is particularly suited to the following classes of applications:

- ➤ Content distribution applications, including the file-sharing applications discussed earlier
- ➤ Collaboration applications, such as desktop sharing and shared whiteboard applications

- Multi-user communication applications that allow users to communicate and exchange data directly rather than through a server
- Distributed processing applications, as an alternative to supercomputing applications that process enormous amounts of data
- Web 2.0 applications that combine some or all the above in dynamic, next-generation web applications

MICROSOFT WINDOWS PEER-TO-PEER NETWORKING

The Microsoft Windows Peer-to-Peer Networking platform is Microsoft's implementation of P2P technology. It is part of Windows XP SP2, Windows Vista, and Windows 7, and is also available as an add-on for Windows XP SP1. It includes two technologies that you can use when creating .NET P2P applications:

- The Peer Name Resolution Protocol (PNRP), which is used to publish and resolve peer addresses
- The People Near Me server, which is used to locate local peers (currently for Vista and Windows 7 only)

In this section you learn about these technologies.

Peer Name Resolution Protocol (PNRP)

You can of course use any protocol at your disposal to implement a P2P application, but if you are working in a Microsoft Windows environment (and, let's face it, if you're reading this book you probably are) it makes sense to at least consider PNRP. There have been two versions of PNRP released to date. PNRP version 1 was included in Windows XP SP2, Windows XP Professional x64 Edition, and Windows XP SP1 with the Advanced Networking Pack for Windows XP. PNRP version 2 was released with Windows Vista, and was made available to Windows XP SP2 users through a separate download (see KB920342 at `support.microsoft.com/kb/920342`). Windows 7 also uses version 2. Version 1 and version 2 of PNRP are not compatible, and this chapter covers only version 2.

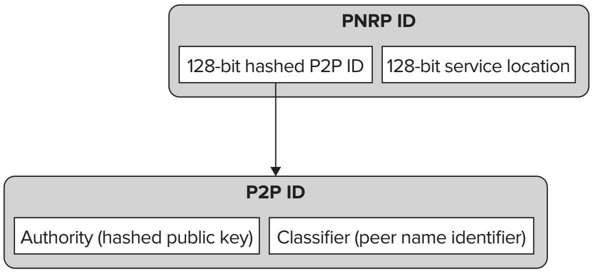
In itself, PNRP doesn't give you everything you need to create a P2P application. Rather, it is one of the underlying technologies that you use to resolve peer addresses. PNRP enables a client to register an endpoint (known as a *peer name*) that is automatically circulated among peers in a cloud. This peer name is encapsulated in a PNRP ID. A peer that discovers the PNRP ID is able to use PNRP to resolve it to the actual peer name, and can then communicate directly with the associated client.

For example, you might define a peer name that represents a WCF service endpoint. You could use PNRP to register this peer name in a cloud as a PNRP ID. A peer running a suitable client application that uses a discovery mechanism that can identify peer names for the service you are exposing might then discover this PNRP ID. Once discovered, the peer would use PNRP to locate the endpoint of the WCF service and then use that service.

PNRP IDs

PNRP IDs are 256-bit identifiers. The low-order 128 bits are used to uniquely identify a particular peer, and the high-order 128 bits identify a peer name. The high-order 128 bits are a hashed combination of a hashed public key from the publishing peer and a string of up to 149 characters that identifies the peer name. The hashed public key (known as the *authority*) combined with this string (the *classifier*) are together referred to as the P2P ID. It is also possible to use a value of 0 instead of a hashed public key, in which case the peer name is said to be *unsecured* (as opposed to *secured* peer names, which use a public key).

The structure of a PNRP ID is illustrated in Figure 45-4.



PNRP ID
128-bit hashed P2P ID
128-bit service location
P2P ID
Authority (hashed public key)
Classifier (peer name identifier)

FIGURE 45-4

The PNRP service on a peer is responsible for maintaining a list of PNRP IDs, including the ones that it publishes as well as a cached list of those it has obtained by PNRP service instances elsewhere in the cloud. When a peer attempts to resolve a PNRP ID, the PNRP service either uses a cached copy of the endpoint to resolve the peer that published the PNRP or it asks its neighbors if they can resolve it. Eventually a connection to the publishing peer is made and the PNRP service can resolve the PNRP ID.

Note that all this happens without you having to intervene in any way. All you have to do is ensure that peers know what to do with peer names after they have resolved them using their local PNRP service.

Peers can use PNRP to locate PNRP IDs that match a particular P2P ID. You can use this to implement a very basic form of discovery for unsecured peer names. This is because if several peers expose an unsecured peer name that uses the same classifier, the P2P ID will be the same. Of course, because any peer can use an unsecured peer name you have no guarantee that the endpoint you connect to will be the sort of endpoint you expect, so this is only really a viable solution for discovery over a local network.

PNRP Clouds

In the preceding discussion you learned how PNRP registers and resolves peer names in clouds. A cloud is maintained by a *seed server,* which can be any server running the PNRP service that maintains a record of at least one peer. Two types of clouds are available to the PNRP service:

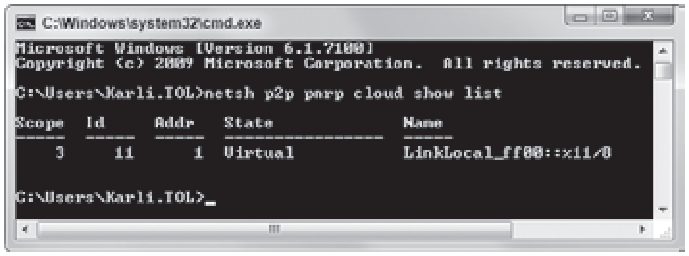
- **Link local** — These clouds consist of the computers attached to a local network. A PC may be connected to more than one link local cloud if it has multiple network adapters.
- **Global** — This cloud consists of computers connected to the Internet by default, although it is also possible to define a private global cloud. The difference is that Microsoft maintains the seed server for the global Internet cloud, whereas if you define a private global cloud you must use your own seed server. If you use your own seed server you must ensure that all peers connect to it by configuring policy settings.

In past releases of PNRP there was a third type of cloud, site local. *This is no longer used and is not covered in this chapter.*

You can discover what clouds you are connected to with the following command:

```
netsh p2p pnrp cloud show list
```

A typical result is shown in Figure 45-5.



```
Microsoft Windows [Version 6.1.7100]

C:\Users\Karli.TOL>netsh p2p pnrp cloud show list

Scope  Id     Addr   State              Name
-----  -----  -----  -----------------  -----
    3     11      1  Virtual            LinkLocal_ff00::%11/0

C:\Users\Karli.TOL>_
```

FIGURE 45-5

Figure 45-5 shows that a single cloud is available, and that it is a link local cloud. You can tell this from both the name and the `Scope` value, which is 3 for link local clouds and 1 for global clouds. To connect to a global cloud you must have a global IPv6 address. The computer used to generate Figure 45-5 does not have one, which is why only a local cloud is available.

Clouds may be in one of the following states:

- **Active** — If the state of a cloud is `active`, you can use it to publish and resolve peer names.
- **Alone** — If the peer you are querying the cloud from is not connected to any other peers, it will have a state of `alone`.
- **No Net** — If the peer is not connected to a network, the cloud state may change from `active` to `no net`.
- **Synchronizing** — Clouds will be in the `synchronizing` state when the peer is connecting to them. This state will change to another state extremely quickly because this connection does not take long, so you will probably never see a cloud in this state.
- **Virtual** — The PNRP service connects to clouds only as required by peer name registration and resolution. If a cloud connection has been inactive for more than 15 minutes it may enter the `virtual` state.

PNRP in Windows 7

With Windows 7, PNRP makes use of a new component called the *Distributed Routing Table (DRT)*. This component is responsible for determining the structure of the keys used by PNRP, the default implementation of which is the PNRP ID previously described. By using the DRT API it is possible to define an alternative key scheme, but the keys must be 256-bit integer values (just like PNRP IDs). This means that you can use any scheme you want, but you are then responsible for the generation and security of the keys. By using this component you can create new cloud topologies beyond the scope of PNRP, and indeed, beyond the scope of this chapter as this is an advanced technique.

Windows 7 also introduces a new way of connecting to other users for the Remote Assistance application: Easy Connect. This connection option uses PNRP to locate users to connect to. Once a session is created, through Easy Connect or by other means (for example an e-mail invitation), users can share their desktops and assist each other through the Remote Assistance interface.

People Near Me

PNRP, as you saw in the previous section, is used to locate peers. This is obviously important as an enabling technology when you consider the discovery/connection/communication process of a P2P application, but in itself is not a complete implementation of any of these stages. The People Near Me service is an implementation of the discovery stage, and enables you to locate peers that are signed in to the Windows People Near Me service in your local area (that is, in a link local cloud that you are connected to).

You may have come across this service because it is built into Vista and Windows 7, and is used in the Windows Meeting Space application, which you can use for sharing applications among peers. You can configure this service through the Change People Near Me settings control panel item (you can navigate to this quickly by typing "people" in the Start menu search box). This control panel item displays the dialog box shown in Figure 45-6.

FIGURE 45-6

After you have signed in, the service is available to any application that is built to use the PNM service.

At the time of writing, PNM is available only on the Windows Vista family of operating systems (and it has been removed from Windows 7). However, it is possible that future service packs or additional downloads may make it available on Windows XP.

BUILDING P2P APPLICATIONS

Now that you have learned what P2P networking is and what technologies are available to .NET developers to implement P2P applications, it's time to look at how you can build them. From the preceding discussion you know that you will be using PNRP to publish, distribute, and resolve peer names, so the first thing you look at here is how to achieve that using .NET. Next you look at how to use PNM as a framework for a P2P application. This can be advantageous because if you use PNM you do not have to implement your own discovery mechanisms.

To examine these subjects you need to learn about the classes in the following namespaces:

- `System.Net.PeerToPeer`
- `System.Net.PeerToPeer.Collaboration`

To use these classes you must have a reference to the `System.Net.dll` assembly.

System.Net.PeerToPeer

The classes in the `System.Net.PeerToPeer` namespace encapsulate the API for PNRP and enable you to interact with the PNRP service. You will use these classes for two main tasks:

- Registering peer names
- Resolving peer names

In the following sections, all the types referred to come from the `System.Net.PeerToPeer` namespace unless otherwise specified.

Registering Peer Names

To register a peer name you must carry out the following steps:

1. Create a secured or unsecured peer name with a specified classifier.
2. Configure a registration for the peer name, providing as much of the following optional information as you choose:
    - A TCP port number
    - The cloud or clouds with which to register the peer name (if unspecified, PNRP will register the peer name in all available clouds)
    - A comment of up to 39 characters
    - Up to 4,096 bytes of additional data
    - Whether to generate endpoints for the peer name automatically (the default behavior, where endpoints will be generated from the IP address or addresses of the peer and, if specified, the port number)
    - A collection of endpoints
3. Use the peer name registration to register the peer name with the local PNRP service.

After Step 3 the peer name will be available to all peers in the selected cloud (or clouds). Peer registration continues until it is explicitly stopped, or until the process that registered the peer name is terminated.

To create a peer name you use the `PeerName` class. You create an instance of this class from a string representation of a P2P ID in the form `authority.classifier` or from a classifier string and a `PeerNameType`. You can use `PeerNameType.Secured` or `PeerNameType.Unsecured`. For example:

```
PeerName pn = new PeerName("Peer classifier", PeerNameType.Secured);
```

Because an unsecured peer name uses an authority value of 0, the following lines of code are equivalent:

```
PeerName pn = new PeerName("Peer classifier", PeerNameType.Unsecured);

PeerName pn = new PeerName("0.Peer classifier");
```

After you have a `PeerName` instance you can use it along with a port number to initialize a `PeerNameRegistration` object:

```
PeerNameRegistration pnr = new PeerNameRegistration(pn, 8080);
```

Alternatively, you can set the `PeerName` and (optionally) the `Port` properties on a `PeerNameRegistration` object created using its default parameter. You can also specify a `Cloud` instance as a third parameter of the `PeerNameRegistration` constructor, or through the `Cloud` property. You can obtain a `Cloud` instance from the cloud name or by using one of the following static members of `Cloud`:

- `Cloud.Global` — This static property obtains a reference to the global cloud. This may be a private global cloud depending on peer policy configuration.

- `Cloud.AllLinkLocal` — This static field gets a cloud that contains all the link local clouds available to the peer.
- `Cloud.Available` — This static field gets a cloud that contains all the clouds that are available to the peer, which includes link local clouds and (if available) the global cloud.

When created, you can set the `Comment` and `Data` properties if you want. Be aware of the limitations of these properties, though. You will receive a `PeerToPeerException` if you try to set `Comment` to a `string` greater than 39 Unicode characters or an `ArgumentOutOfRangeException` if you try to set `Data` to a `byte[]` greater than 4,096 bytes. You can also add endpoints by using the `EndPointCollection` property. This property is a `System.Net.IPEndPointCollection` collection of `System.Net.IPEndPoint` objects. If you use the `EndPointCollection` property you might also want to set the `UseAutoEndPointSelection` property to `false` to prevent automatic generation of endpoints.

When you are ready to register the peer name you can call the `PeerNameRegistration.Start()` method. To remove a peer name registration from the PNRP service you use the `PeerNameRegistration.Stop()` method.

The following code registers a secured peer name with a comment:

```
PeerName pn = new PeerName("Peer classifier", PeerNameType.Unsecured);
PeerNameRegistration pnr = new PeerNameRegistration(pn, 8080);
pnr.Comment = "Get pizza here";
pnr.Start();
```

Resolving Peer Names

To resolve a peer name you must carry out the following steps:

1. Generate a peer name from a known P2P ID or a P2P ID obtained through a discovery technique.
2. Use a resolver to resolve the peer name and obtain a collection of peer name records. You can limit the resolver to a particular cloud and/or a maximum number of results to return.
3. For any peer name records that you obtain, obtain peer name, endpoint, comment, and additional data information as required.

This process starts with a `PeerName` object similar to a peer name registration. The difference here is that you use a peer name that is registered by one or more remote peers. The simplest way to get a list of active peers in your link local cloud is for each peer to register an unsecured peer name with the same classifier and to use the same peer name in the resolving phase. However, this is not a recommended strategy for global clouds because unsecured peer names are easily spoofed.

To resolve peer names you use the `PeerNameResolver` class. When you have an instance of this class you can choose to resolve peer names synchronously by using the `Resolve()` method, or asynchronously using the `ResolveAsync()` method.

You can call the `Resolve()` method with a single `PeerName` parameter, but you can also pass an optional `Cloud` instance to resolve in, an `int` maximum number of peers to return, or both. This method returns a `PeerNameRecordCollection` instance, which is a collection of `PeerNameRecord` objects. For example, the following code resolves an unsecured peer name in all link local clouds and returns a maximum of 5 results:

```
PeerName pn = new PeerName("0.Peer classifier");
PeerNameResolver pnres = new PeerNameResolver();
PeerNameRecordCollection pnrc = pnres.Resolve(pn, Cloud.AllLinkLocal, 5);
```

The `ResolveAsync()` method uses a standard asynchronous method call pattern. You pass a unique `userState` object to the method and listen for `ResolveProgressChanged` events for peers being found and the `ResolveCompleted` event when the method terminates. You can cancel a pending asynchronous request with the `ResolveAsyncCancel()` method.

Event handlers for the ResolveProgressChanged event use the ResolveProgressChangedEventArgs event arguments parameter, which derives from the standard System.ComponentModel.ProgressChangedEventArgs class. You can use the PeerNameRecord property of the event argument object you receive in the event handler to get a reference to the peer name record that was found.

Similarly, the ResolveCompleted event requires an event handler that uses a parameter of type ResolveCompletedEventArgs, which derives from AsyncCompletedEventArgs. This type includes a PeerNameRecordCollection parameter you can use to obtain a complete list of the peer name records that were found.

The following code shows an implementation of event handlers for these events:

```
private pnres_ResolveProgressChanged(object sender,
   ResolveProgressChangedEventArgs e)
{
   // Use e.ProgressPercentage (inherited from base event args)
   // Process PeerNameRecord from e.PeerNameRecord
}

private pnres_ResolveCompleted(object sender,
   ResolveCompletedEventArgs e)
{
   // Test for e.IsCancelled and e.Error (inherited from base event args)
   // Process PeerNameRecordCollection from e.PeerNameRecordCollection
}
```

After you have one or more PeerNameRecord objects you can proceed to process them. This PeerNameRecord class exposes Comment and Data properties to examine the comment and data set in the peer name registration (if any), a PeerName property to get the PeerName object for the peer name record, and, most importantly, an EndPointCollection property. As with PeerNameRegistration, this property is a System.Net.IPEndPointCollection collection of System.Net.IPEndPoint objects. You can use these objects to connect to endpoints exposed by the peer in any way you want.

Code Access Security in System.Net.PeerToPeer

The System.Net.PeerToPeer namespace also includes the following two classes that you can use with Code Access Security (CAS). See Chapter 21, "Security" for more details.

- PnrpPermission, which inherits from CodeAccessPermission
- PnrpPermissionAttribute, which inherits from CodeAccessSecurityAttribute

You can use these classes to provide permissions functionality for PNRP access in the usual CAS way.

Sample Application

The downloadable code for this chapter includes a sample P2P application (P2PSample) that uses the concepts and namespace introduced in this section. It is a WPF application that uses a WCF service for a peer endpoint.

The application is configured with an application configuration file, in which you can specify the name of the peer and a port to listen on as follows:

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <appSettings>
    <add key="username" value="Karli" />
    <add key="port" value="8731" />
  </appSettings>
</configuration>
```

code snippet App.config

After you have built the application you can test it either by copying it to other computers in your local network and running all instances, or by running multiple instances on one computer. If you choose the latter option you must remember to change the port used for each instance by changing individual config files (copy the contents of the `Debug` directory on your local computer and edit each config file in turn). The results will be clearer in both ways of testing this application if you also change the username for each instance.

When the peer applications are running, you can use the Refresh button to obtain a list of peers asynchronously. When you have located a peer you can send a default message by clicking the Message button for the peer.

Figure 45-7 shows this application in action with three instances running on one machine. In the figure, one peer has just messaged another and this has resulted in a dialog box.

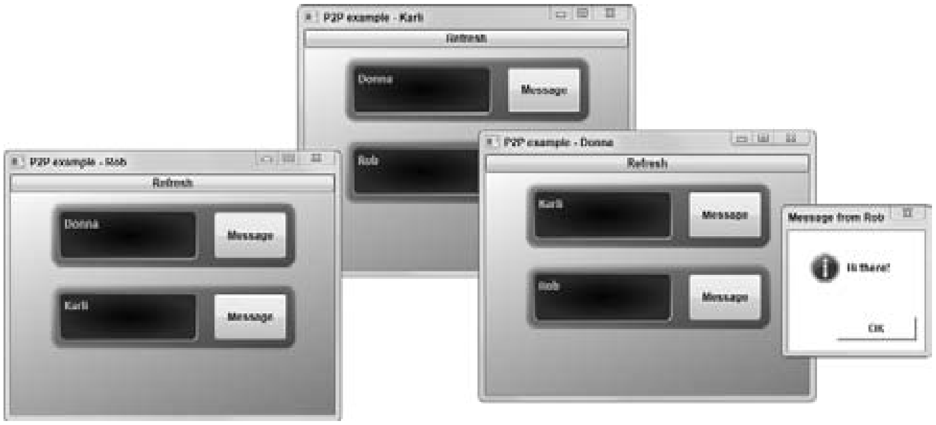

FIGURE 45-7

Most of the work in this application takes place in the `Window_Loaded()` event handler for the `Window1` window. This method starts by loading configuration information and setting the window title with the username:

```
private void Window_Loaded(object sender, RoutedEventArgs e)
{
   // Get configuration from app.config
   string port = ConfigurationManager.AppSettings["port"];
   string username = ConfigurationManager.AppSettings["username"];
   string machineName = Environment.MachineName;
   string serviceUrl = null;

   // Set window title
   this.Title = string.Format("P2P example — {0}", username);
```

code snippet Window1.xaml.cs

Next the peer host address is used along with the configured port to determine the endpoint on which to host the WCF service. The service will use `NetTcpBinding` binding, so the URL of the endpoint uses the `net.tcp` protocol:

```
   // Get service url using IPv4 address and port from config file
   foreach (IPAddress address in Dns.GetHostAddresses(Dns.GetHostName()))
   {
      if (address.AddressFamily ==
         System.Net.Sockets.AddressFamily.InterNetwork)
      {
            serviceUrl = string.Format("net.tcp://{0}:{1}/P2PService",
               address, port);
            break;
         }
      }
```

The endpoint URL is validated, and then the WCF service is registered and started:

```
      // Check for null address
      if (serviceUrl == null)
      {
         // Display error and shutdown
         MessageBox.Show(this, "Unable to determine WCF endpoint.",
           "Networking Error", MessageBoxButton.OK, MessageBoxImage.Stop);
         Application.Current.Shutdown();
      }

      // Register and start WCF service.
      localService = new P2PService(this, username);
      host = new ServiceHost(localService, new Uri(serviceUrl));
      NetTcpBinding binding = new NetTcpBinding();
      binding.Security.Mode = SecurityMode.None;
      host.AddServiceEndpoint(typeof(IP2PService), binding, serviceUrl);
      try
      {
         host.Open();
      }
      catch (AddressAlreadyInUseException)
      {
         // Display error and shutdown
         MessageBox.Show(this, "Cannot start listening, port in use.",
             "WCF Error", MessageBoxButton.OK, MessageBoxImage.Stop);
         Application.Current.Shutdown();
      }
```

A singleton instance of the service class is used to enable easy communication between the host app and the service (for sending and receiving messages). Also, note that security is disabled in the binding configuration for simplicity.

Next, the `System.Net.PeerToPeer` namespace classes are used to register a peer name:

```
      // Create peer name
      peerName = new PeerName("P2P Sample", PeerNameType.Unsecured);

      // Prepare peer name registration in link local clouds
      peerNameRegistration = new PeerNameRegistration(peerName, int.Parse(port));
      peerNameRegistration.Cloud = Cloud.AllLinkLocal;

      // Start registration
      peerNameRegistration.Start();
   }
```

When the Refresh button is clicked the `RefreshButton_Click()` event handler uses `PeerNameResolver.ResolveAsync()` to get peers asynchronously:

```
   private void RefreshButton_Click(object sender, RoutedEventArgs e)
   {
      // Create resolver and add event handlers
      PeerNameResolver resolver = new PeerNameResolver();
      resolver.ResolveProgressChanged +=
         new EventHandler<ResolveProgressChangedEventArgs>(
            resolver_ResolveProgressChanged);
      resolver.ResolveCompleted +=
         new EventHandler<ResolveCompletedEventArgs>(
            resolver_ResolveCompleted);

      // Prepare for new peers
```

```
        PeerList.Items.Clear();
        RefreshButton.IsEnabled = false;

        // Resolve unsecured peers asynchronously
        resolver.ResolveAsync(new PeerName("0.P2P Sample"), 1);
    }
```

The remainder of the code is responsible for displaying and communicating with peers, and you can explore it at your leisure.

Exposing WCF endpoints through P2P clouds is a great way of locating services within an enterprise, as well as being an excellent way to communicate between peers, as in this example.

System.Net.PeerToPeer.Collaboration

The classes in the `System.Net.PeerToPeer.Collaboration` namespace provide a framework you can use to create applications that use the People Near Me service and the P2P collaboration API. As mentioned earlier, at the time of writing this is only possible if you are using Windows Vista or Windows 7.

You can use the classes in this namespace to interact with peers and applications in a number of ways, including

- Signing in and signing out
- Discovering peers
- Managing contacts and detecting peer presence

You can also use the classes in this namespace to invite other users to join an application, and to exchange data between users and applications. However, to do this you need to create your own PNM-capable applications, which is beyond the scope of this chapter.

In the following sections, all the types referred to come from the `System.Net.PeerToPeer.Collaboration` namespace unless otherwise specified.

Signing In and Signing Out

One of the most important classes in the `System.Net.PeerToPeer.Collaboration` namespace is the `PeerCollaboration` class. This is a static class that exposes numerous static methods that you can use for various purposes, as you will see in this and subsequent sections. You can use two of the methods it exposes, `SignIn()` and `SignOut()`, to (unsurprisingly) sign in and sign out of the People Near Me service. Both of these methods take a single parameter of type `PeerScope`, which can be one of the following values:

- `PeerScope.None` — If you use this value, `SignIn()` and `SignOut()` will have no effect.
- `PeerScope.NearMe` — This will sign you in to or out of the link local clouds.
- `PeerScope.Internet` — This will sign you in to or out of the global cloud (which may be necessary to connect to a contact who is not currently on your local subnet).
- `PeerScope.All` — This will sign you in to or out of all available clouds.

If necessary, calling `SignIn()` will cause the People Near Me configuration dialog to be displayed.

When a peer is signed in you can use the `PeerCollaboration.LocalPresenceInfo` property to a value of type `PeerPresenceInfo`. This enables standard IM functionality, such as setting your status to away. You can set the `PeerPresenceInfo.DescriptiveText` property to a Unicode string of up to 255 characters, and the `PeerPresenceInfo.PresenceStatus` property to a value from the `PeerPresenceStatus` enumeration. The values that you can use for this enumeration are as follows:

- `PeerPresenceStatus.Away` — The peer is away.
- `PeerPresenceStatus.BeRightBack` — The peer is away, but will be back soon.

- `PeerPresenceStatus.Busy` — The peer is busy.
- `PeerPresenceStatus.Idle` — The peer isn't active.
- `PeerPresenceStatus.Offline` — The peer is offline.
- `PeerPresenceStatus.Online` — The peer is online and available.
- `PeerPresenceStatus.OnThePhone` — The peer is busy with a phone call.
- `PeerPresenceStatus.OutToLunch` — The peer is away, but will be back after lunch.

Discovering Peers

You can obtain a list of peers near you if you are logged in to the link local cloud. You do this by using the `PeerCollaboration.GetPeersNearMe()` method. This returns a `PeerNearMeCollection` object containing `PeerNearMe` objects.

You can use the `Nickname` property of `PeerNearMe` to obtain the name of a peer, `IsOnline`, to determine whether the peer is online, and (for lower-level operations) the `PeerEndpoints` property to determine endpoints related to the peer. `PeerEndPoints` is also necessary if you want to find out the online status of a `PeerNearMe`. You can pass an endpoint to the `GetPresenceInfo()` method to obtain a `PeerPresenceInfo` object, as described in the previous section.

Managing Contacts and Detecting Peer Presence

Contacts are a way in which you can remember peers. You can add a peer discovered through the People Near Me service and from then onward you can connect to them whenever you are both online. You can connect to a contact through link local or global clouds (assuming you have IPv6 connectivity to the Internet).

You can add a contact from a peer that you have discovered by calling the `PeerNearMe.AddToContactManager()` method. When you call this method you can choose to associate a display name, nickname, and e-mail address with the contact. Typically, though, you will manage contacts by using the `ContactManager` class.

However you manipulate contacts, you will be dealing with `PeerContact` objects. `PeerContact`, like `PeerNearMe`, inherits from the abstract `Peer` base class. `PeerContact` has more properties and methods than `PeerNearMe`. `PeerContact` includes `DisplayName` and `EmailAddress` properties that further describe a PNM peer, for example. Another difference between these two types is that `PeerContact` has a more explicit relationship with the `System.Net.PeerToPeer.PeerName` class. You can get a `PeerName` from a `PeerContact` through the `PeerContact.PeerName` property. After you have done this you can proceed to use techniques you looked at earlier to communicate with any endpoints the `PeerName` exposes.

Information about the local peer is also accessible through the `ContactManager` class, through the static `ContactManager.LocalContact` property. This gets you a `PeerContact` property with details of the local peer.

You can add `PeerNearMe` objects to the local list of contacts by using either the `ContactManager.CreateContact()` or `CreateContactAsync()` method, or `PeerName` objects by using the `GetContact()` method. You can remove contacts represented by a `PeerNearMe` or `PeerName` object with the `DeleteContact()` method.

Finally, there are events that you can handle to respond to changes to contacts. For example, you can use the `PresenceChanged` event to respond to changes of presence for any contacts known by the `ContactManager`.

Sample Application

There is a second sample application in the downloadable code for this chapter that illustrates the use of classes in the `System.Net.PeerToPeer.Collaboration` namespace. This application is similar to the other example, but much simpler. You need two computers that can both sign in to the PNM server to see this application in action, because it enumerates and displays PNM peers from the local subnet.

When you run the application with at least one peer available for discovery the display will be similar to Figure 45-8.

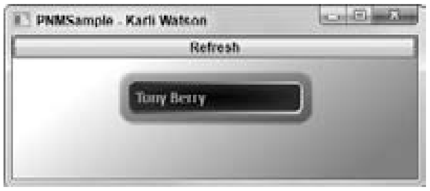

FIGURE 45-8

The code is structured in the same way as the previous example, so if you've read through that code you should be familiar with this code. This time there is not much work to do in the `Window_Loaded()` event handler except sign in, because there is no WCF service to initialize or peer name registration to achieve:

```
private void Window_Loaded(object sender, RoutedEventArgs e)
{
   // Sign in to PNM
   PeerCollaboration.SignIn(PeerScope.NearMe);
```

To make things look a little nicer, though, `ContactManager.LocalContact.Nickname` is used to format the window title:

```
   // Get local peer name to display
   this.Title = string.Format("PNMSample — {0}",
      ContactManager.LocalContact.Nickname);
}
```

In `Window_Closing()` the local peer is automatically signed out of PNM:

```
private void Window_Closing(object sender,
   System.ComponentModel.CancelEventArgs e)
{
   // Sign out of PNM
   PeerCollaboration.SignOut(PeerScope.NearMe);
}
```

Most of the work is done in the `RefreshButton_Click()` event handler. This uses the `PeerCollaboration.GetPeersNearMe()` method to obtain a list of peers and add those peers to the display using the `PeerEntry` class defined in the project, or display a failure message if none are found:

```
private void RefreshButton_Click(object sender, RoutedEventArgs e)
{
   // Get local peers
   PeerNearMeCollection peersNearMe = PeerCollaboration.GetPeersNearMe();

   // Prepare for new peers
   PeerList.Items.Clear();

   // Examine peers
   foreach (PeerNearMe peerNearMe in peersNearMe)
   {
      PeerList.Items.Add(
         new PeerEntry
         {
            PeerNearMe = peerNearMe,
            PresenceStatus = peerNearMe.GetPresenceInfo(
               peerNearMe.PeerEndPoints[0]).PresenceStatus,
            DisplayString = peerNearMe.Nickname
         });
   }

   // Add failure message if necessary
   if (PeerList.Items.Count == 0)
   {
      PeerList.Items.Add(
         new PeerEntry
         {
                DisplayString = "No peers found."
            });
        }
    }
```

As you can see from this example, interacting with the PNM service is made very simple by the classes you have learned about.

SUMMARY

This chapter demonstrated how to implement peer-to-peer functionality in your applications by using the P2P classes in .NET 4.

You have looked at the types of solutions that P2P makes possible and how these solutions are structured, how to use PNRP and PNM, and how to use the types in the `System.Net.PeerToPeer` and `System.Net.PeerToPeer.Collaboration` namespaces. You also saw the extremely useful technique of exposing WCF services as P2P endpoints.

If you are interested in developing P2P applications, it is well worth investigating PNM further. It is also worth looking at the peer channel, by which WCF services can broadcast communications among multiple clients simultaneously.

In the next chapter you look at Message Queuing.

46

Message Queuing

WHAT'S IN THIS CHAPTER?

- ➤ Message Queuing overview
- ➤ Message Queuing architecture
- ➤ Message Queuing administrative tools
- ➤ Programming Message Queuing
- ➤ Course order sample application
- ➤ Message Queuing with WCF

`System.Messaging` is a namespace that includes classes for reading and writing messages with the Message Queuing facility of the Windows operating system. Messaging can be used in a disconnected scenario where the client and server needn't be running at the same time.

This chapter gives you information about the architecture and usage scenarios of Message Queuing, and then you dive into the classes from the `System.Messaging` namespace to create queues, and send and receive messages. You will see how to deal with getting answers from the server with acknowledgement and response queues, and also how to use message queuing with a WCF message queuing binding.

OVERVIEW

Before diving into programming Message Queuing in the rest of this chapter, this section discusses the basic concepts of messaging and compares it to synchronous and asynchronous programming. With synchronous programming, when a method is invoked, the caller has to wait until the method is completed. With asynchronous programming, the calling thread starts the method that runs concurrently. Asynchronous programming can be done with delegates, class libraries that already support asynchronous methods (for example, Web service proxies, `System.Net`, and `System.IO` classes), or by using custom threads (see Chapter 20, "Threads, Tasks, and Synchronization"). With both synchronous and asynchronous programming, the client and the server must be running at the same time.

Although Message Queuing operates asynchronously, because the client (sender) does not wait for the server (receiver) to read the data sent to it, there is a crucial difference between Message Queuing and asynchronous programming: Message Queuing can be done in a disconnected environment. At the time data is sent, the receiver can be offline. Later, when the receiver goes online, it receives the data without intervention from the sending application.

You can compare connected and disconnected programming with talking to someone on the phone and sending an e-mail. When talking to someone on the phone, both participants must be connected at the same time; the communication is synchronous. With an e-mail, the sender isn't sure when the e-mail will be dealt with. People using this technology are working in a disconnected mode. Of course the e-mail may never be dealt with — it may be ignored. That's in the nature of disconnected communication. To avoid this problem, it is possible to ask for a reply to confirm that the e-mail has been read. If the answer doesn't arrive within a time limit, you may be required to deal with this "exception." This is also possible with Message Queuing.

You can think of Message Queuing as e-mail for application-to-application communication, instead of person-to-person communication. Message Queuing offers a lot of features that are not available with mailing services, such as guaranteed delivery, transactions, confirmations, express mode using memory, and so on. As you see in the next section, Message Queuing has a lot of features useful for communication between applications.

With Message Queuing, you can send, receive, and route messages in a connected or disconnected environment. Figure 46-1 shows a very simple way of using messages. The sender sends messages to the message queue, and the receiver receives messages from the queue.

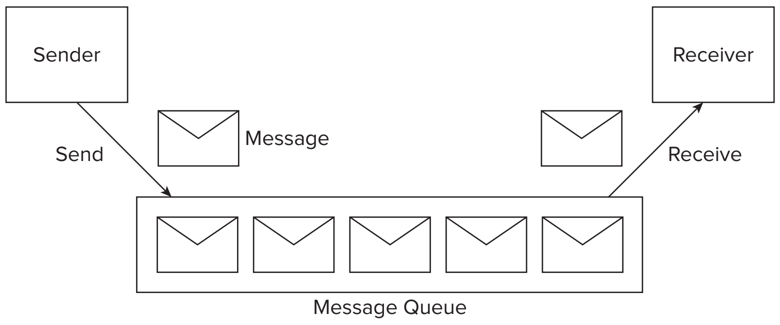

FIGURE 46-1

When to Use Message Queuing

One case in which Message Queuing is useful is when the client application is often disconnected from the network, for example, when a salesperson is visiting a customer onsite. The salesperson can enter order data directly at the customer's site. The application sends a message for each order to the message queue that is located on the client's system (see Figure 46-2). As soon as the salesperson is back in the office, the order is automatically transferred from the message queue of the client system to the message queue of the target system, where the message is processed.

In addition to using a laptop, the salesperson could use a Pocket Windows device where Message Queuing is available.

Message Queuing can also be useful in a connected environment. Imagine an e-commerce site (see Figure 46-3) where the server is fully loaded with order transactions at certain times, for example, early evening and weekends, but the load is low at nighttime. A solution would be to buy a faster server or to add additional servers to the system so that the peaks can be handled. But there's a cheaper solution: flatten the peak loads by moving transactions from the times with higher loads to the times with lower loads. In this scheme, orders are sent to the message queue, and the receiving side reads the orders at the rates that are useful for the database system. The load of the system is now flattened over time so that the server dealing with the transactions can be less expensive than an upgrade of the database server(s).

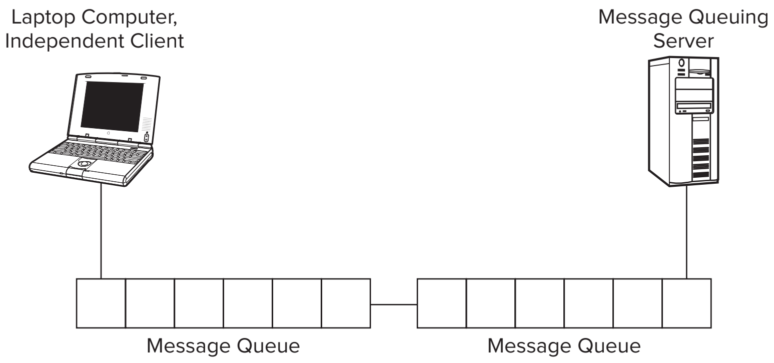

FIGURE 46-2

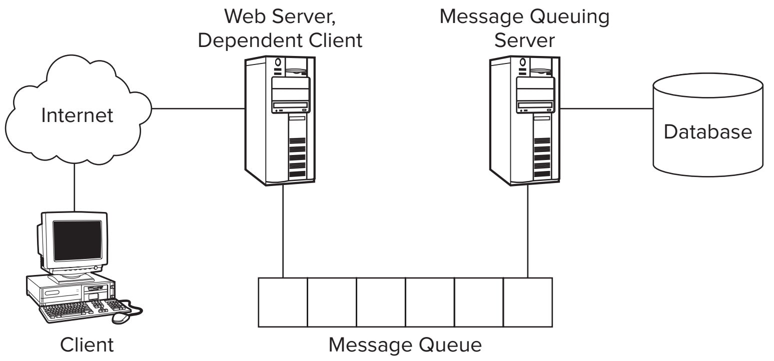

FIGURE 46-3

Message Queuing Features

Message Queuing is part of the Windows operating system. The main features of this service are:

- Messages can be sent in a disconnected environment. It is not necessary for the sending and receiving applications to run at the same time.
- With express mode, messages can be sent very quickly. Express-mode messages are just stored in memory.
- For a recoverable mechanism, messages can be sent using guaranteed delivery. Recoverable messages are stored within files. They are delivered even in cases when the server reboots.
- Message queues can be secured with access-control lists to define which users can send or receive messages from a queue. Messages can also be encrypted to avoid network sniffers reading them. Messages can be sent with priorities so that high-priority items are handled faster.
- Message Queuing 3.0 supports sending multicast messages.

Message Queuing 4.0 supports *poison messages*. A poison message is one that isn't getting resolved. You can define a *poison queue* where unresolved messages are moved. For example, if the job after reading the message from the normal queue was to insert it into the database, but the message did not get into the database and thus this job failed, it would get sent to the poison queue. It is someone's job to handle the poison queue — and that person should deal with the message in a way that resolves it.

- Message Queuing 5.0 supports more secure authentication algorithms and can handle a larger number of queues. (Message Queuing 4.0 had performance problems with several thousand queues.)

> *Because Message Queuing is part of the operating system, you cannot install Message Queuing 5.0 on a Windows XP or Windows Server 2003 system. Message Queuing 5.0 is part of Windows Server 2008 R2 and Windows 7.*

The remainder of this chapter discusses how these features can be used.

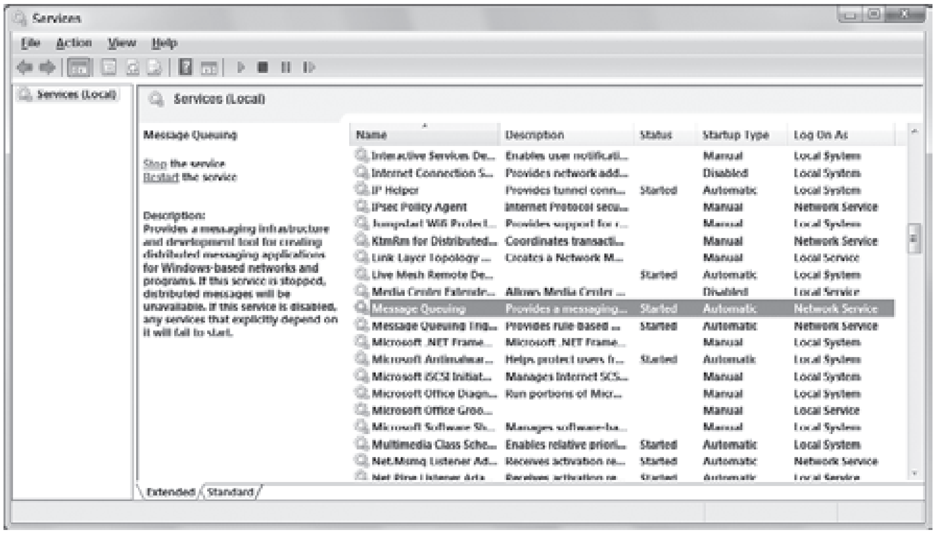
MESSAGE QUEUING PRODUCTS

Message Queuing 5.0 is part of Windows 7 and Windows Server 2008 R2. Windows 2000 was delivered with Message Queuing 2.0, which didn't have support for the HTTP protocol and multicast messages. Message Queuing 3.0 is part of Windows XP and Windows Server 2003. Message Queuing 4.0 is part of Windows Vista and Windows Server 2008.

When you use the link "Turn Windows Features on or off" in Configuring Programs and Features of Windows 7, there is a separate section for Message Queuing options. With this section, you can select these components:

- **Microsoft Message Queue (MSMQ) Server Core** — The Core subcomponent is required for base functionality with Message Queuing.
- **Active Directory Domain Services Integration** — With the Active Directory Domain Services Integration, message queue names are written to the Active Directory. With this option, it is possible to find queues with the Active Directory integration, and to secure queues with Windows users and groups.
- **MSMQ HTTP Support** — MSMQ HTTP Support allows you to send and receive messages using the HTTP protocol.
- **Triggers** — With triggers, applications can be instantiated on the arrival of a new message.
- **Multicast Support** — With multicasting, a message can be sent to a group of servers.
- **MSMQ DCOM Proxy** — With the DCOM proxy, a system can connect to a remote server by using the DCOM API.

When Message Queuing is installed, the Message Queuing service (see Figure 46-4) must be started. This service reads and writes messages and communicates with other Message Queuing servers to route messages across the network.



Message Queuing

Stop the service
Restart the service

Description:
Provides a messaging infrastructure and development tool for creating distributed messaging applications for Windows-based networks and programs. If this service is stopped, distributed messages will be unavailable. If this service is disabled, any services that explicitly depend on it will fail to start.

FIGURE 46-4

MESSAGE QUEUING ARCHITECTURE

With Message Queuing, messages are written to and read from a message queue. Messages and message queues have several attributes that must be further elaborated.

Messages

A message is sent to a message queue. The message includes a body containing the data that is sent and a label that is the title of the message. Any information can be put into the body of the message. With .NET, several formatters convert data to be put into the body. In addition to the label and the body, the message includes more information about the sender, timeout configuration, transaction ID, or priority.

Message queues have several types of messages:

A *normal message* is sent by an application.

An *acknowledgment message* reports the status of a normal message. Acknowledgment messages are sent to administration queues to report success or failure when sending normal messages.

Response messages are sent by receiving applications when the original sender requires some special answer.

A *report message* is generated by the Message Queuing system. Test messages and route-tracking messages belong to this category.

A message can have a priority that defines the order in which the messages will be read from the queue. The messages are sorted in the queue according to their priority, so the next message read in the queue is the one with the highest priority.

Messages have two delivery modes: *express* and *recoverable*. Express messages are delivered very quickly because memory is used only for the message store. Recoverable messages are stored in files at every step along the route until the message is delivered. This way, delivery of the message is assured, even with a computer reboot or network failure.

Transactional messages are a special version of recoverable messages. With transactional messaging, it is guaranteed that messages arrive only once and in the same order that they were sent. Priorities cannot be used with transactional messages.

Message Queue

A message queue is a storage bin for messages. Messages that are stored on disk can be found in the `<windir>\system32\msmq\storage` directory.

Public or private queues are usually used for sending messages, but other queue types also exist:

A *public queue* is published in the Active Directory. Information about these queues is replicated across Active Directory domains. You can use browse and search features to get information about these queues. A public queue can be accessed without knowing the name of the computer where it is placed. It is also possible to move such a queue from one system to another without the client knowing it. It's not possible to create public queues in a Workgroup environment because the Active Directory is needed. The Active Directory is discussed in online Chapter 52, "Directory Services."

Private queues are not published in the Active Directory. These queues can be accessed only when the full pathname to the queue is known. Private queues can be used in a Workgroup environment.

Journal queues are used to keep copies of messages after they have been received or sent. Enabling journaling for a public or private queue automatically creates a journal queue. With journal queues, two different queue types are possible: source journaling and target journaling. *Source journaling* is turned on with the properties of a message; journal messages are stored with the source system. *Target journaling* is turned on with the properties of a queue; these messages are stored in the journal queue of the target system.

Dead-letter queues store messages if a message doesn't arrive at the target system before a specific timeout is reached. Contrary to synchronous programming where errors are immediately detected, errors must be dealt with differently using Message Queuing. The dead-letter queue can be checked for messages that didn't arrive.

Administration queues contain acknowledgments for messages sent. The sender can specify an administration queue from which it receives notification of whether the message was sent successfully.

A *response queue* is used if more than a simple acknowledgment is needed as an answer from the receiving side. The receiving application can send response messages back to the original sender.

A *report queue* is used for test messages. Report queues can be created by changing the type (or category) of a public or private queue to the predefined ID `{55EE8F33-CCE9-11CF-B108-0020AFD61CE9}`. Report queues are useful as a testing tool to track messages on their route.

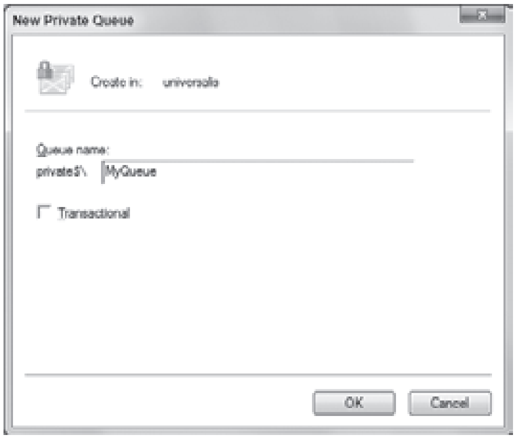
System queues are private and are used by the Message Queuing system. These queues are used for administrative messages, storing of notification messages, and to guarantee the correct order of transactional messages.

MESSAGE QUEUING ADMINISTRATIVE TOOLS

Before looking at how to deal with Message Queuing programmatically, this section looks at the administrative tools that are part of the Windows operating system to create and manage queues and messages.

Creating Message Queues

Message queues can be created with the Computer Management MMC snap-in. On a Windows 7 system, you can start the Computer Management MMC snap-in with the Start ➪ Control Panel ➪ Administrative Tools ➪ Computer Management menu. In the tree view pane, Message Queuing is located below the Services and Applications entry. By selecting Private Queues or Public Queues, new queues can be created from the Action menu (see Figure 46-5). Public queues are available only if Message Queuing is configured in Active Directory mode.



New Private Queue

Create in: universalis

Queue name:
private$\ MyQueue

☐ Transactional

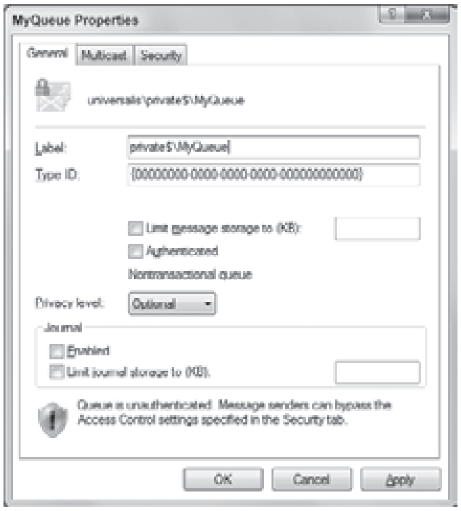
FIGURE 46-5

Message Queue Properties

After a queue is created, you can modify the queue's properties with the Computer Management snap-in by selecting the queue in the tree pane and selecting the Action Properties menu (see Figure 46-6).

Several options can be configured:

- ➤ The label is the name of the queue that can be used to search for the queue.
- ➤ The type ID, which is by default, set to {00000000–0000–0000–0000–000000000000} to map multiple queues to a single category or type. Report queues use a specific type ID, as discussed earlier. A type ID is a universal unique ID (UUID) or GUID.



MyQueue Properties

universalis\private$\MyQueue

Label: private$\MyQueue

Type ID: {00000000-0000-0000-0000-000000000000}

☐ Limit message storage to (KB):

☐ Authenticated

Nontransactional queue

Privacy level: Optional

Journal

☐ Enabled

☐ Limit journal storage to (KB):

Queue is unauthenticated. Message senders can bypass the Access Control settings specified in the Security tab.

FIGURE 46-6

Custom type identifiers can be created with the `uuidgen.exe` *or* `guidgen.exe` *utilities.* `uuidgen.exe` *is a command-line utility used to create unique IDs, and* `guidgen.exe` *is a graphical version to create UUIDs.*

- ➤ The maximum size of all messages of a queue can be limited to avoid filling up the disk.
- ➤ When checked, the Authenticated option allows only authenticated users to write and read messages to and from the queue.
- ➤ With the Privacy Level option, the content of the message can be encrypted. The possible values to set are None, Optional, or Body. None means that no encrypted messages are accepted, Body accepts only encrypted messages, and the default Optional value accepts both.
- ➤ Target journaling can be configured with the Journal settings. With this option, copies of the messages received are stored in the journal. The maximum size of disk space that is occupied can be configured for the journal messages of a queue. When the maximum size is reached, target journaling is ceased.
- ➤ With the configuration option Multicast, you can define a multicast IP address for the queue. The same multicast IP address can be used with different nodes in the network, so that a message sent to a single address is received with multiple queues.

PROGRAMMING MESSAGE QUEUING

Now that you understand the architecture of Message Queuing, you can look into the programming. In the next sections, you see how to create and control queues, and how to send and receive messages.

You also build a small course order application that consists of a sending and a receiving part.

Creating a Message Queue

You've already seen how to create message queues with the Computer Management utility. Message queues can be created programmatically with the `Create()` method of the `MessageQueue` class.

With the `Create()` method, the path of the new queue must be passed. The path consists of the host name where the queue is located and the name of the queue. In the following example, the queue

`MyNewPublicQueue` is created on the local host. To create a private queue, the pathname must include `Private$`; for example, `\Private$\MyNewPrivateQueue`.

After the `Create()` method is invoked, properties of the queue can be changed. For example, using the `Label` property, the label of the queue is set to `Demo Queue`. The sample program writes the path of the queue and the format name to the console. The format name is automatically created with a UUID that can be used to access the queue without the name of the server:

```
using System;
using System.Messaging;

namespace Wrox.ProCSharp.Messaging
{
   class Program
   {
      static void Main()
      {
         using (var queue = MessageQueue.Create(@".\MyNewPublicQueue"))
         {
            queue.Label = "Demo Queue";
            Console.WriteLine("Queue created:");
            Console.WriteLine("Path: {0}", queue.Path);
            Console.WriteLine("FormatName: {0}", queue.FormatName);
         }
      }
   }
}
```

code snippet CreateMessageQueue/Program.cs

Administrative privileges are required to create a queue. Usually, you cannot expect the user of your application to have administrative privileges. That's why queues usually are created with installation programs. Later in this chapter, you see how message queues can be created with the `MessageQueueInstaller` *class.*

Finding a Queue

The pathname and the format name can be used to identify queues. To find queues, you must differentiate between public and private queues. Public queues are published in the Active Directory. For these queues, it is not necessary to know the system where they are located. Private queues can be found only if the name of the system where the queue is located is known.

You can find public queues in the Active Directory domain by searching for the queue's label, category, or format name. You can also get all queues on a machine. The class `MessageQueue` has static methods to search for queues: `GetPublicQueuesByLabel()`, `GetPublicQueuesByCategory()`, and `GetPublicQueuesByMachine()`. The method `GetPublicQueues()` returns an array of all public queues in the domain:

```
using System;
using System.Messaging;

namespace Wrox.ProCSharp.Messaging
{
   class Program
   {
        static void Main()
        {
           foreach (var queue in MessageQueue.GetPublicQueues())
           {
              Console.WriteLine(queue.Path);
           }
        }
     }
  }
```

code snippet FindQueues/Program.cs

The method `GetPublicQueues()` is overloaded. One version allows passing an instance of the `MessageQueueCriteria` class. With this class, you can search for queues created or modified before or after a certain time, and you can also look for a category, label, or machine name.

Private queues can be searched with the static method `GetPrivateQueuesByMachine()`. This method returns all private queues from a specific system.

Opening Known Queues

If the name of the queue is known, it is not necessary to search for it. Queues can be opened by using the path or format name. They both can be set in the constructor of the `MessageQueue` class.

Pathname

The path specifies the machine name and the queue name to open the queue. This code example opens the queue `MyPublicQueue` on the local host. To be sure that the queue exists, you use the static method `MessageQueue.Exists()`:

```
using System;
using System.Messaging;

namespace Wrox.ProCSharp.Messaging
{
   class Program
   {
      static void Main()
      {
         if (MessageQueue.Exists(@".\MyPublicQueue"))
         {
            var queue = new MessageQueue(@".\MyPublicQueue");
            //.
         }
         else
         {
            Console.WriteLine("Queue .\MyPublicQueue not existing");
         }
      }
   }
}
```

code snippet OpenQueue/Program.cs

Depending on the queue type, different identifiers are required when queues are opened. The following table shows the syntax of the queue name for specific types.

QUEUE TYPE	SYNTAX
Public queue	`MachineName\QueueName`
Private queue	`MachineName\Private$\QueueName`
Journal queue	`MachineName\QueueName\Journal$`
Machine journal queue	`MachineName\Journal$`
Machine dead-letter queue	`MachineName\DeadLetter$`
Machine transactional dead-letter queue	`MachineName\XactDeadLetter$`

When you use the pathname to open public queues, it is necessary to pass the machine name. If the machine name is not known, the format name can be used instead. The pathname for private queues can be used only on the local system. The format name must be used to access private queues remotely.

Format Name

Instead of the pathname, you can use the format name to open a queue. The format name is used for searching the queue in the Active Directory to get the host where the queue is located. In a disconnected environment where the queue cannot be reached at the time the message is sent, it is necessary to use the format name:

```
MessageQueue queue = new MessageQueue(
      @"FormatName:PUBLIC=09816AFF-3608-4c5d-B892-69754BA151FF");
```

The format name has some different uses. It can be used to open private queues and to specify a protocol that should be used:

- To access a private queue, the string that has to be passed to the constructor is `FormatName:PRIVATE=MachineGUID\QueueNumber`. The queue number for private queues is generated when the queue is created. You can see the queue numbers in the `<windows>\System32\msmq\storage\lqs` directory.
- With `FormatName:DIRECT=Protocol:MachineAddress\QueueName`, you can specify the protocol that should be used to send the message. The HTTP protocol is supported since Message Queuing 3.0.
- `FormatName:DIRECT=OS:MachineName\QueueName` is another way to specify a queue using the format name. This way you don't have to specify the protocol but still can use the machine name with the format name.

Sending a Message

You can use the `Send` method of the `MessageQueue` class to send a message to the queue. The object passed as an argument of the `Send()` method is serialized to the associated queue. The `Send()` method is overloaded so that a label and a `MessageQueueTransaction` object can be passed. Transactional behavior of Message Queuing is discussed later.

The code example first checks if the queue exists. If it doesn't exist, a queue is created. Then the queue is opened and the message `Sample Message` is sent to the queue using the `Send()` method.

The pathname specifies a dot (just like a period) for the server name, which is the local system. Pathnames to private queues work only locally:

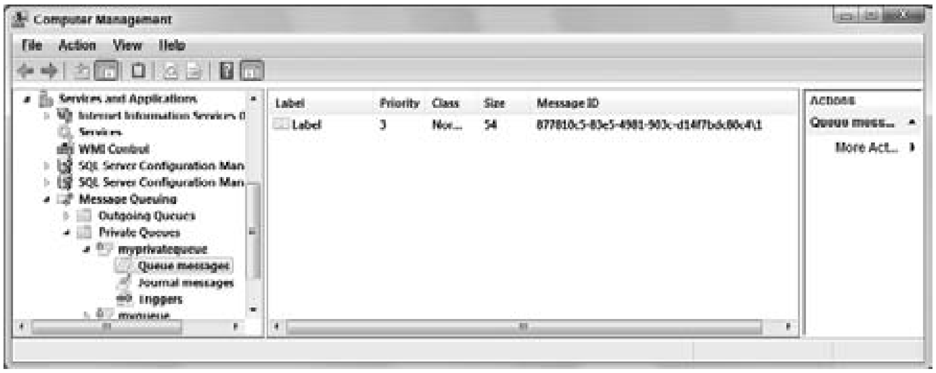
```
using System;
using System.Messaging;

namespace Wrox.ProCSharp.Messaging
{
   class Program
   {
      static void Main()
      {
            try
            {
               if (!MessageQueue.Exists(@".\Private$\MyPrivateQueue"))
               {
                  MessageQueue.Create(@".\Private$\MyPrivateQueue");
               }
               var queue = new MessageQueue(@".\Private$\MyPrivateQueue");

               queue.Send("Sample Message", "Label");
            }
            catch (MessageQueueException ex)
            {
               Console.WriteLine(ex.Message);
            }
         }
      }
   }
```

code snippet SendMessage/Program.cs

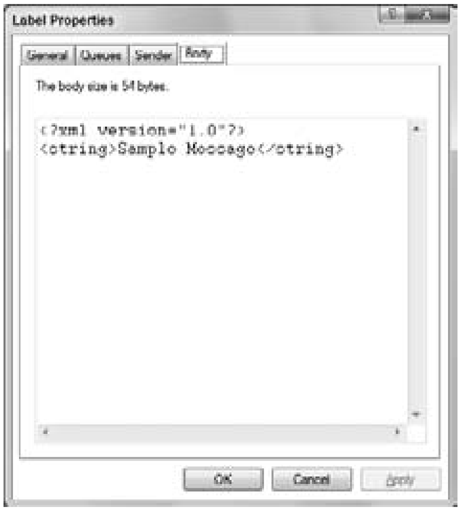
Figure 46-7 shows the Computer Management admin tool where you can see the message that arrived in the queue.



Label	Priority	Class	Size	Message ID
Label	3	Nor...	54	877810c5-83e5-4981-903c-d14f7bdc80c4\1

FIGURE 46-7

By opening the message and selecting the Body tab (see Figure 46-8) of the dialog box, you can see that the message was formatted using XML. Determining how the message is formatted is the function of the formatter that's associated with the message queue.



The body size is 54 bytes.

```
<?xml version="1.0"?>
<string>Sample Message</string>
```

FIGURE 46-8

Message Formatter

The format in which messages are transferred to the queue depends on the formatter. The `MessageQueue` class has a `Formatter` property through which a formatter can be assigned. The default formatter, `XmlMessageFormatter`, will format the message in XML syntax as shown in the previous example.

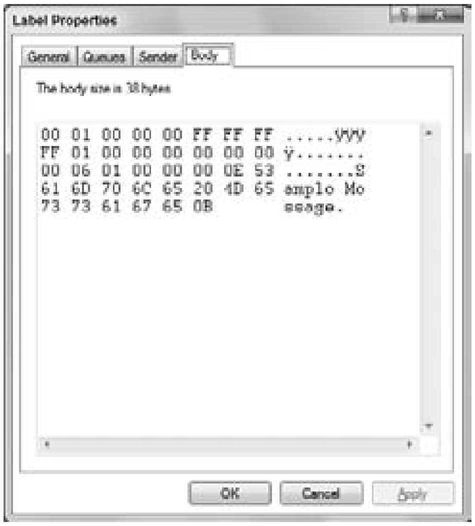
A message formatter implements the interface `IMessageFormatter`. Three message formatters are available with the namespace `System.Messaging`:

➤ The `XmlMessageFormatter` is the default formatter. It serializes objects using XML. See Chapter 33, "Manipulating XML," for more on XML formatting.

➤ With the `BinaryMessageFormatter`, messages are serialized in a binary format. These messages are shorter than the messages formatted using XML.

➤ The `ActiveXMessageFormatter` is a binary formatter so that messages can be read or written with COM objects. Using this formatter, it is possible to write a message to the queue with a .NET class and to read the message from the queue with a COM object or vice versa.

The sample message shown in Figure 46-8 with XML is formatted with the `BinaryMessageFormatter` in Figure 46-9.



The body size is 38 bytes

```
00 01 00 00 00 FF FF FF .....ÿÿÿ
FF 01 00 00 00 00 00 00 ÿ.......
00 06 01 00 00 00 0E 53 .......S
61 6D 70 6C 65 20 4D 65 ample Me
73 73 61 67 65 0B       ssage.
```

FIGURE 46-9

Sending Complex Messages

Instead of passing strings, it is possible to pass objects to the `Send()` method of the `MessageQueue` class. The type of the class must fulfill some specific requirements, but they depend on the formatter.

For the binary formatter, the class must be serializable with the `[Serializable]` attribute. With the .NET runtime serialization, all fields are serialized (this includes private fields). Custom serialization can be defined by implementing the interface `ISerializable`. You can read more about the .NET runtime serialization in Chapter 29, "Manipulating Files and the Registry."

XML serialization takes place with the XML formatter. With XML serialization, all public fields and properties are serialized. The XML serialization can be influenced by using attributes from the `System.Xml.Serialization` namespace. You can read more about XML serialization in Chapter 33.

Receiving Messages

To read messages, again, you can use the `MessageQueue` class. With the `Receive()` method, a single message is read and removed from the queue. If messages are sent with different priorities, the message with the highest priority is read. Reading messages with the same priority may mean that the first message sent is not the first message read because the order of messages across the network is not guaranteed. For a guaranteed order, you should use transactional message queues.

In the following example, a message is read from the private queue `MyPrivateQueue`. Previously, a simple string was passed to the message. When you read a message using the `XmlMessageFormatter`, you have to pass the types of the objects that are read to the constructor of the formatter. In the example, the type `System.String` is passed to the argument array of the `XmlMessageFormatter` constructor. This constructor allows either a `String` array that contains the types as strings to be passed or a `Type` array.

The message is read with the `Receive()` method, and then the message body is written to the console:

```
using System;
using System.Messaging;

namespace Wrox.ProCSharp.Messaging
{
   class Program
   {
         static void Main()
         {
            var queue = new MessageQueue(@".\Private$\MyPrivateQueue");
            queue.Formatter = new XmlMessageFormatter(
                  new string[] {"System.String"});

            Message message = queue.Receive();
            Console.WriteLine(message.Body);
         }
      }
   }
```

code snippet SendMessage/Program.cs

The `Receive()` message behaves synchronously and waits until a message is in the queue if there is none.

Enumerating Messages

Instead of reading message by message with the `Receive()` method, you can use an enumerator to walk through all messages. The `MessageQueue` class implements the interface `IEnumerable` and thus can be used with a `foreach` statement. Here, the messages are not removed from the queue, but you get just a peek at the messages to get their content:

```
var queue = new MessageQueue(@".\Private$\MyPrivateQueue");
queue.Formatter = new XmlMessageFormatter(
      new string[] {"System.String"});

foreach (Message message in queue)
{
   Console.WriteLine(message.Body);
}
```

Instead of using the `IEnumerable` interface, the class `MessageEnumerator` can be used. `MessageEnumerator` implements the interface `IEnumerator`, but has some more features. With the `IEnumerable` interface, the messages are not removed from the queue. The method `RemoveCurrent()` of the `MessageEnumerator` removes the message from the current cursor position of the enumerator.

In the example, the `MessageQueue` method `GetMessageEnumerator()` is used to access the `MessageEnumerator`. The `MoveNext()` method takes a peek message by message with the `MessageEnumerator`. The `MoveNext()` method is overloaded to allow a time span as an argument. This is one of the big advantages when using this enumerator. Here, the thread can wait until a message arrives in the queue, but only for the specified time span. The `Current` property, which is defined by the `IEnumerator` interface, returns a reference to a message:

```
var queue = new MessageQueue(@".\Private$\MyPrivateQueue");
queue.Formatter = new XmlMessageFormatter(
      new string[] {"System.String"});

using (MessageEnumerator messages = queue.GetMessageEnumerator())
{
   while (messages.MoveNext(TimeSpan.FromMinutes(30)))
   {
      Message message = messages.Current;
      Console.WriteLine(message.Body);
   }
}
```

Asynchronous Read

The `Receive` method of the `MessageQueue` class waits until a message from the queue can be read. To avoid blocking the thread, a timeout can be specified in an overloaded version of the `Receive` method. To read the message from the queue after the timeout, `Receive()` must be invoked again. Instead of polling for messages, the asynchronous method `BeginReceive()` can be called. Before starting the asynchronous read with `BeginReceive()`, the event `ReceiveCompleted` should be set. The `ReceiveCompleted` event requires a `ReceiveCompletedEventHandler` delegate that references the method that is invoked when a message arrives in the queue and can be read. In the example, the method `MessageArrived` is passed to the `ReceivedCompletedEventHandler` delegate:

```
var queue = new MessageQueue(@".\Private$\MyPrivateQueue");
queue.Formatter = new XmlMessageFormatter(
      new string[] {"System.String"});

queue.ReceiveCompleted += MessageArrived;
queue.BeginReceive();
// thread does not wait
```

code snippet ReceiveMessageAsync/Program.cs

The handler method `MessageArrived` requires two parameters. The first parameter is the origin of the event, the `MessageQueue`. The second parameter is of type `ReceiveCompletedEventArgs` that contains the message and the asynchronous result. In the example, the method `EndReceive()` from the queue is invoked to get the result of the asynchronous method, the message:

```
public static void MessageArrived(object source, ReceiveCompletedEventArgs e)
{
   MessageQueue queue = (MessageQueue)source;
   Message message = queue.EndReceive(e.AsyncResult);
   Console.WriteLine(message.Body);
}
```

If the message should not be removed from the queue, the `BeginPeek()` and `EndPeek()` methods can be used with asynchronous I/O.

COURSE ORDER APPLICATION

To demonstrate the use of Message Queuing, in this section you create a sample solution to order courses. The sample solution is made up of three assemblies:

- ➤ A component library (`CourseOrder`) that includes entity classes for the messages that are sent and received in the queue
- ➤ A WPF application (`CourseOrderSender`) that sends messages to the message queue
- ➤ A WPF application (`CourseOrderReceiver`) that receives messages from the message queue

Course Order Class Library

Both the sending and the receiving application need the order information. For this reason, the entity classes are put into a separate assembly. The `CourseOrder` assembly includes three entity classes: `CourseOrder`, `Course`, and `Customer`. With the sample application, not all properties are implemented as they would be in a real application, but just enough properties to show the concept.

In the file `Course.cs`, the class `Course` is defined. This class has just one property for the title of the course:

```
namespace Wrox.ProCSharp.Messaging
{
   public class Course
   {
      public string Title { get; set; }
   }
}
```

code snippet CourseOrder/Course

The file `Customer.cs` includes the class `Customer`, which includes properties for the company and contact names:

```
namespace Wrox.ProCSharp.Messaging
{
   public class Customer
   {
      public string Company { get; set; }
      public string Contact { get; set; }
   }
}
```

code snippet CourseOrder/Customer.cs

The class `CourseOrder` in the file `CourseOrder.cs` maps a customer and a course inside an order and defines whether the order is high priority. This class also defines the name of the queue that is set to a format name of a public queue. The format name is used to send the message, even if the queue cannot be reached currently. You can get the format name by using the Computer Management snap-in to read the ID of the message queue. If you don't have access to an Active Directory to create a public queue, you can easily change the code to use a private queue.

```
namespace Wrox.ProCSharp.Messaging
{
   public class CourseOrder
   {
      public const string CourseOrderQueueName =
 "FormatName:Public=D99CE5F3-4282-4a97-93EE-E9558B15EB13";

      public Customer Customer { get; set; }
      public Course Course { get; set; }
   }
}
```

code snippet CourseOrder/CourseOrder.cs

Course Order Message Sender

The second part of the solution is a Windows application called `CourseOrderSender`. With this application, course orders are sent to the message queue. The assemblies `System.Messaging` and `CourseOrder` must be referenced.

The user interface of this application is shown in Figure 46-10. The items of the combo box `comboBoxCourses` include several courses such as Advanced .NET Programming, Programming with LINQ, and Distributed Application Development using WCF.

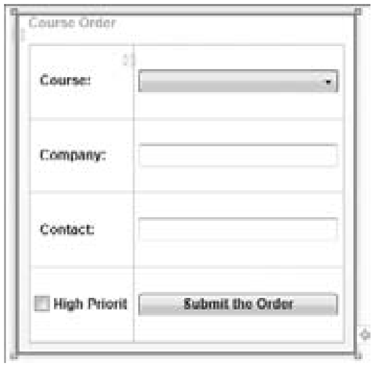


FIGURE 46-10

When the Submit the Order button is clicked, the handler method `buttonSubmit_Click()` is invoked. With this method, a `CourseOrder` object is created and filled with the content from the `TextBox` and `ComboBox` controls. Then a `MessageQueue` instance is created to open a public queue with a format name. With the `Send()` method, the `CourseOrder` object is passed to serialize it with the default `XmlMessageFormatter` and to write it to the queue:

```
private void buttonSubmit_Click(object sender, RoutedEventArgs e)
{
   try
   {
      var order = new CourseOrder();
```

```
            order.Course = new Course()
            {
               Title = comboBoxCourses.SelectedItem.ToString()
            };
            order.Customer = new Customer()
            {
               Company = textCompany.Text,
               Contact = textContact.Text
            };

            using (var queue = new MessageQueue(CourseOrder.CourseOrderQueueName))
            {
               queue.Send(order, String.Format("Course Order {{0}}",
                     order.Customer.Company));
            }
            MessageBox.Show("Course Order submitted", "Course Order",
                  MessageBoxButton.OK, MessageBoxImage.Information);
         }
         catch (MessageQueueException ex)
         {
            MessageBox.Show(ex.Message, "Course Order Error",
                  MessageBoxButton.OK, MessageBoxImage.Error);
         }
      }
```

code snippet CourseOrderSender/CourseOrderWindow.xaml.cs

Sending Priority and Recoverable Messages

Messages can be prioritized by setting the `Priority` property of the `Message` class. If messages are specially configured, a `Message` object must be created where the body of the message is passed in the constructor.

In the example, the priority is set to `MessagePriority.High` if the `checkBoxPriority` check box is checked. `MessagePriority` is an enumeration that allows you to set values from `Lowest` (0) to `Highest` (7). The default value, `Normal`, has a priority value of 3.

To make the message recoverable, the property `Recoverable` is set to `true`:

```
      private void buttonSubmit_Click(object sender, RoutedEventArgs e)
      {
         try
         {
            var order = new CourseOrder
            {
               Course = new Course
               {
                  Title = comboBoxCourses.Text
               },
               Customer = new Customer
               {
                  Company = textCompany.Text,
                  Contact = textContact.Text
               }
            };

            using (var queue = new MessageQueue(CourseOrder.CourseOrderQueueName))
            using (var message = new Message(order))
            {
               if (checkBoxPriority.IsChecked == true)
               {
                  message.Priority = MessagePriority.High;
               }
```

```
                message.Recoverable = true;
                queue.Send(message,  String.Format("Course Order {{{0}}}",
                      order.Customer.Company));
             }
             MessageBox.Show("Course Order submitted");
          }
          catch (MessageQueueException ex)
          {
             MessageBox.Show(ex.Message, "Course Order Error",
                   MessageBoxButton.OK, MessageBoxImage.Error);
          }
       }
```

code snippet CourseOrderSender/CourseOrderWindow.xaml.cs

By running the application, you can add course orders to the message queue (see Figure 46-11).

FIGURE 46-11

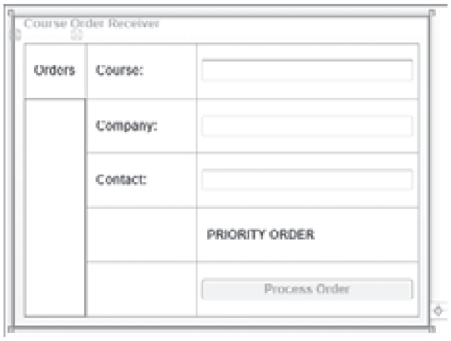

FIGURE 46-12

Course Order Message Receiver

The design view of the Course Order receiving application that reads messages from the queue is shown in Figure 46-12. This application displays labels of every order in the `listOrders` list box. When an order is selected, the content of the order is displayed with the controls on the right side of the application.

In the constructor of the `Window` class `CourseOrderReceiverWindow`, the `MessageQueue` object is created that references the same queue that was used with the sending application. For reading messages, the `XmlMessageFormatter` with the types that are read is associated with the queue using the `Formatter` property.

To display the available messages in the list, a new task is created that peeks at messages in the background. The task's main method is `PeekMessages`.

```
using System;
using System.Messaging;
using System.Threading;
using System.Windows;
using System.Windows.Controls;
using System.Windows.Threading;

namespace Wrox.ProCSharp.Messaging
{
   public partial class CourseOrderReceiverWindow: Window
   {
      private MessageQueue orderQueue;

      public CourseOrderReceiverWindow()
      {
         InitializeComponent();

         string queueName = CourseOrder.CourseOrderQueueName;
         orderQueue = new MessageQueue(queueName);
         orderQueue.Formatter = new XmlMessageFormatter(
            new Type[]
            {
               typeof(CourseOrder),
               typeof(Customer),
               typeof(Course)
            });

         // start the task that fills the ListBox with orders
         Task t1 = new Task(PeekMessages);
         t1.Start();
      }
```

code snippet CourseOrderReceiver/CourseOrderReceiverWindow.xaml.cs

The task's main method, `PeekMessages()`, uses the enumerator of the message queue to display all messages. Within the `while` loop, the `messagesEnumerator` checks to see if there is a new message in the queue. If there is no message in the queue, the thread waits three hours for the next message to arrive before it exits.

To display every message from the queue in the list box, the thread cannot directly write the text to the list box, but needs to forward the call to the list box's creator thread. Because WPF controls are bound to a single thread, only the creator thread is allowed to access methods and properties. The `Dispatcher.Invoke()` method forwards the request to the creator thread:

```
      private void PeekMessages()
      {
         using (MessageEnumerator messagesEnumerator =
               orderQueue.GetMessageEnumerator2())
         {
            while (messagesEnumerator.MoveNext(TimeSpan.FromHours(3)))
            {
               var labelId = new LabelIdMapping()
               {
                  Id = messagesEnumerator.Current.Id,
                  Label = messagesEnumerator.Current.Label
               };
               Dispatcher.Invoke(DispatcherPriority.Normal,
                     new Action<LabelIdMapping>(AddListItem),
                     labelId);
            }
         }
         MessageBox.Show("No orders in the last 3 hours. Exiting thread",
              "Course Order Receiver", MessageBoxButton.OK,
               MessageBoxImage.Information);
      }
```

```
private void AddListItem(LabelIdMapping labelIdMapping)
{
   listOrders.Items.Add(labelIdMapping);
}
```

The `ListBox` control contains elements of the `LabelIdMapping` class. This class is used to display the labels of the messages in the list box, but to keep the ID of the message hidden. The ID of the message can be used to read the message at a later time:

```
private class LabelIdMapping
{
   public string Label { get; set; }
   public string Id { get; set; }

   public override string ToString()
   {
      return Label;
   }
}
```

The `ListBox` control has the `SelectedIndexChanged` event associated with the method `listOrders_SelectionChanged()`. This method gets the `LabelIdMapping` object from the current selection, and uses the ID to peek at the message once more with the `PeekById()` method. Then the content of the message is displayed in the `TextBox` control. Because by default the priority of the message is not read, the property `MessageReadPropertyFilter` must be set to receive the `Priority`:

```
private void listOrders_SelectionChanged(object sender,
      RoutedEventArgs e)
{
   LabelIdMapping labelId = listOrders.SelectedItem as LabelIdMapping;
   if (labelId == null)
      return;

   orderQueue.MessageReadPropertyFilter.Priority = true;
   Message message = orderQueue.PeekById(labelId.Id);

   CourseOrder order = message.Body as CourseOrder;
   if (order != null)
   {
      textCourse.Text = order.Course.Title;
      textCompany.Text = order.Customer.Company;
      textContact.Text = order.Customer.Contact;
      buttonProcessOrder.IsEnabled = true;

      if (message.Priority > MessagePriority.Normal)
      {
         labelPriority.Visibility = Visibility.Visible;
      }
      else
      {
         labelPriority.Visibility = Visibility.Hidden;
      }
   }
   else
   {
      MessageBox.Show("The selected item is not a course order",
            "Course Order Receiver", MessageBoxButton.OK,
            MessageBoxImage.Warning);
   }
}
```

When the Process Order button is clicked, the handler method `OnProcessOrder()` is invoked. Here again, the currently selected message from the list box is referenced, and the message is removed from the queue by calling the method `ReceiveById()`:

```
        private void buttonProcessOrder_Click(object sender, RoutedEventArgs e)
        {
           LabelIdMapping labelId = listOrders.SelectedItem as LabelIdMapping;
           Message message = orderQueue.ReceiveById(labelId.Id);

           listOrders.Items.Remove(labelId);
           listOrders.SelectedIndex = -1;
           buttonProcessOrder.IsEnabled = false;
           textCompany.Text = string.Empty;
           textContact.Text = string.Empty;
           textCourse.Text = string.Empty;

           MessageBox.Show("Course order processed", "Course Order Receiver",
                 MessageBoxButton.OK, MessageBoxImage.Information);
        }
     }
  }
```

Figure 46-13 shows the running receiving application that lists three orders in the queue, and one order is currently selected.

FIGURE 46-13

RECEIVING RESULTS

With the current version of the sample application, the sending application never knows if the message is ever dealt with. To get results from the receiver, acknowledgment queues or response queues can be used.

Acknowledgment Queues

With an acknowledgment queue, the sending application can get information about the status of the message. With acknowledgments, you can define if you would like to receive an answer, if everything went okay, or if something went wrong. For example, acknowledgments can be sent when the message reaches the destination queue or when the message is read, or if it didn't reach the destination queue or was not read before a timeout elapsed.

In the example, the `AdministrationQueue` of the `Message` class is set to the `CourseOrderAck` queue, which must be created similar to a normal queue. This queue is just used the other way around: the original sender receives acknowledgments. The `AcknowledgeType` property is set to `AcknowledgeTypes.FullReceive` to get an acknowledgment when the message is read:

```
Message message = new Message(order);

message.AdministrationQueue = new MessageQueue(@".\CourseOrderAck");
message.AcknowledgeType = AcknowledgeTypes.FullReceive;

queue.Send(message, String.Format("Course Order {{0}}",
      order.Customer.Company);

string id = message.Id;
```

The *correlation ID* is used to determine what acknowledgment message belongs to which message sent. Every message that is sent has an ID, and the acknowledgment message that is sent in response to that message holds the ID of the originating message as its correlation ID. The messages from the acknowledgment queue can be read using `MessageQueue.ReceiveByCorrelationId()` to receive the associated acknowledgment.

Instead of using acknowledgments, the dead-letter queue can be used for messages that didn't arrive at their destination. With the `UseDeadLetterQueue` property of the `Message` class set to `true`, the message is copied to the dead-letter queue if it didn't arrive at the target queue before the timeout was reached.

Timeouts can be set with the `Message` properties `TimeToReachQueue` and `TimeToBeReceived`.

Response Queues

If more information than an acknowledgment is needed from the receiving application, a response queue can be used. A response queue is like a normal queue, but the original sender uses the queue as a receiver and the original receiver uses the response queue as a sender.

The sender must assign the response queue with the `ResponseQueue` property of the `Message` class. The sample code here shows how the receiver uses the response queue to return a response message. With the response message `responseMessage,` the property `CorrelationId` is set to the ID of the original message. This way the client application knows to which message the answer belongs. This is similar to acknowledgment queues. The response message is sent with the `Send()` method of the `MessageQueue` object that is returned from the `ResponseQueue` property:

```
public void ReceiveMessage(Message message)
{
   Message responseMessage = new Message("response");
   responseMessage.CorrelationId = message.Id;

   message.ResponseQueue.Send(responseMessage);
}
```

TRANSACTIONAL QUEUES

With recoverable messages, it is not guaranteed that the messages will arrive in order and just once. Failures on the network can cause messages to arrive multiple times; this happens also if both the sender and receiver have multiple network protocols installed that are used by Message Queuing.

Transactional queues can be used when these guarantees are required:

- Messages arrive in the same order they have been sent.
- Messages arrive only once.

With transactional queues, a single transaction doesn't span the sending and receiving of messages. The nature of Message Queuing is that the time between send and receive can be quite long. In contrast, transactions should be short. With Message Queuing, the first transaction is used to send the message into the queue, the second transaction forwards the message on the network, and the third transaction is used to receive the messages.

The next example shows how to create a transactional message queue and how to send messages using a transaction.

A transactional message queue is created by passing `true` with the second parameter of the `MessageQueue.Create()` method.

If you want to write multiple messages to a queue within a single transaction, you have to instantiate a `MessageQueueTransaction` object and invoke the `Begin()` method. When you are finished with sending all messages that belong to the transaction, the `Commit()` method of the `MessageQueueTransaction` object must be called. To cancel a transaction (and have no messages written to the queue), the `Abort()` method must be called, as you can see within the `catch` block:

```
using System;
using System.Messaging;

namespace Wrox.ProCSharp.Messaging
{
   class Program
   {
      static void Main()
      {
         if (!MessageQueue.Exists(@".\MyTransactionalQueue"))
         {
            MessageQueue.Create(@".\MyTransactionalQueue", true);
         }

         var queue = new MessageQueue(@".\MyTransactionalQueue");
         var transaction = new MessageQueueTransaction();

         try
         {
            transaction.Begin();
            queue.Send("a", transaction);
            queue.Send("b", transaction);
            queue.Send("c", transaction);
            transaction.Commit();
         }
         catch
         {
            transaction.Abort();
         }
      }
   }
}
```

MESSAGE QUEUING WITH WCF

Chapter 43, "Windows Communication Foundation," covers the architecture and core features of WCF. With WCF, you can configure a Message Queuing binding that makes use of the Windows Message Queuing architecture. With this, WCF offers an abstraction layer to Message Queuing. Figure 46-14 explains the architecture using a simple picture. The client application invokes a method of a WCF proxy to send a message to the queue. The message is created by the proxy. For the client developer, there's no need to know that a message is sent to the queue. The client developer just invokes a method of the proxy. The proxy abstracts dealing with the classes from the `System.Messaging` namespace and sends a message to the queue. The MSMQ listener channel on the service side reads messages from the queue, converts them to method calls, and invokes the method calls with the service.

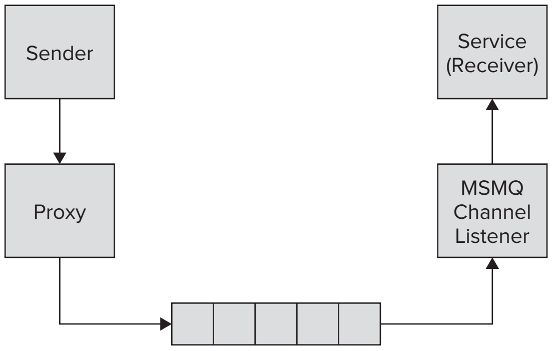

FIGURE 46-14

Next, the Course Ordering application gets converted to make use of Message Queuing from a WCF viewpoint. With this solution, the three projects done earlier are modified, and one more assembly is added that includes the contract of the WCF service:

- ➤ The component library (`CourseOrder`) includes entity classes for the messages that are sent across the wire. These entity classes are modified to fulfill the data contract for serialization with WCF.

- A new library is added (`CourseOrderService`) that defines the contract offered by the service.
- The WPF sender application (`CourseOrderSender`) is modified to not send messages but instead invoke methods of a WCF proxy.
- The WPF receiving application (`CourseOrderReceiver`) is modified to make use of the WCF service that implements the contract.

Entity Classes with a Data Contract

In the library `CourseOrder`, the classes `Course`, `Customer`, and `CourseOrder` are modified to apply the data contract with the attributes `[DataContract]` and `[DataMember]`. For using these attributes, you have to reference the assembly `System.Runtime.Serialization` and import the namespace `System.Runtime.Serialization`:

```
using System.Runtime.Serialization;

namespace Wrox.ProCSharp.Messaging
{
   [DataContract]
   public class Course
   {
      [DataMember]
      public string Title { get; set; }
   }
}
```

code snippet CourseOrder/Course.cs

The `Customer` class requires the data contract attributes as well:

```
   [DataContract]
   public class Customer
   {
      [DataMember]
      public string Company { get; set; }

      [DataMember]
      public string Contact { get; set; }
   }
```

code snippet CourseOrder/Customer.cs

With the class `CourseOrder`, not only the data contract attributes are added, but an override of the `ToString()` method as well to have a default string representation of these objects:

```
   [DataContract]
   public class CourseOrder
   {
      [DataMember]
      public Customer Customer { get; set; }

      [DataMember]
      public Course Course { get; set; }
```

```
        public override string ToString()
        {
           return String.Format("Course Order {{{0}}}", Customer.Company);
        }
     }
```

code snippet CourseOrder/CourseOrder.cs

WCF Service Contract

To offer the service with a WCF service contract, add a WCF service library with the name `CourseOrderServiceContract`. The contract is defined by the interface `ICourseOrderService`. This contract needs the attribute `[ServiceContract]`. If you want to restrict using this interface only with message queues, you can apply the `[DeliveryRequirements]` attribute and assign the property `QueuedDeliveryRequirements`. Possible values of the enumeration `QueuedDeliveryRequirementsMode` are `Required`, `Allowed`, and `NotAllowed`. The method `AddCourseOrder()` is offered by the service. Methods used by Message Queuing can only have input parameters. Because the sender and receiver can run independent of each other, the sender cannot expect an immediate result. With the attribute `[OperationContract]`, the `IsOneWay` property is set. The caller of this operation does not wait for an answer from the service:

```
using System.ServiceModel;

namespace Wrox.ProCSharp.Messaging
{
   [ServiceContract]
   [DeliveryRequirements(
         QueuedDeliveryRequirements=QueuedDeliveryRequirementsMode.Required)]
   public interface ICourseOrderService
   {
      [OperationContract(IsOneWay = true)]
      void AddCourseOrder(CourseOrder courseOrder);
   }
}
```

code snippet CourseOrderServiceContract/ICourseOrderService.cs

You can use acknowledgment and response queues to get answers to the client.

WCF Message Receiver Application

The WPF application `CourseOrderReceiver` is now modified to implement the WCF service and receive the messages. References to the assembly `System.ServiceModel` and the WCF contract assembly `CourseOrderServiceContract` are required.

The class `CourseOrderService` implements the interface `ICourseOrderService`. With the implementation, the event `CourseOrderAdded` is fired. The WPF application will register to this event to receive `CourseOrder` objects.

Because WPF controls are bound to a single thread, the property `UseSynchronizationContext` is set with the `[ServiceBehavior]` attribute. This is a feature of the WCF runtime to pass the method call invocation to the thread that is defined by the synchronization context of the WPF application:

```
using System.ServiceModel;

namespace Wrox.ProCSharp.Messaging
{
   [ServiceBehavior(UseSynchronizationContext=true)]
```

```
      public class CourseOrderService: ICourseOrderService
      {
         public static event EventHandler<CourseOrderEventArgs>
             CourseOrderAdded;

         public void AddCourseOrder(CourseOrder courseOrder)
         {
            if (CourseOrderAdded != null)
               CourseOrderAdded(this, new CourseOrderEventArgs(courseOrder));
         }
      }

      public class CourseOrderEventArgs : EventArgs
      {
         public CourseOrderEventArgs(CourseOrder courseOrder)
         {
            this.CourseOrder = courseOrder;
         }
         public CourseOrder CourseOrder { get; private set; }
      }
   }
```

code snippet CourseOrderReceiver/CourseOrderService.cs

Chapter 20 explains the synchronization context.

With the constructor of the class `CourseReceiverWindow`, a `ServiceHost` object is instantiated and opened to start the listener. The binding of the listener will be done in the application configuration file.

In the constructor, the event `CourseOrderAdded` of the `CourseOrderService` is subscribed. Because the only thing that happens here is adding the received `CourseOrder` object to a collection, a simple Lambda expression is used.

Lambda expressions are explained in Chapter 8, "Delegates, Lambdas, and Events."

The collection class that is used here is `ObservableCollection<T>` from the namespace `System.Collections.ObjectModel`. This collection class implements the interface `INotifyCollectionChanged`, and thus the WPF controls bound to the collection are informed about dynamic changes to the list:

```
   using System;
   using System.Collections.ObjectModel;
   using System.ServiceModel;
   using System.Windows;

   namespace Wrox.ProCSharp.Messaging
   {
      public partial class CourseOrderReceiverWindow: Window
      {
         private ObservableCollection<CourseOrder> courseOrders =
              new ObservableCollection<CourseOrder>();

         public CourseOrderReceiverWindow()
         {
            InitializeComponent();
         CourseOrderService.CourseOrderAdded += (sender, e) =
            {
                courseOrders.Add(e.CourseOrder);
                buttonProcessOrder.IsEnabled = true;
            }

         var host = new ServiceHost(typeof(CourseOrderService));
         try
         {
            host.Open();
         }
         catch (Exception ex)
         {
            Console.WriteLine(ex.Message);
         }

         this.DataContext = courseOrders;
      }
```

code snippet CourseOrderReceiver/CourseOrderReceiverWindow.xaml.cs

The WPF elements in the XAML code now make use of data binding. The `ListBox` is bound to the data context, and the single-item controls are bound to properties of the current item of the data context:

```
<ListBox Grid.Row="1" x:Name="listOrders" ItemsSource="{Binding}"
            IsSynchronizedWithCurrentItem="true" />

      <!-- ... -->

      <TextBox x:Name="textCourse" Grid.Row="0" Grid.Column="1"
          Text="{Binding Path=Course.Title}" />
      <TextBox x:Name="textCompany" Grid.Row="1" Grid.Column="1"
          Text="{Binding Path=Customer.Company}" />
      <TextBox x:Name="textContact" Grid.Row="2" Grid.Column="1"
          Text="{Binding Path=Customer.Contact}" />
```

code snippet CourseOrderReceiver/CourseOrderReceiverWindow.xaml

The application configuration file defines the `netMsmqBinding`. For reliable messaging, transactional queues are required. To receive and send messages to non-transactional queues, the `exactlyOnce` property must be set to `false`.

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <system.serviceModel>
    <bindings>
      <netMsmqBinding>
        <binding name="NonTransactionalQueueBinding" exactlyOnce="false">
          <security mode="None" />
        </binding>
      </netMsmqBinding>
    </bindings>
    <services>
      <service name="Wrox.ProCSharp.Messaging.CourseOrderService">
```

```
          <endpoint address="net.msmq://localhost/private/courseorder"
            binding="netMsmqBinding"
            bindingConfiguration="NonTransactionalQueueBinding"
            name="OrderQueueEP"
            contract="Wrox.ProCSharp.Messaging.ICourseOrderService" />
        </service>
      </services>
    </system.serviceModel>
  </configuration>
```

The `Click` event handler of the `buttonProcessOrder` button removes the selected course order from the collection class:

```
private void buttonProcessOrder_Click(object sender, RoutedEventArgs e)
{
   CourseOrder courseOrder = listOrders.SelectedItem as CourseOrder;
   courseOrders.Remove(courseOrder);
   listOrders.SelectedIndex = -1;
   buttonProcessOrder.IsEnabled = false;

   MessageBox.Show("Course order processed", "Course Order Receiver",
      MessageBoxButton.OK, MessageBoxImage.Information);

}
```

code snippet CourseOrderReceiver/CourseOrderReceiverWindow.xaml.cs

WCF Message Sender Application

The sending application is modified to make use of a WCF proxy class. For the contract of the service, the assembly `CourseOrderServiceContract` is referenced, and the assembly `System.ServiceModel` is required for use of the WCF classes.

In the `Click` event handler of the `buttonSubmit` control, the `ChannelFactory` class returns a proxy. The proxy sends a message to the queue by invoking the method `AddCourseOrder()`:

```
private void buttonSubmit_Click(object sender, RoutedEventArgs e)
{
   try
   {
      var order = new CourseOrder
      {
         Course = new Course()
         {
            Title = comboCourses.Text
         },
         Customer = new Customer()
         {
            Company = textCompany.Text,
            Contact = textContact.Text
         }
      };

      var factory = new ChannelFactory<ICourseOrderService>("queueEndpoint");
      ICourseOrderService proxy = factory.CreateChannel();
      proxy.AddCourseOrder(order);
      factory.Close();

      MessageBox.Show("Course order submitted", "Course Order",
            MessageBoxButton.OK, MessageBoxImage.Information);
   }
   catch (Exception ex)
```

```
            {
               MessageBox.Show(ex.Message, "Course Order Error",
                     MessageBoxButton.OK, MessageBoxImage.Error);
            }
         }
```

code snippet CourseOrderSender/CourseOrderWindow.xaml.cs

The application configuration file defines the client part of the WCF connection. Again, the `netMsmqBinding` is used:

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
    <system.serviceModel>
        <bindings>
            <netMsmqBinding>
                <binding name="nonTransactionalQueueBinding"
                      exactlyOnce="false">
                    <security mode="None" />
                </binding>
            </netMsmqBinding>
        </bindings>
        <client>
            <endpoint address="net.msmq://localhost/private/courseorder"
                binding="netMsmqBinding"
                bindingConfiguration="nonTransactionalQueueBinding"
                contract="Wrox.ProCSharp.Messaging.ICourseOrderService"
                name="queueEndpoint" />
        </client>
    </system.serviceModel>
</configuration>
```

code snippet CourseOrderSender/app.config

When you start the application now, it works in a similar way as before. There is no longer a need to use classes of the `System.Messaging` namespace to send and receive messages. Instead, you write the application in a similar way as using TCP or HTTP channels with WCF.

However, to create message queues and to purge messages, you still need the `MessageQueue` class. WCF is only an abstraction to send and receive messages.

MESSAGE QUEUE INSTALLATION

Message queues can be created with the `MessageQueue.Create()` method. However, the user running an application usually doesn't have the administrative privileges that are required to create message queues.

Usually, message queues are created with an installation program, using the class `MessageQueueInstaller`. If an installer class is part of an application, the command-line utility `installutil.exe` (or a Windows Installation Package) invokes the `Install()` method of the installer.

Visual Studio has special support for using the `MessageQueueInstaller` with Windows Forms applications. If a `MessageQueue` component is dropped from the toolbox onto the form, the smart tag of the component allows you to add an installer with the menu entry Add Installer. The `MessageQueueInstaller` object can be configured with the properties editor to define transactional queues, journal queues, the type of the formatter, the base priority, and so on.

SUMMARY

In this chapter, you've seen how Message Queuing can be used. Message Queuing is an important technology that offers not only asynchronous, but also disconnected communication. The sender and receiver can be running at different times, which makes Message Queuing an option for smart clients and also useful to distribute the load on the server over time.

The most important classes with Message Queuing are `Message` and `MessageQueue`. The `MessageQueue` class allows sending, receiving, and peeking at messages, and the `Message` class defines the content that is sent.

WCF offers an abstraction to Message Queuing. You can use the concepts offered by WCF to send messages by calling methods of a proxy and to receive messages by implementing a service.

The next chapter dives into Directory Services, how and when to use these hierarchical data stores, and different ways to connect to this service.

47 Syndication

WHAT'S IN THIS CHAPTER?

- `System.ServiceModel.Syndication`
- Syndication Reader
- Syndication Feeds

Do you have some structured data to offer, data that changes from time to time? With many web sites, Really Simple Syndication (RSS) or Atom (another syndication format) allow you to subscribe with feed readers. RSS is an XML format that allows syndicate information. RSS became very popular with blogs. This XML information makes it easy to subscribe to using RSS readers.

Nowadays, RSS is not only used with blogs but with many different data sources, such as online news magazines. Any data that changes from time to time is offered by RSS or by its successor protocol Atom. Microsoft Internet Explorer and Microsoft Outlook include RSS and Atom readers that are integrated into the product.

Windows Communication Foundation (WCF) includes an extension for syndication features in the namespace `System.ServiceModel.Syndication`. This namespace provides classes that can be used to both read and write RSS and Atom feeds.

This chapter shows you how to create syndication readers, as well as how data can be offered.

OVERVIEW OF SYSTEM.SERVICEMODEL.SYNDICATION

For syndication you can use the namespace `System.ServiceModel.Syndication`, which offers classes for syndication in an RSS or Atom format.

With the release of RSS version 2.0, RSS is now the shorthand notation for Really Simple Syndication. In earlier versions, it had the name Resource Description Framework (RDF) Site Summary and Rich Site Summary. The first version of RDF was created by Netscape to describe content of its portal site. It became successful when the *New York Times* began offering its readers subscriptions to RSS news feeds in 2002.

The Atom syndication format was designed to be the successor for RSS and is a proposed standard with RFC 4287: `www.ietf.org/rfc/rfc4287.txt`. The major difference between RSS and Atom is in the content that can be defined with an item. With RSS, the description element can contain simple text or HTML content in which the reading application does not care about this content. Atom requires that you define a specific type for the content with a type attribute, and it also allows you to have XML content with defined namespaces.

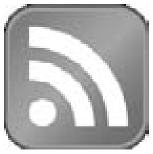

FIGURE 47-1

Figure 47-1 shows the logo that is used by RSS and Atom feeds. If a site shows this logo, then an RSS or Atom feed is offered.

The following table lists classes and elements that allow you to create a syndication feed. These classes are independent of the syndication type, RSS or Atom.

CLASS	DESCRIPTION
`SyndicationFeed`	`SyndicationFeed` represents the top-level element of a feed. With Atom, the top-level element is `<feed>`; RSS defines `<rss>` as the top-level element. With the static method `Load()`, a feed can be read using an `XmlReader`. Properties of this class such as `Authors`, `Categories`, `Contributors`, `Copyright`, `Description`, `ImageUrl`, `Links`, `Title`, and `Items` allow you to define child elements.
`SyndicationPerson`	`SyndicationPerson` represents a person with `Name`, `Email`, and `Uri` that can be assigned to the `Authors` and `Contributors` collection.
`SyndicationItem`	A feed consists of multiple items. Some of the properties of an item are `Authors`, `Contributors`, `Copyright`, and `Content`.
`SyndicationLink`	`SyndicationLink` represents a link within a feed or an item. This class defines the properties `Title` and `Uri`.
`SyndicationCategory`	A feed can group items into categories. The keyword of a category can be set to the `Name` and `Label` properties of `SyndicationCategory`.
`SyndicationContent`	`SyndicationContent` is an abstract base class that describes the content of an item. Content can be of type HTML, plain text, XHTML, XML, or a URL, described with the concrete classes `TextSyndicationContent`, `UrlSyndicationContent`, and `XmlSyndicationContent`.
`SyndicationElementExtension`	With an extension element, you can add additional content. The `SyndicationElementExtension` can be used to add information to a feed, a category, a person, a link, and an item.

To format a feed to the RSS and Atom formats, you can use classes that derive from `SyndicationFeedFormatter` and `SyndicationItemFormatter`. With .NET 4, the formatters for feeds are `Atom10FeedFormatter` and `Rss20FeedFormatter`, and for items are `Atom10ItemFormatter` and `Rss20ItemFormatter`.

READING SYNDICATION FEEDS SAMPLE

The first sample is a Syndication Reader application with a user interface developed with Windows Presentation Format (WPF). The user interface of the WPF application is shown in Figure 47-2.

PDC 2008 - XAML with .NET 4.0

from #pdc2008: XAML enhancements!
XAML nowadays is used with the UI (WPF, Silverlight), Workflows (WF), and Electronic Paper (XPS).
XPS is just going to be an ECMA standard!

With all these uses XAML is going into a language evolution. Goals of this is to make XAML faster and easier to use.

The XAML language extensions are defined by this list:

- improved named references
- support for built-in types
- full generics support
- support for arbitrary dictionary values
- declarative events without compiling
- declarative definition of types
- arguments for non-default constructors
- factory methods

The notepad for XAML, XAMLPad, has been enhanced. Besides the XML and object box it now gives a DOM box to display the

FIGURE 47-2

To use the Syndication API, the assembly `System.ServiceModel` is referenced with the application. The `OnGetFeed()` event handler method is set to the `Click` event of the button showing the Get Feed text. The code needed to read the application is really simple. First, the XML content from the RSS feed is read into the `XmlReader` class from the `System.Xml` namespace. `Rss20FeedFormatter` accepts an `XmlReader` with the `ReadFrom()` method. For data binding, the `Feed` property that returns a `SyndicationFeed` is assigned to the `DataContext` of the `Window`, and the `Feed.Items` property that returns `IEnumerable<SyndicationItem>` is assigned to the `DataContext` of a `DockPanel` container:

```
private void OnGetFeed(object sender, RoutedEventArgs e)
{
   try
   {
      using (var reader = XmlReader.Create(textUrl.Text))
      {
         var formatter = new Rss20FeedFormatter();
         formatter.ReadFrom(reader);
         this.DataContext = formatter.Feed;
         this.feedContent.DataContext = formatter.Feed.Items;
      }
   }
   catch (WebException ex)
   {
      MessageBox.Show(ex.Message, "Syndication Reader");
   }
}
```

code snippet SyndicationReader/SyndicationReader.xaml.cs

The XAML code that defines the user interface is shown next. The `Title` property of the `Window` class is bound to the `Title.Text` property of the `SyndicationFeed` to display the title of the feed.

In the XAML code, a `DockPanel` named `heading`, which contains a `Label` bound to `Title.Text` and a `Label` bound to `Description.Text`, is defined. Because these labels are contained within the `DockPanel` named `feedContent`, and `feedContent` is bound to the `Feed.Items` property, these labels give title and description information about the current selected item.

A list of items is displayed in a `ListBox` that uses an `ItemTemplate` to bind a label to the `Title`.

The `DockPanel` named `content` contains a `Frame` element that binds the `Source` property to the first link of an item. With that setting, the `Frame` control uses the web browser control to display the content from the link:

```
<Window x:Class="Wrox.ProCSharp.Syndication.SyndicationReaderWindow"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
    Title="{Binding Path=Title.Text}" Height="300" Width="450">

   <DockPanel x:Name="feedContent">
      <Grid DockPanel.Dock="Top">
         <Grid.ColumnDefinitions>
            <ColumnDefinition Width="50" />
            <ColumnDefinition Width="*" />
            <ColumnDefinition Width="90" />
         </Grid.ColumnDefinitions>
         <Label Grid.Column="0" Margin="5">URL:</Label>
         <TextBox Grid.Column="1" x:Name="textUrl" MinWidth="150"
               Margin="5">http://blogs.thinktecture.com/cnagel/rss.aspx
         </TextBox>
         <Button Grid.Column="2" Margin="5" MinWidth="80"
               Click="OnGetFeed">Get Feed</Button>
      </Grid>
      <StackPanel Orientation="Vertical" Background="LightGreen"
            DockPanel.Dock="Top" x:Name="heading">
         <Label DockPanel.Dock="Top" Content="{Binding Path=Title.Text}"
               FontSize="16" />
         <Label DockPanel.Dock="Top" Content="{Binding Path=Description.Text}" />
      </StackPanel>
      <ListBox DockPanel.Dock="Left" ItemsSource="{Binding}"
            Style="{StaticResource listTitleStyle}"
            IsSynchronizedWithCurrentItem="True"
            HorizontalContentAlignment="Stretch" />
      <DockPanel x:Name="content" >
         <Label DockPanel.Dock="Top" Content="{Binding Path=Description.Text}" />
         <Frame Source="{Binding Path=Links[0].Uri}" />
      </DockPanel>
   </DockPanel>
</Window>
```

code snippet SyndicationReader/SyndicationReader.xaml

OFFERING SYNDICATION FEEDS SAMPLE

Reading syndication feeds is one scenario in which the Syndication API can be used. Another is to offer a syndication feed to RSS and Atom clients.

For this, Visual Studio 2010 offers the Syndication Service Library template, which you can use to start with. This template defines a reference to the `System.ServiceModel` library, and adds an application configuration file to define a WCF endpoint.

To offer data for the syndication feed, the ADO.NET Entity Framework is helpful. In the sample application, the Formula-1 database is used, which you can download from the Wrox web site at `www.wrox.com` with the sample applications for the book. The ADO.NET Entity Data Model item with the name `Formula1Model.edmx` is added to the project. Here, the tables Racers, RaceResults, Races, and Circuits are mapped to entity classes `Racer`, `RaceResult`, `Race`, and `Circuit`, as shown in Figure 47-3.

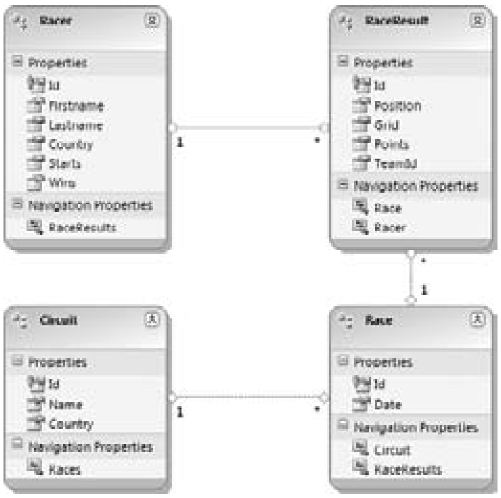

FIGURE 47-3

Check out Chapter 31, "ADO.NET Entity Framework," for more information.

The project template creates a file `IService1.cs` that contains the contract of the WCF service. The interface contains the `CreateFeed()` method, which returns a `SyndicationFeedFormatter`. Because `SyndicationFeedFormatter` is an abstract class, and the real types returned are either `Atom10FeedFormatter` or `Rss20FeedFormatter`, these types are listed with the `ServiceKnownTypeAttribute`, so the type is known for serialization.

The attribute `WebGet` defines that the operation can be called from a simple HTTP GET request that can be used to request syndication feeds. `WebMessageBodyStyle.Bare` defines that the result (the XML from the syndication feed) is sent as it is without adding an XML wrapper element around it:

```
using System.ServiceModel;
using System.ServiceModel.Syndication;
using System.ServiceModel.Web;

namespace Wrox.ProCSharp.Syndication
{
   [ServiceContract]
   [ServiceKnownType(typeof(Atom10FeedFormatter))]
   [ServiceKnownType(typeof(Rss20FeedFormatter))]
   public interface IFormula1Feed
   {
      [OperationContract]
      [WebGet(UriTemplate = "*", BodyStyle = WebMessageBodyStyle.Bare)]
      SyndicationFeedFormatter CreateFeed();
   }
}
```

code snippet SyndicationService/IFormula1Feed.cs

The implementation of the service is done in the class `Formula1Feed`. Here, a `SyndicationFeed` item is created, and various properties of this class such as `Generator`, `Language`, `Title`, `Categories`, and `Authors` are assigned. The `Items` property is filled from a LINQ query that requests the winners of Formula-1 races of the requested date. The select clause of this query creates a new anonymous type that is filled with a few properties which then is used by a `Select()` method to create a `SyndicationItem` for every winner. With `SyndicationItem`, the `Title` property is assigned to plain text containing the country of the race. The `Content` property is filled with the help of LINQ to XML. `XElement` classes are used to create XHTML code that can be interpreted by the browser. This content shows the date of the race, the country, and the name of the winner.

Depending on the query string to request the syndication, the `SyndicationFeed` is formatted with the `Atom10FeedFormatter` or the `Rss20FeedFormatter`:

```
using System;
using System.Linq;
using System.ServiceModel.Syndication;
using System.ServiceModel.Web;
using System.Xml.Linq;

namespace Wrox.ProCSharp.Syndication
{
   public class Formula1Feed: IFormula1Feed
   {
      public SyndicationFeedFormatter CreateFeed()
      {
         DateTime fromDate = DateTime.Today - TimeSpan.FromDays(365);
         DateTime toDate = DateTime.Today;
      string from = WebOperationContext.Current.IncomingRequest.UriTemplateMatch
         .QueryParameters["from"];
      string to = WebOperationContext.Current.IncomingRequest.UriTempateMatch
         .QueryParameters["to"];

      if (from != null && to != null)
      {
         try
         {
            fromDate = DateTime.Parse(from);
            toDate = DateTime.Parse(to);
         }
         catch (FormatException)
         {
            // keep the default dates
         }
      }

      // Create a new Syndication Feed.
      var feed = new SyndicationFeed();
      feed.Generator = "Pro C# 4.0 Sample Feed Generator";
      feed.Language = "en-us";
      feed.LastUpdatedTime = new DateTimeOffset(DateTime.Now);
      feed.Title = SyndicationContent.CreatePlaintextContent(
                        "Formula1 results");
      feed.Categories.Add(new SyndicationCategory("Formula1"));
      feed.Authors.Add(new SyndicationPerson("web@christiannagel.com",
             "Christian Nagel", "http://www.christiannagel.com"));
      feed.Description = SyndicationContent.CreatePlaintextContent(
             "Sample Formula 1");
      using (var data = new Formula1Entities())
      {
         var races = (from racer in data.Racers
                      from raceResult in racer.RaceResults
                      where raceResult.Race.Date > fromDate &&
                            raceResult.Race.Date < toDate &&
                            raceResult.Position == 1
                      orderby raceResult.Race.Date
                      select new
                      {
                         Country = raceResult.Race.Circuit.Country,
                         Date = raceResult.Race.Date,
                         Winner = racer.Firstname + " " + racer.Lastname
                      }).ToArray();

         feed.Items = races.Select(race =>
            {
               return new SyndicationItem
               {
                  Title = SyndicationContent.CreatePlaintextContent(
                             String.Format("G.P. {0}", race.Country)),
                  Content = SyndicationContent.CreateXhtmlContent(
                               new XElement("p",
                                  new XElement("h3", String.Format("{0}, {1}",
                                     race.Country,
                                     race.Date.ToShortDateString())),
                                  new XElement("b", String.Format("Winner: {0}",
                                     race.Winner))).ToString())
               };
            });

  // Return ATOM or RSS based on query string
```

```
     // rss -> http://localhost:8732/Design_Time_Addresses/SyndicationService/
     //     Feed1/
     // atom -> http://localhost:8732/Design_Time_Addresses/SyndicationService/
     //     Feed1/?format=atom
            string query = WebOperationContext.Current.IncomingRequest.
                  UriTemplateMatch.QueryParameters["format"];
            SyndicationFeedFormatter formatter = null;
            if (query == "atom")
            {
               formatter = new Atom10FeedFormatter(feed);
            }
            else
            {
               formatter = new Rss20FeedFormatter(feed);
            }
            return formatter;
         }
      }
   }
}
```

code snippet SyndicationService/Formula1Feed.cs

When you start the service from within Visual Studio 2010, the WCF Service Host starts up to host the service, and you can see the feed result with the URL parameter `?from=1970/1/1&to=1971/1/1` formatted in Internet Explorer, as shown in Figure 47-4.

FIGURE 47-4

With the default request to the service, the RSS feed is returned. An extract of the RSS feed with the `rss` root element follows. With RSS, the `Title` property is translated to the `title` element, and the `Description` property goes to the `description` element. The `Authors` property of the `SyndicationFeed` that contains `SyndicationPerson` uses the e-mail address to create the `managingEditor` element. With RSS, the content of the `item`'s description element is encoded:

```
<?xml version="1.0" encoding="utf-8"?>
<rss version="2.0" xmlns:a10="http://www.w3.org/2005/Atom">
  <channel>
    <title>Formula1 results</title>
    <description>Sample Formula 1</description>
    <language>en-us</language>
    <managingEditor>web@christiannagel.com</managingEditor>
    <lastBuildDate>Sat, 25 Jul 2009 11:25:31+0200</lastBuildDate>
    <category>Formula1</category>

          &#xD;&lt;b&gt;Winner: Jack Brabham&lt;/b&gt;&#xD;&lt;/p&gt;

      </description>
    </item>
    <item>
      <!-- -->
  </channel>
</rss>
```

An Atom-formatted feed is returned with the query `?from=1970/1/1&to=1971/1/1&format=atom` with the result shown. The root element now is the `feed` element; the `Description` property turns into a `subtitle` element; and the values for the `Author` property are now shown completely differently from the RSS feed shown earlier. Atom allows the content to be unencoded. You can easily find the XHTML elements:

```
<feed xml:lang="en-us" xmlns="http://www.w3.org/2005/Atom">
  <title type="text">Formula1 results</title>
  <subtitle type="text">Sample Formula 1</subtitle>
  <id>uuid:c19284e7-aa40-4bc2-9be8-f1960b0f747e;id=1</id>

```

SUMMARY

In this chapter, you have seen how the classes from the `System.ServiceModel.Syndication` namespace can be used to create an application that receives a feed, as well as an application that offers a feed. The syndication API supports RSS 2.0 and Atom 1.0. As syndication standards emerge, new formatters will be available. You have seen that the SyndicationXXX classes are independent of the format that is generated.

The concrete implementation of the abstract class `SyndicationFeedFormatter` defines what properties are used and how they are translated to the specific format.

This chapter concludes the communication part of the book. You've read about communication technologies to directly use sockets, and abstraction layers that are offered. Windows Communication Foundation is a technology that has been discussed in several chapters. With Message Queuing (Chapter 46, "Message Queuing"), WCF offers a disconnected communication model.

There's still more to read. The appendices cover the Windows API code pack, a .NET extension to Windows 7 and Windows Server 2008 R2, and guidelines for developing applications on these platforms.

APPENDIX

Guidelines for Windows 7 and Windows Server 2008 R2

WHAT'S IN THIS APPENDIX?

- ➤ The Windows API Code Pack
- ➤ Restart Manager
- ➤ User account control
- ➤ Windows 7 directory structure
- ➤ Command links and task dialogs
- ➤ The taskbar and Jump List

OVERVIEW

The Windows API has many new calls that expose new functionality available with Windows 7 and Windows Server 2008 R2; however, as of the .NET 4 release many of these calls are not available from the .NET Framework. The *Windows API Code Pack* helps here as it contains .NET classes that wrap native API calls to make them available from a .NET library. You can use this library within your .NET applications. You can download the Windows API Code Pack from `http://code.msdn.microsoft.com/WindowsAPICodePack`. This toolkit is used with most samples in this appendix. You can either use the libraries that come with this toolkit or copy the source code to your application. Typically, the classes from this toolkit are a thin wrapper around the Windows API.

Another toolkit you can use to target applications for the Windows platform is the *Windows Software Logo Kit*. On the Microsoft downloads page, you can find the Windows 7 Client Software Logo program documentation and toolkit that contains information about what's necessary for an application to get the Windows 7 software logo. Even if you're not interested in receiving a logo for your application, this documentation and toolkit is still interesting, as it explains what is required for an application to be considered well-behaved on the Windows operating system.

What are the requirements to receive a logo for an application? Here's a short list of the requirements; you can get many more details in the Windows 7 Client Software Logo document.

- The application may not contain spyware or malware. Of course, that's a requirement that should be fulfilled with every application. Interestingly, this is verified for logo compliance.
- Windows resource protected files may not be replaced.
- Errors must be reported with Windows Error Reporting (WER).
- The application must cleanly install and uninstall. Read chapter 17, "Deployment," for information on creating installation programs. The application should not force a reboot with the installation.
- The application should install to the correct folders. User data should not be written to the application folders. In the "Directory Structure" section of this appendix you can read how to find the correct folders for application and user data.
- Files and drivers must be digitally signed. Read Chapter 21, "Security," for information how to sign applications.
- 64-bit systems must be supported. This means that 16-bit code is not allowed. It's okay to run 32-bit applications on 64-bit. With .NET applications, you can set the platform configuration to Any CPU, x86, x64, or Itanium. Any CPU lets your application run with 32 bits on a 32-bit platform and with 64 bits on a 64-bit platform. When you set the configuration to Any CPU, you may not directly wrap native code with platform invoke in the assembly. Using native code restricts you to the native-code native API calls that are used, and thus Any CPU will not work on both versions.
- Version check with the installation must be done to check if the operating system has a minimum version required, but it's not allowed to check for a specific version.
- User account control guidelines must be followed. This is discussed in detail in this appendix.
- The applications may not block shutdown. You can use the Restart Manager to return the application to a working state after a reboot or failure. This is discussed in the section "Application Recovery."
- Multiuser sessions must be supported. Different users on one system should be able to use the application. This requirement is because of the fast user switching facility of Windows.

APPLICATION RECOVERY

Maybe you've already seen that some applications recover to a previous state if they crash or the system is rebooted. Such applications (for example, Microsoft Office and Visual Studio) make use of the *Application Recovery and Restart* (ARR) API that has been part of the Windows API since Windows Vista.

An application can register with the Restart Manager, and if the application crashes or becomes unresponsive (after running for at least 60 seconds), Windows Error Reporting (WER) restarts the application. An application can also register for recovery so that if the application hangs, it is recovered.

To see this in action, this example shows the creation of a simple WPF editor. This application registers for a restart and recovery if it fails. For reading and writing files, the class `CurrentFile` defines the `IsDirty` and `Content` properties, and `Load()` and `Save()` methods. The application makes use of tracing to write verbose messages to a trace listener so that you can retrace the events from the application.

```
using System;
using System.Diagnostics;
using System.IO;

namespace Wrox.ProCSharp.Windows7
{
    public class CurrentFile
    {
        public bool IsDirty { get; set; }
        public string Content { get; set; }

        public void Load(string fileName)
        {
            App.Source.TraceEvent(TraceEventType.Verbose, 0,
                                  String.Format("begin Load {0}", fileName));
            Content = File.ReadAllText(fileName);
            IsDirty = false;
            App.Source.TraceEvent(TraceEventType.Verbose, 0,
                                  String.Format("end Load {0}", fileName));
        }

        public void Save(string fileName)
        {
            App.Source.TraceEvent(TraceEventType.Verbose, 0,
                                  String.Format("begin Save {0}", fileName));
            File.WriteAllText(fileName, Content);
            IsDirty = false;
            App.Source.TraceEvent(TraceEventType.Verbose, 0,
                                  String.Format("end Save {0}", fileName));
        }
    }
}
```

code snippet EditorDemo/CurrentFile.cs

If the application is restarted because of a crash, the `/restart:[filename]`command-line argument is passed to the executable. To retrieve command-line information, the `OnStartup()` handler method is assigned to the `Startup` event of the `App` class. With the second argument, which is of type `StartupEventArgs`, the command-line arguments can be retrieved. With the `/restart:` argument, the following filename is assigned to the `RestartPath` property. The `App` class also contains the `TraceSource` object, which is used for tracing.

```
using System;
using System.Diagnostics;
using System.Windows;

namespace Wrox.ProCSharp.Windows7
{
    public partial class App : Application
    {
        public static TraceSource Source = new TraceSource("RestartDemo");

        private void OnStartup(object sender, StartupEventArgs e)
```

```
            {
                Source.TraceEvent(TraceEventType.Verbose, 0,
                                  "RestartDemo begin OnStartup");

                foreach (var arg in e.Args)
                {
                    Source.TraceEvent(TraceEventType.Verbose, 0,
                                      String.Format("argument {0}", arg));
                    if (arg.StartsWith("/restart:",
                                       StringComparison.InvariantCultureIgnoreCase))
                    {
                        Source.TraceEvent(TraceEventType.Verbose, 0,
                                          "/restart: argument found");
                        RestartPath = arg.Substring(9);
                        Source.TraceEvent(TraceEventType.Verbose, 0,
                                          String.Format("RestartPath: {0}",
                                                        RestartPath));
                    }
                }
            }
            public string RestartPath { get; private set; }
        }
    }
```

code snippet EditorDemo/App.xaml.cs

The main window (see Figure A-1) just contains a `TextBox` for editing the text in the middle area, a `TextBlock` control in the bottom area for status messages, and a `Menu` control.

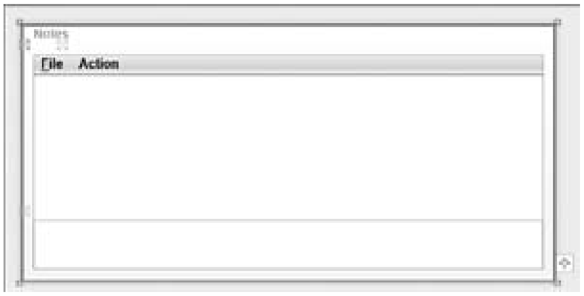

FIGURE A-1

The constructor of the `MainWindow` class checks to see if the application was started from a recovery, by checking the `RestartPath` property from the `App` class. If the application was started because of a recovery, the filename assigned to the `RestartPath` property is used to load this file and assign it to the `DataContext` of the `TextBox`. If the application was started normally, a new filename for recovery is created.

Inside the constructor, a `DispatcherTimer` is also created that fires after 60 seconds. This is used to inform the user that the application can only recover from a crash after running for at least 60 seconds.

The most important calls in this scenario are the helper methods `RegisterForRestart()` and `RegisterForRecovery()`, which are called to register with the Restart Manager.

```
using System;
using System.Diagnostics;
using System.Threading;
using System.Windows;
using System.Windows.Controls;
using System.Windows.Input;
using System.Windows.Threading;
using Microsoft.WindowsAPICodePack.ApplicationServices;

namespace Wrox.ProCSharp.Windows7
{
    public partial class MainWindow : Window
    {
        private DispatcherTimer minuteTimer;
private CurrentFile currentFile = new CurrentFile();
private string tempPath;

public MainWindow()
{
    InitializeComponent();
    if ((Application.Current as App).RestartPath != null)
    {
        tempPath = (Application.Current as App).RestartPath;
        currentFile.Load(tempPath);
        App.Source.TraceEvent(TraceEventType.Verbose, 0,
            String.Format("Application recovered data from the file {0}",
                          tempPath));
    }
    else
    {
        string tempFileName = String.Format("{0}.txt", Guid.NewGuid());
        tempPath = System.IO.Path.Combine(Environment.GetFolderPath(
                       Environment.SpecialFolder.LocalApplicationData),
                       tempFileName);
        App.Source.TraceEvent(TraceEventType.Verbose, 0,
            String.Format("Normal start with temp-filename {0}",
                          tempPath));
    }
    this.text1.DataContext = currentFile;

    minuteTimer = new DispatcherTimer(TimeSpan.FromSeconds(60),
        DispatcherPriority.Normal, On60Seconds,
        Dispatcher.CurrentDispatcher);
    minuteTimer.Start();

    RegisterForRestart();
    RegisterForRecovery();
}
```

code snippet EditorDemo/MainWindow.xaml.cs

The application is only restarted if it runs for at least 60 seconds. This makes sense, as it's better not to restart applications that crash within the first 60 seconds; the user probably will not have lost too much data within that time. When testing this feature, you always need to wait for 1 minute before crashing the application.

To mark that the content has changed, the `IsDirty` property of the *`currentFile`* is set with the handler of the `TextChanged` event of the `TextBox` control:

```
private void OnTextChanged(object sender, TextChangedEventArgs e)
{
    if (!currentFile.IsDirty)
    {
        currentFile.IsDirty = true;
        textStatus.Text += String.Format("{0:T}: Set IsDirty\n",
                                         DateTime.Now);
    }
}
```

The handler method of the `DispatcherTimer` class, `On60Seconds()`, writes status information to the `TextBlock` *`textStatus`*, noting that the 60-second limit has gone by and it's now possible to crash the application for recovery.

```
private void On60Seconds(object sender, EventArgs e)
{
    this.textStatus.Text += String.Format("{0:T}: Application can crash " +
                                "now\n", DateTime.Now);
    minuteTimer.Stop();
}
```

The method `RegisterForRestart()` invokes the `RegisterForApplicationRestart()` method of the `ApplicationRestartRecoveryManager` class. `ApplicationRestartRecoveryManager` is defined in the namespace `Microsoft.WindowsAPICodePack.ApplicationServices`. The method `RegisterForApplicationRestart()` wraps the Windows API call `RegisterApplicationRestart()` function. With this method, you can define the command-line arguments that should be used to restart the application and the cases when the application should not be restarted. In this example, it is defined that the application should not be restarted on a reboot or on installation of a patch. You can also specify that the application should not restart on an application crash and on application hang.

```
private void RegisterForRestart()
{
    var settings = new RestartSettings(
        String.Format("/restart:{0}", tempPath),
        RestartRestrictions.NotOnReboot | RestartRestrictions.NotOnPatch);
    ApplicationRestartRecoveryManager.RegisterForApplicationRestart(
        settings);
    textStatus.Text += String.Format("{0:T}: Registered for restart\n",
                                    DateTime.Now);
    App.Source.TraceEvent(TraceEventType.Verbose, 0,
                         "Registered for restart");
}
```

Within the Windows API Code Pack, the Windows API call is defined to be invoked by using P/Invoke:

```
[DllImport("kernel32.dll")]
[PreserveSig]
internal static extern HRESULT RegisterApplicationRestart(
    [MarshalAs(UnmanagedType.BStr)] string commandLineArgs,
    RestartRestrictions flags);
```

With this facility, if the application crashes or hangs, it is restarted. With the Restart Manager, you can also define a handler method that is invoked before the application is stopped because of a crash or a hang. This is done by invoking the `RegisterForApplicationRecovery()` method of the `ApplicationRestartRecoveryManager` class. This method wraps the Windows API function `RegisterApplicationRecoveryCallback()`. `RegisterForApplicationRecovery()` can be configured with an object of type `RecoverySettings`. With `RecoverySettings`, you assign an object of type `RecoveryData` and a recovery ping interval. This ping interval is defined in 100 ns units, and the callback method must give progress information to the recovery manager within that time span. By default, with a value of 0 the time interval is 5 seconds. The maximum value that can be set is 5 minutes. With `RecoveryData` you specify the method that is invoked by the Restart Manager to do the recovery, and an argument that is passed to that method:

```
private void RegisterForRecovery()
{
    var settings = new RecoverySettings(new RecoveryData(
                                        DoRecovery, tempPath), 0);
    ApplicationRestartRecoveryManager.RegisterForApplicationRecovery(
            settings);
            textStatus.Text += String.Format("{0:T}: Registered for recovery\n",
                                    DateTime.Now);
            App.Source.TraceEvent(TraceEventType.Verbose, 0,
                                "Registered for recovery");
        }
```

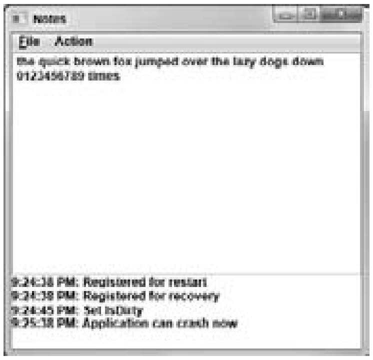
`DoRecovery()` is the callback method that is defined by the `RegisterForApplicationRecovery()` method call and is invoked by WER. Within the handler, the Recovery Manager is informed that recovery is in progress by calling the method `ApplicationRecoveryInProgress()`. This method returns `true` if the user canceled the recovery. You can verify user cancellation during the recovery to stop the recovery in case it was canceled by the user. Here, the content of the `TextBox` is written to the temporary file that is used when restarting the application. At the end of the recovery process, the Restart Manager is informed of its success by invoking `ApplicationRecoveryFinished()`.

```
        private int DoRecovery(object state)
        {
            App.Source.TraceEvent(TraceEventType.Verbose, 0, "begin Recovery");
            this.tempPath = (string)state;
            bool canceled = ApplicationRestartRecoveryManager.
                                ApplicationRecoveryInProgress();
            if (canceled)
            {
                textStatus.Text += String.Format(
                    "{0:T}: Recovery canceled, shutting down\n", DateTime.Now);
                App.Source.TraceEvent(TraceEventType.Verbose, 0,
                    "end Recovery with cancel");
                ApplicationRestartRecoveryManager.ApplicationRecoveryFinished(
                        false);
                return 0;
            }
            SaveFile(tempPath);

            App.Source.TraceEvent(TraceEventType.Verbose, 0, "end Recovery");
            ApplicationRestartRecoveryManager.ApplicationRecoveryFinished(true);
            return 0;
        }
```

With all this in place, you can run the application, as shown in Figure A-2. The `TextBlock` on the bottom gives status information such as when registering for restart and recovery happened, and after 60 seconds, information that the application can now crash.

Selecting the menu Action ➪ Crash invokes the handler method `OnCrash()`, which does a fast fail. The method `Environment.FailFast()` can be used to terminate a process in a fast way. This method writes an application event log and creates a dump of the application before the process is terminated. Only `CriticalFinalizerObject` objects are executed. Try-finally blocks and finalizers are not executed.



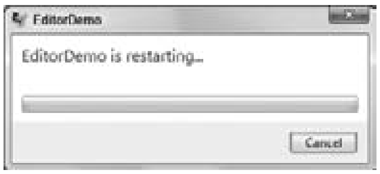
the quick brown fox jumped over the lazy dogs down 0123456789 times

```
9:24:38 PM: Registered for restart
9:24:38 PM: Registered for recovery
9:24:45 PM: Set IsDirty
9:25:38 PM: Application can crash now
```

FIGURE A-2

```
      private void OnCrash(object sender, ExecutedRoutedEventArgs e)
        {
            Environment.FailFast("RestartDemo stopped from Menu command");
        }
```

After crashing, the application is restarted and you can see the dialog shown in Figure A-3.

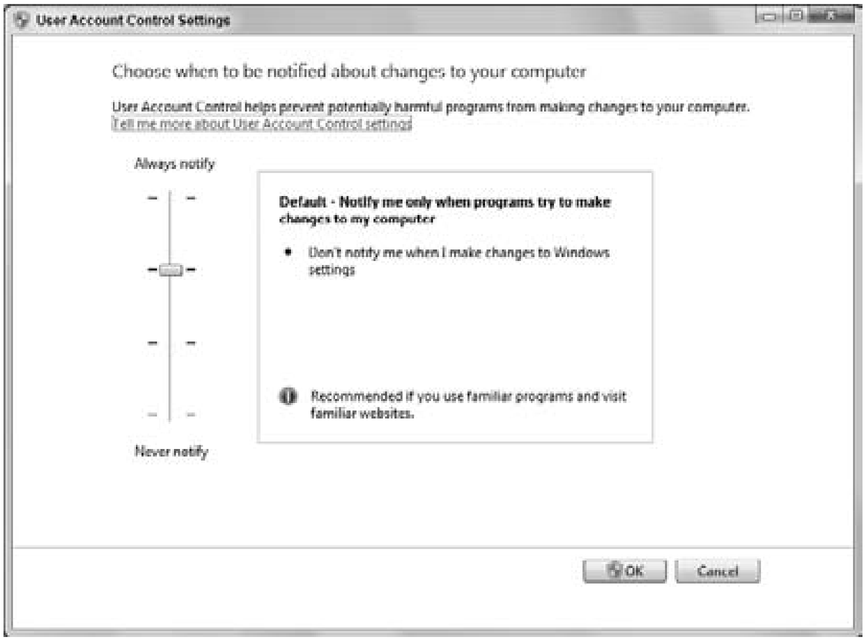


EditorDemo is restarting...

FIGURE A-3

USER ACCOUNT CONTROL

As a developer, *user account control* (UAC) is one of the features you can see immediately with Windows Vista: every time an administrative task is done, a dialog pops up asking for admin rights. In Windows 7, you can now configure this feature, as shown in Figure A-4. The default setting is to provide no notifications if admin changes are required from applications that are part of the operating system.



Choose when to be notified about changes to your computer

User Account Control helps prevent potentially harmful programs from making changes to your computer.
Tell me more about User Account Control settings

Default - Notify me only when programs try to make changes to my computer

- Don't notify me when I make changes to Windows settings

Recommended if you use familiar programs and visit familiar websites.

FIGURE A-4

What's the purpose behind the hassle of these dialogs? Although Windows guidelines have always mentioned that applications should not require admin privileges if it's not really necessary, many applications still need to run with the administrator account. For example, a normal user is not allowed to write data to the program files directory; administrative privileges are required. Because many applications don't run without administrative privileges as the developers didn't follow the guidelines, many users log in to the system with an Administrator account. By using the Administrator account on daily work you can unintentionally install Trojan horse programs.

Windows Vista and later versions avoid this problem because the Administrator, by default, doesn't have administrative privileges. The process has two security tokens associated with it, one with normal user privileges and one with admin privileges (for the case where the login is done to the Administrator account). With applications that require administrative privileges, the user can elevate the application to run with Administrator rights. This is either be done from the context menu Run as Administrator option, or the Compatibility Properties of an application can be configured to always require administrator privileges to run it. This setting adds application compatibility flags to the registry at `HKCU\Software\Microsoft\Windows NT\CurrentVersion\AppCompatFlags\Layers` with a value for `RUNASADMIN`.

Applications Requiring Admin Privileges

For applications that require administrative privileges, you can also add an application manifest. Visual Studio 2010 has an item template to add an application manifest to an application. Such a manifest can be created either by adding a manifest file to an existing application or by embedding a Win32 resource file within the assembly. In the Application tab of the Project Properties, you can select the manifest file of the application that's included as a native resource.

An application manifest is an XML file similar to the application configuration file. While the application configuration file has the file extension `.config`, the manifest ends with `.manifest`. The name of the file must be set to the name of the application, including the `.exe` file extension followed by `.manifest`. Visual Studio renames and copies the `app.manifest` file just as it does an application configuration file. The manifest file contains XML data, as shown here. The root element is `<assembly>`, which contains the child element `<trustInfo>`. The administrator requirement is defined with the `level` attribute of the `<requestedExecutionLevel>` element.

```
<?xml version="1.0" encoding="utf-8"?>
<asmv1:assembly manifestVersion="1.0" xmlns="urn:schemas-microsoft-com:asm.v1"
     xmlns:asmv1="urn:schemas-microsoft-com:asm.v1"
     xmlns:asmv2="urn:schemas-microsoft-com:asm.v2"
     xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance">
  <assemblyIdentity version="1.0.0.0" name="MyApplication.app"/>
  <trustInfo xmlns="urn:schemas-microsoft-com:asm.v2">
    <security>
      <requestedPrivileges xmlns="urn:schemas-microsoft-com:asm.v3">
        <requestedExecutionLevel level="requireAdministrator" uiAccess="false" />
      </requestedPrivileges>
    </security>
  </trustInfo>
</asmv1:assembly>
```

code snippet AdminRightsRequired/app.manifest

When starting the application this way, you get an elevation prompt where the user is asked if he or she trusts the application to run with administrative privileges.

With the `requestedExecutionLevel` setting, you can specify the values `requireAdministrator`, `highestAvailable`, and `asInvoker`. The value `highestAvailable` means that the application gets the privileges the user has — but only after getting the consent from the user. The value `requireAdministrator` requires Administrator privileges. If the user is not logged on to the system as Administrator, a login dialog appears where the user can log in as Administrator for the application. The value `asInvoker` means that the application is running with the security token of the user.

The `uiAccess` attribute specifies if the application requires input to a higher-privilege-level window on the desktop. For example, an onscreen keyboard needs to drive input to other windows on the desktop, so the setting should be set to `true` for the application to display the onscreen keyboard. Non-UI-accessible applications should have this attribute set to `false`.

Shield Icon

If an application or a task from an application requires administrative privileges, the user is informed by an easily recognizable shield icon. The shield icon is attached to the controls that require elevation. The user expects to see an elevation prompt when clicking on an item with a shield. Figures A-5 and A-6 show the shield in use. The Task Manager requires elevation to see processes from all users. Within User Accounts, adding or removing user accounts requires elevation as well as setting up parental controls.

FIGURE A-6

You can create shield icons in your application by using the new command link control that is shown later in this appendix.

When the user clicks a control with a shield icon, an elevation prompt is shown. Elevation prompts are different, depending on the type of application that is elevated. The system differentiates between applications that are delivered with Windows (with the default setting of Windows 7, this prompt is not shown at all), applications that contain a certificate, and applications without a certificate. Of course, for applications without a certificate the prompt is shown with a special emphasis by highlighting it in color and marking the unknown publisher in bold.

DIRECTORY STRUCTURE

The directory structure of Windows changed with Windows Vista and that new structure continues with Windows 7. There's no longer a directory `c:\Documents and Settings\<username>`. It has been replaced by the new folder `c:\Users\<username>`. Windows XP defines the subdirectory `My Documents` for storing user-specific data. Windows 7 defines `c:\Users\<username>\Documents`.

If you just follow the simple rule not to use hard-coded path values with the program, it doesn't matter where the real folders are located. The folders differ with different Windows languages anyway. For special folders, use the `Environment` class and the `SpecialFolder` enumeration:

```
string folder = Environment.GetFolderPath(Environment.SpecialFolder.Personal);
```

Some of the folders defined by the `SpecialFolder` enumeration are described in the following table.

CONTENT	SPECIALFOLDER ENUMERATION	WINDOWS 7 DEFAULT DIRECTORY
User-specific documents	`Personal`	`C:\Users\<User>\Documents`
User-specific data for roaming users	`ApplicationData`	`C:\Users\<User>\AppData\Roaming`
User-specific data that is local to a system	`LocalApplicationData`	`C:\Users\<User>\Appdata\Local`
Program files	`ProgramFiles`	`C:\Program Files`
Program files that are shared among different programs	`CommonProgramFiles`	`C:\Program Files\Common Files`
Application data common to all users	`CommonApplicationData`	`C:\ProgramData`

At logoff, the content of roaming directories is copied to the server, so if the user logs on to a different system, the same content is copied and is, thus, available on all systems accessed by the user.

With the special folders, you must be careful that a normal user doesn't have write access to the program files directory. You can write user-specific data from the application to `LocalApplicationData`, or for roaming users, to `ApplicationData`. Data that should be shared among different users can be written to `CommonApplicationData`.

NEW CONTROLS AND DIALOGS

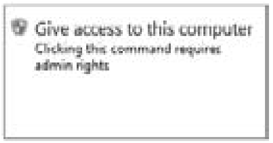
Windows Vista and Windows 7 deliver several new controls. The command link control is an extension to the `Button` control and is used in combination with several other controls. The task dialog is a next-generation `MessageBox`, and for opening and saving files, new dialogs are available as well.

Command Link

Command link controls are an extension of the Windows `Button` control. Command links contain an optional icon and note text. This control is often used in task dialogs and wizards and gives much more information than button controls with OK and Cancel content.

With .NET applications, you can create command link controls by using the Windows API Code Pack. If you add the project Microsoft.WindowsAPICodePack.Shell to your solution, you can add a Windows Forms `CommandLink` controls from the toolbox to your Windows Forms application. The class `CommandLink` derives from the `System.Windows.Forms.Button` class. A command link is an extension of the native Windows `Button` and defines additional Windows messages and a new style to configure the `Button`. The wrapper class `CommandLink` sends the Windows messages `BCM_SETNOTE` and `BCM_SETSHIELD` and sets the style `BS_COMMANDLINK`. The public methods and properties offered in addition to the members of the `Button` class are `NoteText` and `ShieldIcon`.

The following code segment creates a new command link control that sets the `NoteText` and `ShieldIcon`. Figure A-7 shows the configured command link during runtime.



Give access to this computer
Clicking this command requires admin rights

FIGURE A-7

```
this.commandLink1 =
new Microsoft.WindowsAPICodePack.Controls.
                            WindowsForms.CommandLink();
this.commandLink1.FlatStyle =
System.Windows.Forms.FlatStyle.System;
this.commandLink1.Location = new System.Drawing.Point(44, 54);
this.commandLink1.Name = "commandLink1";
this.commandLink1.NoteText = "Clicking this command requires " +
                             "admin rights";
this.commandLink1.ShieldIcon = true;
this.commandLink1.Size = new System.Drawing.Size(193, 121);
this.commandLink1.TabIndex = 0;
this.commandLink1.Text = "Give access to this computer";
this.commandLink1.UseVisualStyleBackColor = true;
this.commandLink1.Click += new System.EventHandler(
                                   this.OnClickCommandLink);
```

code snippet WindowsFormsCommandLink/Form1.Designer.cs

For WPF, the command link is redefined as a WPF user control. This control is located in the namespace `Microsoft.WindowsAPICodePack.Controls.WindowsPresentationFoundation` with the name `CommandLink`. The `Icon` property allows you to specify an `IconSource`, the `Link` property, the value of the main text, and the `Note` property, the value of the additional text. Figure A-8 shows the result of this command link.

FIGURE A-8

```
<shell:CommandLink Icon="Images/Globe.ico" x:Name="commandLink1"
                   Link="Browse the Web"
                   Note="Find data on the World Wide Web"
                   Click="OnBrowse" Margin="5" Height="57"
                   VerticalAlignment="Top"
                   HorizontalAlignment="Center" />
```

code snippet WPFCommandLink/MainWindow.xaml

Task Dialog

The task dialog is a next-generation dialog that replaces the old message box. The task dialog is part of the new common controls. The Windows API defines the functions `TaskDialog` and `TaskDialogIndirect` to create task dialogs. `TaskDialog` allows you to create simple dialogs; `TaskDialogIndirect` is used to create more complex dialogs that contain command link controls and expanded content.

With the Windows API Code Pack, the native API call to `TaskDialogIndirect()` is wrapped with P/Invoke:

```
[DllImport(CommonDllNames.ComCtl32, CharSet = CharSet.Auto,
    SetLastError = true)]
internal static extern HRESULT TaskDialogIndirect(
    [In] TaskDialogNativeMethods.TASKDIALOGCONFIG pTaskConfig,
    [Out] out int pnButton,
    [Out] out int pnRadioButton,
    [MarshalAs(UnmanagedType.Bool)][Out]
             out bool pVerificationFlagChecked);
```

The first parameter of `TaskDialogIndirect()` is defined as a `TASKDIALOGCONFIG` class that maps to the same structure of the native API call:

```
[StructLayout(LayoutKind.Sequential, CharSet = CharSet.Auto, Pack = 4)]
internal class TASKDIALOGCONFIG
{
    internal uint cbSize;
    internal IntPtr hwndParent;
    internal IntPtr hInstance;
    internal TASKDIALOG_FLAGS dwFlags;
    internal TASKDIALOG_COMMON_BUTTON_FLAGS dwCommonButtons;
    [MarshalAs(UnmanagedType.LPWStr)]
    internal string pszWindowTitle;
    internal TASKDIALOGCONFIG_ICON_UNION MainIcon;
            // NOTE: 32-bit union field, holds pszMainIcon as well
    [MarshalAs(UnmanagedType.LPWStr)]
    internal string pszMainInstruction;
    [MarshalAs(UnmanagedType.LPWStr)]
    internal string pszContent;
    internal uint cButtons;
    internal IntPtr pButtons;           // Ptr to TASKDIALOG_BUTTON structs
    internal int nDefaultButton;
    internal uint cRadioButtons;
    internal IntPtr pRadioButtons;      // Ptr to TASKDIALOG_BUTTON structs
    internal int nDefaultRadioButton;
    [MarshalAs(UnmanagedType.LPWStr)]
    internal string pszVerificationText;
    [MarshalAs(UnmanagedType.LPWStr)]
    internal string pszExpandedInformation;
    [MarshalAs(UnmanagedType.LPWStr)]
    internal string pszExpandedControlText;
    [MarshalAs(UnmanagedType.LPWStr)]
    internal string pszCollapsedControlText;
    internal TASKDIALOGCONFIG_ICON_UNION FooterIcon;
            // NOTE: 32-bit union field, holds pszFooterIcon as well
    [MarshalAs(UnmanagedType.LPWStr)]
    internal string pszFooter;
    internal PFTASKDIALOGCALLBACK pfCallback;
    internal IntPtr lpCallbackData;
    internal uint cxWidth;
}
```

To use the new version of the common controls with a WPF application, an application manifest with the reference to version 6 of the common controls library must be added:

```
<?xml version="1.0" encoding="utf-8"?>
<asmv1:assembly manifestVersion="1.0" xmlns="urn:schemas-microsoft-com:asm.v1"
                xmlns:asmv1="urn:schemas-microsoft-com:asm.v1"
                xmlns:asmv2="urn:schemas-microsoft-com:asm.v2"
                xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance">
  <assemblyIdentity version="1.0.0.0" name="MyApplication.app"/>
  <dependency>
    <dependentAssembly>
      <assemblyIdentity type="win32"
                        name="Microsoft.Windows.Common-Controls"
                        version="6.0.0.0"
                        processorArchitecture="*"
                        publicKeyToken="6595b64144ccf1df"
                        language="*" />
    </dependentAssembly>
  </dependency>
</asmv1:assembly>
```

code snippet TaskDialogDemo/app.manifest

The public class from the Windows API Code Pack used to show task dialogs is `TaskDialog`. To display a simple dialog, only the static method `Show()` must be invoked. The simple dialog is shown in Figure A-9.

```
TaskDialog.Show("Simple Task Dialog",
"Additional Information", "Title");
```

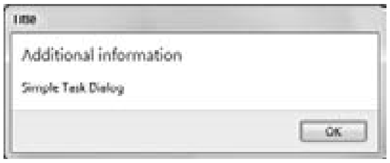


FIGURE A-9

code snippet TaskDialogDemo/MainWindow.xaml.cs

For more features of the `TaskDialog` class, you can set the `Caption`, `Text`, `StandardButtons`, and `MainIcon` properties. You can see the result in Figure A-10.

```
var dlg1 = new TaskDialog();
dlg1.Caption = "Title";
dlg1.Text = "Some Information";
dlg1.StandardButtons =
TaskDialogStandardButtons.Ok |
                        TaskDialogStandardButtons.Cancel;
dlg1.Icon = TaskDialogStandardIcon.Information;
dlg1.Show();
```

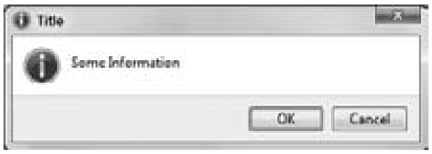

FIGURE A-10

With the task dialog, you can set the shield icon that was first shown with command links. Also, you can expand it by setting the `ExpansionMode` property. With the enumeration `TaskDialogExpandedInformationLocation`, you can specify that either the content or the footer should be expanded. Figure A-11 shows the task dialog in collapsed mode.

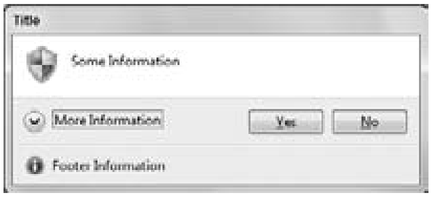

FIGURE A-11

```
var dlg2 = new TaskDialog();
dlg2.Caption = "Title";
dlg2.Text = "Some Information";
dlg2.StandardButtons = TaskDialogStandardButtons.Yes |
                        TaskDialogStandardButtons.No;
dlg2.Icon = TaskDialogStandardIcon.Shield;
dlg2.DetailsExpandedText = "Additional Text";
dlg2.DetailsExpandedLabel = "Less Information";
dlg2.DetailsCollapsedLabel = "More Information";
dlg2.ExpansionMode = TaskDialogExpandedDetailsLocation.ExpandContent;
dlg2.FooterText = "Footer Information";
dlg2.FooterIcon = TaskDialogStandardIcon.Information;
dlg2.Show();
```

A task dialog can also contain other controls. In the following code snippet, a task dialog is created that contains two radio buttons, a command link, and a progress control. You've already seen command links in the previous section, and indeed, command links are used very frequently within task dialogs. Figure A-12 shows the task dialog with the controls in the content area. Of course, you can also combine the expansion mode with controls.

```
var radio1 = new TaskDialogRadioButton();
radio1.Name = "radio1";
radio1.Text = "One";
var radio2 = new TaskDialogRadioButton();
radio2.Name = "radio2";
radio2.Text = "Two";
```

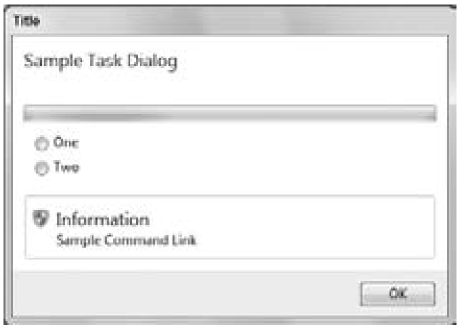

FIGURE A-12

```
var commandLink = new TaskDialogCommandLink();
commandLink.Name = "link1";
commandLink.ShowElevationIcon = true;
commandLink.Text = "Information";
commandLink.Instruction = "Sample Command Link";
var progress = new TaskDialogProgressBar();
progress.Name = "progress";
progress.State = TaskDialogProgressBarState.Marquee;

var dlg3 = new TaskDialog();
dlg3.Caption = "Title";
dlg3.InstructionText = "Sample Task Dialog";

dlg3.Controls.Add(radio1);
dlg3.Controls.Add(radio2);
dlg3.Controls.Add(commandLink);
dlg3.Controls.Add(progress);
dlg3.StandardButtons = TaskDialogStandardButtons.Ok;
dlg3.Show();
```

Taskbar and Jump List

Windows 7 has a new taskbar. In the taskbar, you see not only the running applications, but also fast access icons. The user can pin most-often-used applications for fast access. When you hover over an item of the taskbar, you can see a preview of the currently running application. The item can also have visual state so the user can receive feedback from the items on the taskbar. Did you copy some large files using Explorer? You can see progress information on the Explorer item. Progress information is shown with the visual state. Another feature of the taskbar is the Jump List. Clicking the right mouse key on a taskbar button opens the Jump List. This list can be customized per application. With Microsoft Outlook, you can go directly to the Inbox, Calendar, Contacts, and Tasks or create a new e-mail. With Microsoft Word, you can open the recent documents.

The capability to add all these features to WPF applications is included with the .NET Framework 4 in the namespace `System.Windows.Shell`.

The sample application shown in this section lets you plays videos, gives you visual feedback on the taskbar button as to whether the video is running or stopped, and allows you to start and stop a video directly from the taskbar. The main window of the application consists of a grid with two rows, as shown in Figure A-13. The first row contains a `ComboBox` to display available videos, and two buttons to start and stop the player. The second row contains a `MediaElement` for playing the videos.

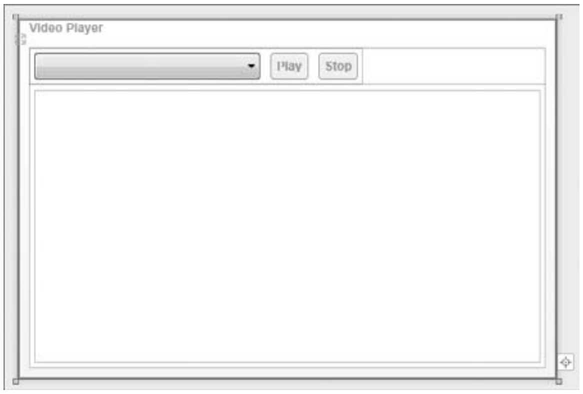

FIGURE A-13

The XAML code of the user interface is shown below. The buttons are associated with the commands `MediaCommands.Play` and `MediaCommands.Stop`, which map to the handler methods `OnPlay()` and `OnStop()`. With the `MediaElement` the property `LoadedBehavior` is set to `Manual` so that the player doesn't start immediately on loading the video.

```
<Window.CommandBindings>
    <CommandBinding Command="MediaCommands.Play" Executed="OnPlay" />
    <CommandBinding Command="MediaCommands.Stop" Executed="OnStop" />
</Window.CommandBindings>
<Grid>
```

```
        <Grid.RowDefinitions>
            <RowDefinition Height="Auto" />
            <RowDefinition Height="*" />
        </Grid.RowDefinitions>
        <StackPanel Grid.Row="0" Orientation="Horizontal"
                    HorizontalAlignment="Left">
            <ComboBox x:Name="comboVideos" ItemsSource="{Binding}" Width="220"
                      Margin="5" IsSynchronizedWithCurrentItem="True" />
            <Button x:Name="buttonPlay" Content="Play" Margin="5" Padding="4"
                    Command="MediaCommands.Play" />
            <Button x:Name="buttonStop" Content="Stop" Margin="5" Padding="4"
                    Command="MediaCommands.Stop" />
        </StackPanel>
        <MediaElement x:Name="player" Grid.Row="1" LoadedBehavior="Manual"
                Margin="5"
                Source="{Binding ElementName=comboVideos, Path=SelectedValue}" />
    </Grid>
```

code snippet TaskbarDemo/MainWindow.xaml

To configure the taskbar item, the namespace `System.Windows.Shell` contains a dependency property for the `Window` class to add taskbar information. The `TaskbarItemInfo` property can contain a `TaskbarItemInfo` element. With `TaskbarItemInfo`, you can set the `Description` property, which is shown as tooltip information. With the properties `ProgressState` and `ProgressValue`, feedback can be given on a current state of the application. `ProgressState` is of type `TaskbarItemProgressState`, which defines the enumeration values `None`, `Intermediate`, `Normal`, `Error`, and `Paused`. Depending on the value of this setting, progress indicators are shown on the taskbar item. The `Overlay` property allows you to define an image that is displayed over the icon in the taskbar. This property will be set from code-behind.

The taskbar item can contain a `ThumbButtonInfoCollection`, which is assigned to the `TumbButtonInfos` property of the `TaskbarItemInfo`. Here, you can add buttons of type `ThumbButtonInfo`, which are displayed in the preview of the application. The sample contains two `ThumbButtonInfo` elements, which have `Command` set to the same commands as the play and stop `Button` elements created previously. With these buttons, you can control the application in the same way as with the other `Button` elements in the application. The image for the buttons in the taskbar is taken from resources with the keys `StartImage` and `StopImage`.

```
    <Window.TaskbarItemInfo>
        <TaskbarItemInfo x:Name="taskBarItem" Description="Sample Application">
            <TaskbarItemInfo.ThumbButtonInfos>
                <ThumbButtonInfo IsEnabled="True" Command="MediaCommands.Play"
                                 CommandTarget="{Binding ElementName=buttonPlay}"
                                 Description="Play"
                                 ImageSource="{StaticResource StartImage}" />
                <ThumbButtonInfo IsEnabled="True" Command="MediaCommands.Stop"
                                 CommandTarget="{Binding ElementName=buttonStop}"
                                 Description="Stop"
                                 ImageSource="{StaticResource StopImage}" />
            </TaskbarItemInfo.ThumbButtonInfos>
        </TaskbarItemInfo>
    </Window.TaskbarItemInfo>
```

The images referenced from the `ThumbButtonInfo` elements are defined within the `Resources` section of the `Window`. One image is made up from a light green ellipse, the other image from two orange-red lines.

```
    <Window.Resources>
        <DrawingImage x:Key="StopImage">
            <DrawingImage.Drawing>
                <DrawingGroup>
                    <DrawingGroup.Children>
                        <GeometryDrawing>
                            <GeometryDrawing.Pen>
                                <Pen Thickness="5" Brush="OrangeRed" />
                            </GeometryDrawing.Pen>
                            <GeometryDrawing.Geometry>
                                <GeometryGroup>
                                    <LineGeometry StartPoint="0,0"
                                                  EndPoint="20,20" />
                                    <LineGeometry StartPoint="0,20"
                                                  EndPoint="20,0" />
                                </GeometryGroup>
                            </GeometryDrawing.Geometry>
                        </GeometryDrawing>
                    </DrawingGroup.Children>
                </DrawingGroup>
            </DrawingImage.Drawing>
        </DrawingImage>
        <DrawingImage x:Key="StartImage">
            <DrawingImage.Drawing>
                <DrawingGroup>
                    <DrawingGroup.Children>
                        <GeometryDrawing Brush="LightGreen">
                            <GeometryDrawing.Geometry>
                                <EllipseGeometry RadiusX="20" RadiusY="20"
                                                 Center="20,20" />
                            </GeometryDrawing.Geometry>
                        </GeometryDrawing>
                    </DrawingGroup.Children>
                </DrawingGroup>
            </DrawingImage.Drawing>
        </DrawingImage>
    </Window.Resources>
```

In the code-behind, all videos from the special My Videos folder are assigned to the `DataContext` to the `Window` object, and thus, because the `ComboBox` is data-bound, listed in the `ComboBox`. In the `OnPlay()` and `OnStop()` event handlers, the `Play()` and `Stop()` methods of the `MediaElement` are invoked. To give visual feedback to the taskbar item, as well on playing and stopping a video, image resources are accessed and assigned to the `Overlay` property of the `TaskbarItemInfo` element.

```
using System;
using System.Collections.Generic;
using System.IO;
using System.Text;
using System.Windows;
using System.Windows.Input;
using System.Windows.Media;
using System.Windows.Shell;

namespace Wrox.ProCSharp.Windows7
{
    public partial class MainWindow : Window
    {
        public MainWindow()
        {
            InitializeComponent();
            string videos = Environment.GetFolderPath(
                                Environment.SpecialFolder.MyVideos);
```

```
                this.DataContext = Directory.EnumerateFiles(videos);
            }

            private void OnPlay(object sender, ExecutedRoutedEventArgs e)
            {
                object image = TryFindResource("StartImage");
                if (image is ImageSource)
                    taskBarItem.Overlay = image as ImageSource;
                player.Play();
            }

            private void OnStop(object sender, ExecutedRoutedEventArgs e)
            {
                object image = TryFindResource("StopImage");
                if (image is ImageSource)
                    taskBarItem.Overlay = image as ImageSource;
                player.Stop();
            }
        }
    }
```

code snippet TaskbarDemo/MainWindow.xaml.cs

Now you can run the application, start and stop the video from the taskbar, and see visual feedback, as shown in Figure A-14.

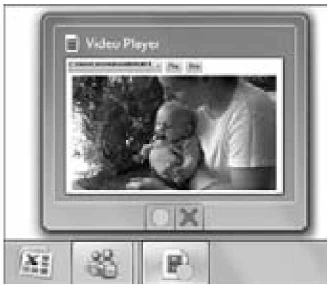

FIGURE A-14

Customizing the Jump List is done by adding a `JumpList` to the application class. This can either be done in code by invoking the static method `JumpList.SetJumpList()` or by adding `JumpList` elements as a child of the `Application` element.

The sample code creates the Jump List in the code-behind. `JumpList.SetJumpList()` requires as the first argument the object of the application, which is returned from the `Application.Current` property. The second argument requires an object of type `JumpList`. The *`jumpList`* is created with a `JumpList` constructor passing `JumpItem` elements and two Boolean values. By default, a Jump List contains frequent and recent items. Setting the Boolean values, you can influence this default behavior. The items you can add to a `JumpList` derive from the base class `JumpItem`. The classes available are `JumpTask` and `JumpPath`. With `JumpTask`, you can define a program that should be started when the user selects this item from the Jump List. `JumpTask` defines the properties that are needed to start the application and give information to the user, which are `CustomCategory`, `Title`, `Description`, `ApplicationPath`, `IconResourcePath`, `WorkingDirectory`, and `Arguments`. With the `JumpTask` that is defined in the code snippet, `notepad.exe` is started and initialized with the `readme.txt` document. With a `JumpPath` item, you can define a file that should be listed in the Jump List to start the application from the file. `JumpPath` defines a `Path` property for assigning the filename. Using a `JumpPath` item requires that the file extension be registered with the application. Otherwise, the registration of the items is rejected. To find the reasons for items being rejected, you can register a handler to the `JumpItemsRejected` event. Here, you can get a list of the rejected items (`RejectedItems`) and the reasons for them (`RejectedReasons`).

```
            var jumpItems = new List<JumpTask>();
            var workingDirectory = Environment.CurrentDirectory;
            var windowsDirectory = Environment.GetFolderPath(
                                       Environment.SpecialFolder.Windows);
            var notepadPath = System.IO.Path.Combine(windowsDirectory,
                                                     "Notepad.exe");
            jumpItems.Add(new JumpTask
            {
                CustomCategory="Read Me",
                Title="Read Me",
                Description="Open read me in Notepad.",
                ApplicationPath=notepadPath,
                IconResourcePath=notepadPath,
                WorkingDirectory=workingDirectory,
                Arguments="readme.txt"
            });

            var jumpList = new JumpList(jumpItems, true, true);
            jumpList.JumpItemsRejected += (sender1, e1) =>
                {
                    var sb = new StringBuilder();
                    for (int i = 0; i < e1.RejectedItems.Count; i++)
                    {
                        if (e1.RejectedItems[i] is JumpPath)
                            sb.Append((e1.RejectedItems[i] as JumpPath).Path);
                        if (e1.RejectedItems[i] is JumpTask)
                            sb.Append((e1.RejectedItems[i] as JumpTask).
                                      ApplicationPath);
                        sb.Append(e1.RejectionReasons[i]);
                        sb.AppendLine();
                    }
                    MessageBox.Show(sb.ToString());
                };

            JumpList.SetJumpList(Application.Current, jumpList);
```

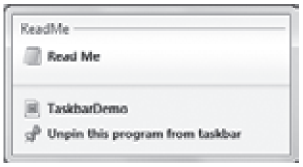

FIGURE A-15

When you run the application and click the right mouse button, you see the Jump List, as shown in Figure A-15.

SUMMARY

In this appendix, you saw various features available in Windows 7 and Windows Server 2008 R2 that are important for the development of applications.

Microsoft has defined guidelines for many years that state that non-administrative applications should not require administrative privileges. Because many applications have failed to comply with that requirement, the operating system is now strict about UAC. The user must explicitly elevate admin rights to applications. You saw how this affects applications.

This appendix covered several dialogs that were introduced in Windows Vista for better user interaction. These include the new task dialog that replaces the message box, and the command link extension to the button control. New with Windows 7 are the taskbar items and Jump Lists.

More features that are available only since Windows Vista and Windows Server 2008 are covered in other chapters:

- Chapter 19, “Instrumentation,” discusses the event logging facility, Event Tracing for Windows (ETW).
- Chapter 21, “Security,” gives you information about Cryptography Next Generation (CNG), the Crypto API.
- Chapter 23, “System.Transactions,” gives you information about file-based and registry-based transactions.
- Chapter 43, “Windows Communication Foundation,” uses Windows Activation Services (WAS) to host a WCF service.

INDEX

48 Graphics with GDI+

WHAT'S IN THIS CHAPTER?

- Principles of drawing
- Colors and the safety palette
- Pens and brushes
- Lines and simple shapes
- BMP images and other image files
- Drawing Text
- Fonts and font families
- Dealing with printing

You will notice that quite a number of chapters in this book deal with user interaction and the .NET Framework. Chapter 39, "Windows Forms," focused on how to display either a dialog box or a Single Document Interface (SDI) or Multiple Document Interface (MDI) window, and how to place various controls such as buttons, text boxes, and list boxes. It also looked at how to work with data in Windows Forms using a number of the Windows Forms controls that work with the disparate data sources that you might encounter.

Although these standard controls are powerful and, by themselves, quite adequate for the complete user interface for many applications, some situations require more flexibility. For example, you might want to draw text in a given font in a precise position in a window, or display images without using a picture box control, or draw simple shapes or other graphics. None of this can be done with the controls discussed in Chapter 39. To display that kind of output, the application must instruct the operating system what to display and where in the window to display it.

In the process, you need to use a variety of helper objects, including pens (to define the characteristics of lines), brushes (to define how areas are filled in), and fonts (to define the shape of the characters of text). This chapter also goes into some detail about how devices interpret and display different colors.

The chapter starts, however, by discussing a technology called Graphics Device Interface or *GDI+*. GDI+ consists of the set of .NET base classes that are available to control custom drawing onscreen. These classes arrange for the appropriate instructions to be sent to graphics device drivers to ensure the correct output is placed onscreen (or printed to a hard copy).

UNDERSTANDING DRAWING PRINCIPLES

This section examines the basic principles that you need to start drawing to the screen. It starts by giving an overview of GDI and the underlying technology on which GDI+ is based. It also shows how GDI and GDI+ are related. Then some simple examples are given.

GDI and GDI+

In general, one of the strengths of Windows — and indeed of modern operating systems in general — lies in its ability to abstract the details of particular devices without input from the developer. For example, you do not need to understand anything about your hard drive device driver to programmatically read and write files to and from disk. You simply call the appropriate methods in the relevant .NET classes (or in pre-.NET days, the equivalent Windows API functions). This principle is also true when it comes to drawing. When the computer draws anything to the screen, it does so by sending instructions to the video card. However, hundreds of different video cards are on the market, most of which have different instruction sets and capabilities. If you had to take that into account and write specific code for each video driver, writing any such application would be an almost impossible task. The Windows Graphics Device Interface (GDI) has been around since the earliest versions of Windows because of these reasons.

GDI provides a layer of abstraction, hiding the differences between the different video cards. You simply call the Windows API function to do the specific task, and internally the GDI figures out how to get the client's particular video card to do whatever it is you want when the client runs your particular piece of code. Not only does GDI accomplish this, but if the client has several display devices — for example, monitors and printers — GDI achieves the remarkable feat of making the printer look the same as the screen, as far as the application is concerned. If the client wants to print something instead of displaying it, your application will simply inform the system that the output device is the printer, and then call the same API functions in exactly the same way.

As you can see, the device context (DC) object (covered shortly) is a very powerful object, and you won't be surprised to learn that under GDI *all* drawing had to be done through a device context. The DC was even used for operations that do not involve drawing to the screen or to any hardware device, such as modifying images in memory.

Although GDI exposes a relatively high-level API to developers, it is still an API that is based on the old Windows API, with C-style functions. GDI+, to a large extent, sits as a layer between GDI and your application, providing a more intuitive, inheritance-based object model. Although GDI+ is basically a wrapper around GDI, Microsoft has been able, through GDI+, to provide new features and performance improvements to some of the older features of GDI as well.

The GDI+ part of the .NET base class library is huge, and this chapter barely scratches the surface of its features because trying to cover more than a tiny fraction of the library would have turned this chapter into a huge reference guide that simply listed classes and methods. It is more important to understand the fundamental principles involved in drawing so that you are in a good position to explore the available classes. Full lists of all the classes and methods available in GDI+ are, of course, available in the SDK documentation.

GDI+ Namespaces

The following table provides an overview of the main namespaces you will need to explore to find the GDI+ base classes.

You should note that almost all the classes and structs used in this chapter are taken from the `System.Drawing` namespace.

NAMESPACE	DESCRIPTION
`System.Drawing`	Contains most of the classes, structs, enums, and delegates concerned with the basic functionality of drawing.
`System.Drawing.Drawing2D`	Provides most of the support for advanced 2-D and vector drawing, including anti-aliasing, geometric transformations, and graphics paths.
`System.Drawing.Imaging`	Contains various classes that assist in the manipulation of images (bitmaps, GIF files, and so on).
`System.Drawing.Printing`	Contains classes to assist when specifically targeting a printer or print preview window as the "output device."
`System.Drawing.Design`	Contains some predefined dialog boxes, property sheets, and other user interface elements concerned with extending the design-time user interface.
`System.Drawing.Text`	Contains classes to perform more advanced manipulation of fonts and font families.

Device Contexts and the Graphics Object

In GDI, you identify which device you want your output to go to with an object known as the DC. The DC stores information about a particular device and is able to translate calls to the GDI API functions into whatever instructions need to be sent to that device. You can also query the device context to find out what the capabilities of the corresponding device are (for example, whether a printer prints in color or only in black and white), so the output can be adjusted accordingly. If you ask the device to do something it is not capable of, the DC will normally detect this and take appropriate action (which, depending on the situation, might mean throwing an exception or modifying the request to get the closest match that the device is actually capable of using).

However, the DC does not deal only with the hardware device. It acts as a bridge to Windows and is able to take account of any requirements or restrictions placed on the drawing by Windows. For example, if Windows knows that only a portion of your application's window needs to be redrawn, the DC can trap and nullify attempts to draw outside that area. Because of the DC's relationship with Windows, working through the device context can simplify your code in other ways.

For example, hardware devices need to be told where to draw objects, and they usually want coordinates relative to the top-left corner of the screen (or output device). Usually, however, your application will be thinking of drawing something at a certain position within the client area (the area reserved for drawing) of its own window, possibly using its own coordinate system. Because the window might be positioned anywhere on the screen, and a user might move it at any time, translating between the two coordinate systems is potentially a difficult task. However, the DC always knows where your window is and is able to perform this translation automatically.

With GDI+, the DC is wrapped up in the .NET base class `System.Drawing.Graphics`. Most drawing is done by calling methods on an instance of `Graphics`. In fact, because the `Graphics` class is the class that is responsible for handling most drawing operations, very little gets done in GDI+ that does not involve a `Graphics` instance somewhere, so understanding how to manipulate this object is the key to understanding how to draw to display devices with GDI+.

Drawing Shapes

This section starts with a short example, `DisplayAtStartup`, to illustrate drawing to an application's main window. The examples in this chapter are all created in Visual Studio 2010 as C# Windows applications. Recall that for this type of project the code wizard gives you a class called `Form1`, derived from `System.Windows.Forms.Form`, which represents the application's main window. Also generated for you is a class called `Program` (found in the `Program.cs` file), which represents the application's main starting point. Unless otherwise stated, in all code samples, new or modified code means code that you have added to the wizard-generated code. (You can download the sample code from the Wrox web site at `www.wrox.com`.)

The first example simply creates a form and draws to it in the constructor when the form starts up. Note that this is not actually the best or the correct way to draw to the screen — you will quickly find that this example has a problem because it is unable to redraw anything after starting up. However, this example illustrates quite a few points about drawing without your having to do very much work.

For this example, start Visual Studio 2010 and create a Windows Form Application project. First, set the background color of the form to white. In the example, this line comes after the `InitializeComponent()` method so that Visual Studio 2010 recognizes the line and is able to alter the design view appearance of the form. You can find the `InitializeComponent()` by clicking the arrow icon next to the `Form1.cs` file (this will expand the hierarchy of files related to the `Form1.cs` file). Here, you will find the `Form1.Designer.cs` file. It is in this file that you will find the `InitializeComponent()` method. You could have used the design view to set the background color, but this would have resulted in pretty much the same line being added automatically:

```
private void InitializeComponent()
{
    this.components = new System.ComponentModel.Container();
    this.AutoScaleMode = System.Windows.Forms.AutoScaleMode.Font;
    this.Text = "Form1";
    this.BackColor = System.Drawing.Color.White;
}
```

code download DrawingShapes.sln

Then you add code to the `Form1` constructor. You create a `Graphics` object using the form's `CreateGraphics()` method. This `Graphics` object contains the Windows DC that you need to draw with. The device context created is associated with the display device and also with this window:

```
public Form1()
{
   InitializeComponent();

   Graphics dc = CreateGraphics();
   Show();
   Pen bluePen = new Pen(Color.Blue, 3);
   dc.DrawRectangle(bluePen, 0,0,50,50);
```

```
            Pen redPen = new Pen(Color.Red, 2);
            dc.DrawEllipse(redPen, 0, 50, 80, 60);
        }
```

code download DrawingShapes.sln

As you can see, you then call the `Show()` method to display the window. This is really done to force the window to display immediately because you cannot actually do any drawing until the window has been displayed. If the window is not displayed, there is nothing for you to draw onto.

Finally, you display a rectangle at coordinates (0,0) and with width and height 50, and an ellipse with coordinates (0,50) and with width 80 and height 50. Note that coordinates (x,y) translate to x pixels to the right and y pixels down from the top-left corner of the client area of the window — and these coordinates start from the top-left corner of the shape to be displayed.

The overloads that you are using of the `DrawRectangle()` and `DrawEllipse()` methods each take five parameters. The first parameter of each is an instance of the class `System.Drawing.Pen`. A `Pen` is one of a number of supporting objects to help with drawing — it contains information about how lines are to be drawn. Your first pen instructs the system that lines should be the color blue with a width of 3 pixels; the second pen instructs the system that the lines should be red and have a width of 2 pixels. The final four parameters are coordinates and size. For the rectangle, they represent the (x,y) coordinates of the top-left corner of the rectangle in addition to its width and height. For the ellipse, these numbers represent the same thing, except that you are talking about a hypothetical rectangle that the ellipse just fits into, rather than the ellipse itself. Figure 48-1 shows the result of running this code. Of course, because this book is not in color, you cannot see the colors.

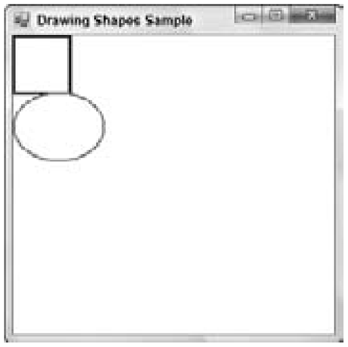

FIGURE 48-1

Figure 48-1 demonstrates a couple of points. First, you can see clearly where the client area of the window is located. It is the white area — the area that has been affected by setting the `BackColor` property. Notice that the rectangle nestles up in the corner of this area, as you would expect when you specify the coordinates of (0,0) for it. Second, notice that the top of the ellipse overlaps the rectangle slightly, which you would not expect from the coordinates given in the code. The culprit here is Windows itself and where it places the lines that border the rectangle and ellipse. By default, Windows will try to center the line on the border of the shape — that is not always possible to do exactly because the line has to be drawn on pixels (obviously). Normally, the border of each shape theoretically lies between two pixels. The result is that lines that are 1 pixel thick will get drawn just *inside* the top and left sides of a shape, but just *outside* the bottom and right sides — which means that shapes that are next to each other have their borders overlapping by one pixel. You have specified wider lines; therefore, the overlap is greater. It is possible to change the default behavior by setting the `Pen.Alignment` property, as detailed in the SDK documentation, but for these purposes, the default behavior is adequate.

Unfortunately, if you actually run the sample, you will notice that the form behaves a bit strangely. It is fine if you just leave it there. It is also fine if you drag it around the screen with the mouse. However, if you try minimizing the window and then restoring it, then your carefully drawn shapes just vanish! The same thing happens if you drag another window across the sample so that it only obscures a portion of your shapes. When you drag the other window away again, you will find that the temporarily obscured portion has disappeared and you are left with half an ellipse or half a rectangle!

So what's going on? The problem arises when part of a window is hidden because Windows usually discards immediately all the information concerning exactly what has been displayed. This is something Windows has to do or else the memory usage for storing screen data would be astronomical. A typical computer might be running with the video card set to display 1024 × 768 pixels, perhaps in a 24-bit color mode, which implies that each pixel on the screen occupies 3 bytes — 2.25MB to display the screen (24-bit color is covered later in this chapter). However, it is not uncommon for a user to work with 10 or 20 minimized windows in the taskbar. In a worst-case scenario, you might have 20 windows, each of which would occupy the whole screen if it was not minimized. If Windows actually stored the visual information those windows contained, ready for when the user restored them, then that would amount to some 45MB! These days, a decent graphics card might have 512MB of memory and be able to cope with that, but it was only a few years ago that 256MB was considered generous in a graphics card — and the excess would need to be stored in the computer's main memory. Many people still have old machines, some of them with only 256MB graphic cards. Clearly, it would not be practical for Windows to manage its user interface like that.

The moment any part of a window is hidden, the "hidden" pixels get lost because Windows frees the memory that was holding those pixels. It does, however, note that a portion of the window is hidden, and when it detects that it is no longer hidden, it asks the application that owns the window to redraw its contents. There are a couple of exceptions to this rule — generally for cases in which a small portion of a window is hidden very temporarily (a good example is when you select an item from the main menu and that menu item drops down, temporarily obscuring part of the window below). In general, however, you can expect that if part of your window is hidden, your application will need to redraw it later.

That is the source of the problem for the sample application. You placed your drawing code in the `Form1` constructor, which is called just once when the application starts up, and you cannot call the constructor again to redraw the shapes when required later on.

When working with Windows Forms server controls, there is no need to know anything about how to accomplish this task. This is because the standard controls are pretty sophisticated, and they are able to redraw themselves correctly whenever Windows asks them to. That is one reason why, when programming controls, you do not need to worry about the actual drawing process at all. If you are taking responsibility for drawing to the screen in your application, you also need to make sure that your application will respond correctly whenever Windows asks it to redraw all or part of its window. In the next section, you modify the sample to do just that.

Painting Shapes Using OnPaint()

If the preceding explanation has you worried that drawing your own user interface is going to be terribly complicated, do not worry. Getting your application to redraw itself when necessary is actually quite easy.

Windows notifies an application that some repainting needs to be done by raising a `Paint` event. Interestingly, the `Form` class has already implemented a handler for this event, so you do not need to add one yourself. The `Form1` handler for the `Paint` event will at some point in its processing call up a virtual method, `OnPaint()`, passing to it a single `PaintEventArgs` parameter. This means that all you need to do is override `OnPaint()` to perform your painting.

Although for this example you work by overriding `OnPaint()`, it is equally possible to achieve the same results by simply adding your own event handler for the `Paint` event (a `Form1_Paint()` method, say) — in much the same way as you would for any other Windows Forms event. This other approach is arguably more convenient because you can add a new event handler through the Visual Studio 2010 properties window, saving yourself from typing some code. However, the approach of overriding `OnPaint()` is slightly more flexible in terms of letting you control when the call to the base class window processing occurs, and it allows you to avoid attaching the control's event handler to its own event.

In this section, you create a new Windows Application called `DrawShapes` to do this. As before, you set the background color to white, using the properties window. You will also change the form's text to `DrawShapes Sample`. Then you add the following code to the generated code for the `Form1` class:

```
protected override void OnPaint( PaintEventArgs e )
{
   base.OnPaint(e);
   Graphics dc = e.Graphics;
   Pen bluePen = new Pen(Color.Blue, 3);
   dc.DrawRectangle(bluePen, 0,0,50,50);
```

```
            Pen redPen = new Pen(Color.Red, 2);
            dc.DrawEllipse(redPen, 0, 50, 80, 60);
        }
```

code download DrawingShapes.sln

Notice that `OnPaint()` is declared as `protected`, because it is normally used internally within the class, so there is no reason for any other code outside the class to know about its existence.

`PaintEventArgs` is a class that is derived from the `EventArgs` class normally used to pass in information about events. `PaintEventArgs` has two additional properties, of which the more important one is a `Graphics` instance, already primed and optimized to paint the required portion of the window. This means that you do not have to call `CreateGraphics()` to get a DC in the `OnPaint()` method — you have already been provided with one. You will look at the other additional property soon. This property contains more detailed information about which area of the window actually needs repainting.

In your implementation of `OnPaint()`, you first get a reference to the `Graphics` object from `PaintEventArgs`, and then you draw your shapes exactly as you did before. When you start this, you call the base class's `OnPaint()` method. This step is important. You have overridden `OnPaint()` to do your own painting, but it is possible that Windows may have some additional work of its own to do in the painting process — any such work will be dealt with in an `OnPaint()` method in one of the .NET base classes.

For this example, you will find that removing the call to `base.OnPaint()` *does not seem to have any effect. However, do not be tempted to leave this call out. You might be stopping Windows from doing its work properly, and the results could be unpredictable.*

`OnPaint()` will also be called when the application first starts up and your window is displayed for the first time. Thus, there is no need to duplicate the drawing code in the constructor.

Running this code gives the same results initially as in the previous example, except that now your application behaves properly when you minimize it or hide parts of the window.

Using the Clipping Region

The `DrawShapes` sample from the previous section illustrates the main principles involved with drawing to a window, although the sample is not very efficient. The reason is that it attempts to draw everything in the window, regardless of how much needs to be drawn. Figure 48-2 shows the result of running the `DrawShapes` example and opening another window and moving it over the `DrawShapes` form so part of it is hidden.

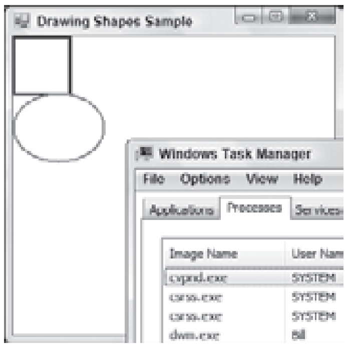

FIGURE 48-2

However, when you move the overlapping window so that the `DrawShapes` window is fully visible again, Windows will, as usual, send a `Paint` event to the form, asking it to repaint itself. The rectangle and ellipse both lie in the top-left corner of the client area, and so were visible all the time. Therefore, there is actually nothing that needs to be done in this case apart from repainting the white background area. However, Windows does not know that, so it thinks it should raise the `Paint` event, resulting in your `OnPaint()` implementation being called. `OnPaint()` will then unnecessarily attempt to redraw the rectangle and ellipse.

Actually, in this case, the shapes will not be repainted because of the device context. Windows has pre-initialized the device context with information concerning what area actually needed repainting. In the days of GDI, the region marked for repainting was known as the *invalidated region,* but with GDI+ the terminology has largely changed to *clipping region*. The device context recognizes this region. Therefore, it will intercept any attempts to draw outside this region and not pass the relevant drawing commands on to the graphics card. That sounds good, but there is still a potential performance hit here. You do not know how much processing the device context had to do before it figured out that the drawing was outside the invalidated region. In some cases, it might be quite a lot because calculating which pixels need to be changed to what color can be very processor-intensive (although a good graphics card will provide hardware acceleration to help with some of this).

The bottom line to this is that asking the `Graphics` instance to do some drawing outside the invalidated region is almost certainly wasting processor time and slowing your application down. In a well-designed application, your code will help the device context by carrying out a few simple checks to see if the proposed drawing work is likely to be needed before it calls the relevant `Graphics` instance methods. In this section, you code a new example, `DrawShapesWithClipping`, by modifying the `DisplayShapes` example to do just that. In your `OnPaint()` code, you will do a simple test to see whether the invalidated region intersects the area you need to draw in, and you will call the drawing methods only if it does.

First, you need to obtain the details of the clipping region. This is where an extra property, `ClipRectangle`, on `PaintEventArgs` comes in. `ClipRectangle` contains the coordinates of the region to be repainted and wrapped up in an instance of a struct, `System.Drawing.Rectangle`. `Rectangle`, which is quite a simple struct. It contains four properties of interest: `Top`, `Bottom`, `Left`, and `Right`. These respectively contain the vertical coordinates of the top and bottom of the rectangle and the horizontal coordinates of the left and right edges.

Next, you need to decide what test you will use to determine whether drawing should take place. You will go for a simple test here. Notice that in your drawing, the rectangle and ellipse are both entirely contained within the rectangle that stretches from point (0,0) to point (80,130) of the client area. Actually, use point (82,132) to be on the safe side because you know that the lines might stray a pixel or so outside this area. So, you will check whether the top-left corner of the clipping region is inside this rectangle. If it is, then you will go ahead and redraw. If it is not, then you won't bother.

The following is the code to do this:

```
protected override void OnPaint( PaintEventArgs e )
{
   base.OnPaint(e);
   Graphics dc = e.Graphics;
   if (e.ClipRectangle.Top < 132 && e.ClipRectangle.Left < 82)
   {
      Pen bluePen = new Pen(Color.Blue, 3);
      dc.DrawRectangle(bluePen, 0,0,50,50);
      Pen redPen = new Pen(Color.Red, 2);
      dc.DrawEllipse(redPen, 0, 50, 80, 60);
   }
}
```

code download DrawingShapes.sln

Note that what is displayed is exactly the same as before. However, performance is improved now by the early detection of some cases in which nothing needs to be drawn. Notice also that the example uses a fairly crude test for whether to proceed with the drawing. A more refined test might be to check separately whether the rectangle or the ellipse needs to be redrawn. However, there is a balance here. You can make your tests in `OnPaint()` more sophisticated, improving performance, but you will also make your own `OnPaint()` code more complex. It is almost always worth putting some test in — because you have written the code, you understand far more about what is being drawn than the `Graphics` instance, which just blindly follows drawing commands.

MEASURING COORDINATES AND AREAS

In the previous example, you encountered the base struct, `Rectangle`, which is used to represent the coordinates of a rectangle. GDI+ actually uses several similar structures to represent coordinates or areas. The following table lists the structs that are defined in the `System.Drawing` namespace.

STRUCT	MAIN PUBLIC PROPERTIES
`Point` and `PointF`	`X`, `Y`
`Size` and `SizeF`	`Width`, `Height`
`Rectangle` and `RectangleF`	`Left`, `Right`, `Top`, `Bottom`, `Width`, `Height`, `X`, `Y`, `Location`, `Size`

Note that many of these objects have a number of other properties, methods, or operator overloads not listed here. This section just discusses some of the most important ones.

Point and PointF

`Point` is conceptually the simplest of these structs. Mathematically, it is equivalent to a 2-dimensional vector. It contains two public integer properties, which represent how far you move horizontally and vertically from a particular location (perhaps on the screen), as shown in Figure 48-3.

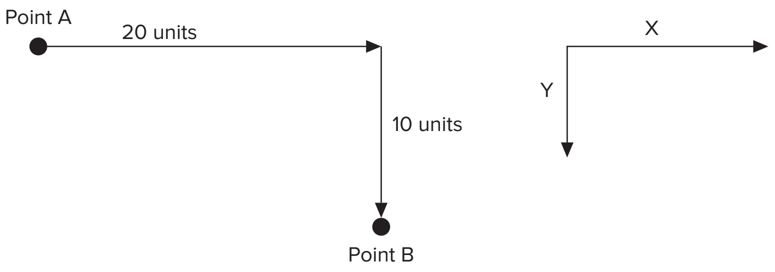

FIGURE 48-3

To get from point A to point B, you move 20 units across and 10 units down, marked as x and y on the diagram because this is how they are commonly referred to. The following `Point` struct represents that line:

```
Point ab = new Point(20, 10);
Console.WriteLine("Moved {0} across, {1} down", ab.X, ab.Y);
```

`X` and `Y` are read-write properties, which means that you can also set the values in a `Point`, such as this:

```
Point ab = new Point();
ab.X = 20;
ab.Y = 10;
Console.WriteLine("Moved {0} across, {1} down", ab.X, ab.Y);
```

Note that although conventionally horizontal and vertical coordinates are referred to as x and y coordinates (lowercase), the corresponding `Point` properties are `X` and `Y` (uppercase) because the usual convention in C# is for public properties to have names that start with an uppercase letter.

`PointF` is essentially identical to `Point`, except that `X` and `Y` are of type `float` instead of `int`. `PointF` is used when the coordinates are not necessarily integer values. A cast has been defined so that you can implicitly convert from `Point` to `PointF`. (Note that because `Point` and `PointF` are structs, this cast involves actually making a copy of the data.) There is no corresponding reverse case — to convert from `PointF` to `Point` you have to copy the values across, or use one of three conversion methods, `Round()`, `Truncate()`, or `Ceiling()`:

```
PointF abFloat = new PointF(20.5F, 10.9F);
// converting to Point
Point ab = new Point();
```

```
    ab.X = (int)abFloat.X;
    ab.Y = (int)abFloat.Y;
    Point ab1 = Point.Round(abFloat);
    Point ab2 = Point.Truncate(abFloat);
    Point ab3 = Point.Ceiling(abFloat);
    // but conversion back to PointF is implicit
    PointF abFloat2 = ab;
```

You might be wondering what a unit is measured in. By default, GDI+ interprets units as pixels along the screen (or printer, whatever the graphics device is). This is how the `Graphics` object methods view any coordinates that they are passed as parameters. For example, the point `new Point(20,10)` represents 20 pixels across the screen and 10 pixels down. Usually these pixels are measured from the top-left corner of the client area of the window, as has been the case in the previous examples. However, that will not always be the case. For example, on some occasions you might want to draw relative to the top-left corner of the whole window (including its border), or even to the top-left corner of the screen. In most cases, however, unless the documentation tells you otherwise, you can assume that you are talking about pixels relative to the top-left corner of the client area.

You learn more on this subject later in this chapter, after scrolling is examined, when we discuss the three different coordinate systems in use — world, page, and device coordinates.

Size and SizeF

As with `Point` and `PointF`, sizes come in two varieties. The `Size` struct is for `int` types. `SizeF` is available if you need to use `float` types. Otherwise, `Size` and `SizeF` are identical. This section focuses on the `Size` struct.

In many ways, the `Size` struct is identical to the `Point` struct. It has two integer properties that represent a distance horizontally and vertically. The main difference is that instead of `X` and `Y`, these properties are named `Width` and `Height`. You can represent the earlier diagram using this code:

```
Size ab = new Size(20,10);
Console.WriteLine("Moved {0} across, {1} down", ab.Width, ab.Height);
```

Although `Size` mathematically represents exactly the same thing as `Point`, conceptually, it is intended to be used in a slightly different way. `Point` is used when you are talking about where something is, and `Size` is used when you are talking about how big it is. However, because `Size` and `Point` are so closely related, there are even supported conversions between these two:

```
    Point point = new Point(20, 10);
    Size size = (Size) point;
    Point anotherPoint = (Point) size;
```

As an example, think about the rectangle you drew earlier, with top-left coordinate (0,0) and size (50,50). The size of this rectangle is (50,50) and might be represented by a `Size` instance. The bottom-right corner is also at (50,50), but would be represented by a `Point` instance. To see the difference, suppose that you draw the rectangle in a different location, so that its top-left coordinate is at (10,10):

```
dc.DrawRectangle(bluePen, 10,10,50,50);
```

Now the bottom-right corner is at coordinate (60,60), but the size is unchanged at (50,50).

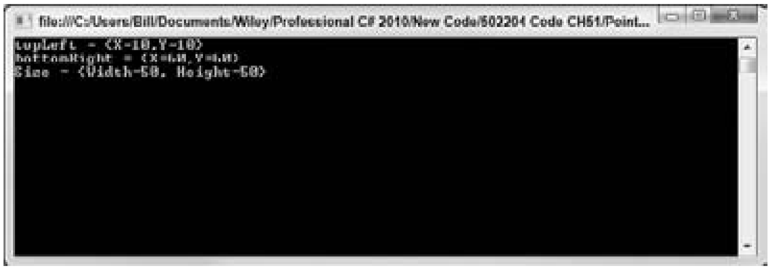
The addition operator has been overloaded for `Point` and `Size` structs so that it is possible to add a `Size` to a `Point` struct, resulting in another `Point` struct:

```
static void Main(string[] args)
{
   Point topLeft = new Point(10,10);
   Size rectangleSize = new Size(50,50);
   Point bottomRight = topLeft + rectangleSize;
   Console.WriteLine("topLeft = " + topLeft);
```

```
        Console.WriteLine("bottomRight = " + bottomRight);
        Console.WriteLine("Size = " + rectangleSize);
    }
```

code download PointsAndSizes.sln

This code, running as a simple console application called `PointsAndSizes`, produces the output shown in Figure 48-4.



file:///C:/Users/Bill/Documents/Wiley/Professional C# 2010/New Code/502204 Code CH51/Point...

```
topLeft = {X=10,Y=10}
bottomRight = {X=60,Y=60}
Size = {Width=50, Height=50}
```

FIGURE 48-4

Note that this output also shows how the `ToString()` method has been overridden in both `Point` and `Size` to display the value in `{X,Y}` format.

It is also possible to subtract a `Size` from a `Point` struct to produce a `Point` struct, and you can add two `Size` structs together, producing another `Size`. It is not possible, however, to add a `Point` struct to another `Point`. Microsoft decided that adding `Point` structs does not conceptually make sense, and so it chose not to supply any overload to the + operator that would have allowed that.

You can also explicitly cast a `Point` to a `Size` struct and vice versa:

```
Point topLeft = new Point(10,10);
Size s1 = (Size)topLeft;
Point p1 = (Point)s1;
```

With this cast, `s1.Width` is assigned the value `topLeft.X`, and `s1.Height` is assigned the value `topLeft.Y`. Hence, `s1` contains (10,10). `p1` will end up storing the same values as `topLeft`.

Rectangle and RectangleF

These structures represent a rectangular region (usually of the screen). Just as with `Point` and `Size`, only the `Rectangle` struct is considered here. `RectangleF` is basically identical except that the properties that represent dimensions all use `float`, whereas those of `Rectangle` use `int`.

A `Rectangle` struct can be thought of as composed of a point, representing the top-left corner of the rectangle, and a `Size` struct, representing how large it is. One of its constructors actually takes a `Point` struct and a `Size` struct as its parameters. You can see this by rewriting the earlier code from the `DrawShapes` sample that draws a rectangle:

```
Graphics dc = e.Graphics;
Pen bluePen = new Pen(Color.Blue, 3);
Point topLeft = new Point(0,0);
Size howBig = new Size(50,50);
Rectangle rectangleArea = new Rectangle(topLeft, howBig);
dc.DrawRectangle(bluePen, rectangleArea);
```

This code also uses an alternative override of `Graphics.DrawRectangle()`, which takes a `Pen` and a `Rectangle` struct as its parameters.

You can also construct a `Rectangle` struct by supplying the top-left horizontal coordinate, top-left vertical coordinate, width and height separately, and in that order, as individual numbers:

```
    Rectangle rectangleArea = new Rectangle(0, 0, 50, 50)
```

`Rectangle` makes quite a few read-write properties available to set or extract its dimensions in different combinations. See the following table for details.

PROPERTY	DESCRIPTION
`int Left`	x-coordinate of left-hand edge
`int Right`	x-coordinate of right-hand edge
`int Top`	y-coordinate of top
`int Bottom`	y-coordinate of bottom
`int X`	Same as `Left`
`int Y`	Same as `Top`
`int Width`	Width of rectangle
`int Height`	Height of rectangle
`Point Location`	Top-left corner
`Size Size`	Size of rectangle

Note that these properties are not all independent. For example, setting `Width` also affects the value of `Right`.

Region

`Region` represents an area of the screen that has some complex shape. For example, the shaded area in Figure 48-5 could be represented by `Region`.

As you can imagine, the process of initializing a `Region` instance is itself quite complex. Broadly speaking, you can do it by indicating either what component simple shapes make up the region or what path you take as you trace around the edge of the region. If you need to start working with areas similar to this, it is worth looking up the `Region` class in the SDK documentation.

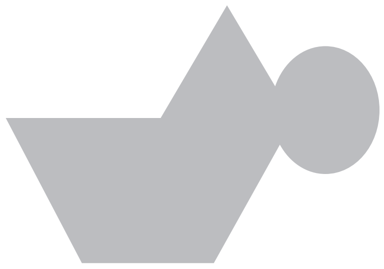


FIGURE 48-5

A NOTE ABOUT DEBUGGING

You are just about ready to do some more advanced types of drawing now. First, however, we just want to say a few things about debugging. If you have tried setting break points in the examples of this chapter, then you have noticed that debugging drawing routines is not quite as simple as debugging other parts of your program because entering and leaving the debugger often causes `Paint` messages to be sent to your application. As a result, setting a break point in your `OnPaint()` override can simply cause your application to keep painting itself over and over again, so it is basically unable to do anything else.

A typical scenario is as follows: You want to find out why your application is displaying something incorrectly, so you set a break point within the `OnPaint()` event. As expected, the application hits your break point and the debugger comes in, at which point your developer environment MDI window comes to the foreground. You more than likely have the developer environments set to full-screen display so that you can more easily view all the debugging information, which means it always completely hides the application you are debugging.

Moving on, you examine the values of some variables and hopefully discover something useful. Then you press F5 to tell the application to continue, so that you can go on to see what happens when the application displays something else after some processing. Unfortunately, the first thing that happens is that the application comes to the foreground, and Windows efficiently detects that the form is visible again and promptly sends it a `Paint` event. This means, of course, that your break point is hit again. If that is what you want, fine. More commonly, what you really want is to hit the break point *later,* when the application is drawing something more interesting, perhaps after you have selected some menu option to read in a file or in some other way changed what is displayed. It looks like you are stuck. Either you do not have a break point in `OnPaint()` at all, or your application can never get beyond the point where it is displaying its initial startup window.

There is a workaround to this problem.

With a big screen, the easiest way is simply to keep your developer environment window tiled rather than maximized. In addition, you want to keep it well away from your application window, so that your application is never hidden in the first place. Unfortunately, in most cases that is not a practical solution because your developer environment window would be too small (you can also get a second monitor). An alternative that uses the same principle is to have your application declare itself as the topmost application while you are debugging. You do this by setting a property in the `Form` class, `TopMost`, which you can easily do in the `InitializeComponent()` method:

```
private void InitializeComponent()
{
   this.TopMost = true;
```

You can also set this property through the properties window in Visual Studio 2010.

Being a `TopMost` window means your application can never be hidden by other windows (except other topmost windows). It always remains above other windows even when another application has the focus. This is how the Task Manager behaves.

Even with this technique, you have to be careful because you can never be certain when Windows might decide for some reason to raise a `Paint` event. If you really want to trap some problem that occurs in `OnPaint()` in some specific circumstance (for example, the application draws something after you select a certain menu option, and something goes wrong at that point), then the best way to do this is to place some dummy code in `OnPaint()` that tests a condition, which will only be `true` in the specified circumstances. Then place the break point inside the `if` block, as shown here:

```
protected override void OnPaint( PaintEventArgs e )
{
   // Condition() evaluates to true when we want to break
   if (Condition())
   {
      int ii = 0;   // <-SET BREAKPOINT HERE!!!
   }
```

This is a quick-and-easy way of setting a conditional break point.

DRAWING SCROLLABLE WINDOWS

The earlier `DrawShapes` example worked very well because everything you needed to draw fit into the initial window size. This section covers what you need to do if that is not the case.

For this example, you expand the `DrawShapes` sample to demonstrate scrolling. To make things a bit more realistic, you start by creating an example, `BigShapes`, in which you make the rectangle and ellipse a bit bigger. Also, while you are at it, you will see how to use the `Point`, `Size`, and `Rectangle` structs by using them to assist in defining the drawing areas. With these changes, the relevant part of the Form1 class looks like this:

```
// member fields
private readonly Point rectangleTopLeft = new Point(0, 0);
private readonly Size rectangleSize = new Size(200,200);
private readonly Point ellipseTopLeft = new Point(50, 200);
private readonly Size ellipseSize = new Size(200, 150);
private readonly Pen bluePen = new Pen(Color.Blue, 3);
private readonly Pen redPen = new Pen(Color.Red, 2);
protected override void OnPaint( PaintEventArgs e )
{
   base.OnPaint(e);
   Graphics dc = e.Graphics;
   if (e.ClipRectangle.Top < 350 || e.ClipRectangle.Left < 250)
   {
      Rectangle rectangleArea =
         new Rectangle (rectangleTopLeft, rectangleSize);
      Rectangle ellipseArea =
         new Rectangle (ellipseTopLeft, ellipseSize);
      dc.DrawRectangle(bluePen, rectangleArea);
      dc.DrawEllipse(redPen, ellipseArea);
   }
}
```

Note that you have also turned the Pen, Size, and Point objects into member fields. This is more efficient than creating a new Pen every time you need to draw anything, as you have been doing so far.

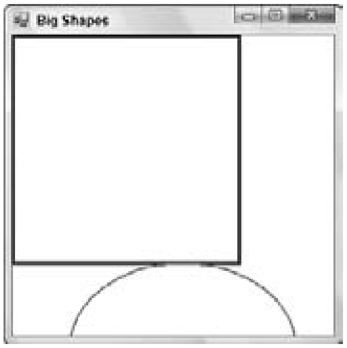

FIGURE 48-6

The result of running this example looks like Figure 48-6.

You can see a problem instantly. The shapes do not fit in your 300 × 300 pixel drawing area.

Normally, if a document is too large to display, an application will add scrollbars to let you scroll the window and look at a chosen part of it. This is another area in which if you were building Windows Forms using standard controls, you would simply allow the .NET runtime and the base classes to handle everything for you. If your form has various controls attached to it, then the Form instance will normally know where these controls are, and it will therefore know if its window becomes so small that scrollbars are necessary. The Form instance automatically adds the scrollbars for you. It is also able to draw correctly the portion of the screen you have scrolled to. In that case, there is nothing you need to do in your code. In this chapter, however, you are taking responsibility for drawing to the screen. Therefore, you need to help the Form instance out when it comes to scrolling.

Adding the scrollbars is actually very easy. The Form can still handle all that for you because the Form does not know how big an area you want to draw in. (The reason it did not do so in the earlier BigShapes example is that Windows does not know they are needed.) You need to determine whether the size of a rectangle that stretches from the top-left corner of the document (or equivalently, the top-left corner of the client area before you have done any scrolling) is big enough to contain the entire document. In this chapter, this area is called the *document area*. As shown in Figure 48-7, the document area for this example is (250 × 350) pixels.

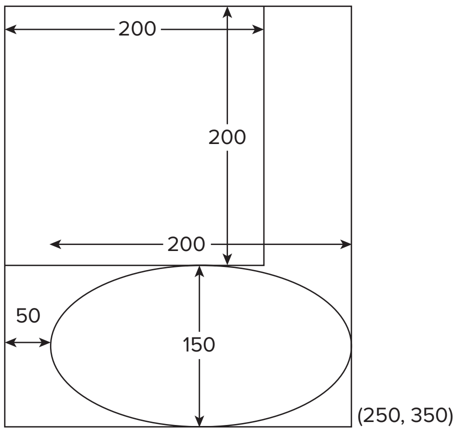

FIGURE 48-7

It is easy to tell the form how big the document is. You use the relevant property, `Form.AutoScrollMinSize`. Therefore, you can add this code to either the `InitializeComponent()` method or the `Form1` constructor:

```
private void InitializeComponent()
{
   this.components = new System.ComponentModel.Container();
   this.AutoScaleMode = System.Windows.Forms.AutoScaleMode.Font;
   this.Text = "Form1";
   this.BackColor = System.Drawing.Color.White;
   this.AutoScrollMinSize = new Size(250, 350);
}
```

Alternatively, the `AutoScrollMinSize` property can be set using the Visual Studio 2010 properties window. Note that to gain access to the `Size` class, you need to add the following `using` statement:

```
using System.Drawing;
```

Setting the minimum size at application startup and leaving it thereafter is fine in this particular example because you know that is how big the screen area will always be. Your document never changes size while this particular application is running. Keep in mind, however, that if your application does things like display contents of files or something else for which the area of the screen might change, you will need to set this property at other times (and in that case you will have to sort out the code manually — the Visual Studio 2010 properties window can help you only with the initial value that a property has when the form is constructed).

Setting `AutoScrollMinSize` is a start, but it is not yet quite enough. Figure 48-8 shows what the example application looks like now — initially you get the screen that correctly displays the shapes.

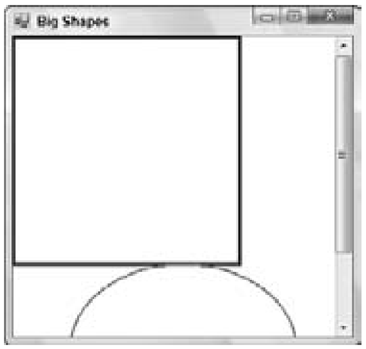

FIGURE 48-8

Notice that not only has the form correctly set the scrollbars, but also it has correctly sized them to indicate what proportion of the document is currently displayed. You can try resizing the window while the sample is running — you will find the scrollbars respond properly, and even disappear if you make the window big enough so that they are no longer needed.

However, look at what happens when you actually use one of the scrollbars to scroll down a bit (see Figure 48-9). Clearly, something has gone wrong!

What's wrong is that you haven't taken into account the position of the scrollbars in the code in your `OnPaint()` override. You can see this very clearly if you force the window to repaint itself completely by minimizing and restoring it (see Figure 48-10).

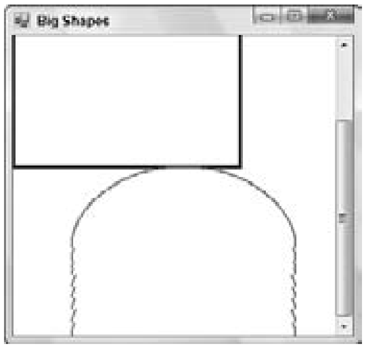

FIGURE 48-9

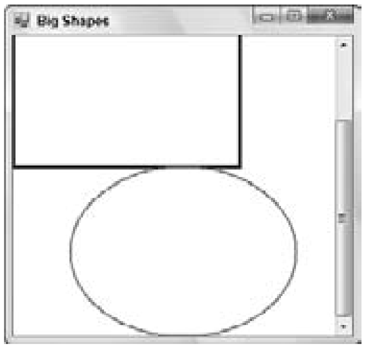

FIGURE 48-10

The shapes have been painted, just as before, with the top-left corner of the rectangle nestled into the top-left corner of the client area — as if you hadn't moved the scrollbars at all.

Before you see how to correct this problem, take a closer look at precisely what is happening in these screenshots.

Start with the `BigShapes` sample, shown in Figure 48-8. In this example, the entire window has just been repainted. Reviewing your code, you learn that it instructs the graphics instance to draw a rectangle with top-left coordinates (0,0) — relative to the top-left corner of the client area of the window — which is what has been drawn. The problem is that the graphics instance by default interprets coordinates as relative to the client window and is unaware of the scrollbars. Your code, as yet, does not attempt to adjust the coordinates for the scrollbar positions. The same goes for the ellipse.

Now, you can tackle the screenshot in Figure 48-9. After you scroll down, you notice that the top half of the window looks fine because it was drawn when the application first started up. When you scroll windows, Windows does not ask the application to redraw what was already on the screen. Windows is smart enough to determine which currently displayed bits can be smoothly moved around to match where the scrollbars are now located. This is a much more efficient process because it may be able to use some hardware acceleration to do that, too. The bit in this screenshot that is wrong is the bottom third of the window. This part of the window was not drawn when the application first appeared because before you started scrolling, it was outside the client area. This means that Windows asks your `BigShapes` application to draw this area. It will raise a `Paint` event passing in just this area as the clipping rectangle. And that is exactly what your `OnPaint()` override has done.

One way to look at the problem is that you are, at the moment, expressing your coordinates relative to the top-left corner of the start of the document — you need to convert them to express them relative to the top-left corner of the client area instead (see Figure 48-11).

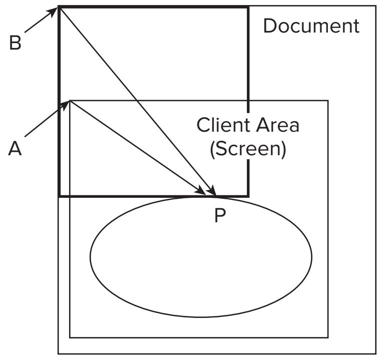

FIGURE 48-11

To make the diagram clearer, the document is actually extended further downward and to the right, beyond the boundaries of the screen, but this does not change our reasoning. It also assumes a small horizontal scroll as well as a vertical one.

In Figure 48-11, the thin rectangles mark the borders of the screen area and of the entire document. The thick lines mark the rectangle and ellipse that you are trying to draw. P marks some arbitrary point that you are drawing and that is being used as an example. When calling the drawing methods, the graphics instance was supplied with the vector from point B to (say) point P, expressed as a `Point` instance. You actually need to give it the vector from point A to point P.

The problem is that you do not know what the vector from A to P is. You know what B to P is; that is just the coordinates of P relative to the top-left corner of the document — the position where you want to draw point P in the document. You also know that the vector from B to A is just the amount you have scrolled by. This is stored in a property of the `Form` class called `AutoScrollPosition`. However, you do not know the vector from A to P.

To solve this problem, you subtract one vector from the other. Say, for example, to get from B to P you move 150 pixels across and 200 pixels down, whereas to get from B to A you move 10 pixels across and 57 pixels down. That means to get from A to P you have to move 140 (150 minus 10) pixels across and 143 (200 minus 57) pixels down. To make it even simpler, the `Graphics` class actually implements a method that will do these calculations for you. It is called `TranslateTransform()`. You pass it the horizontal and vertical coordinates that say where the top left of the client area is relative to the top-left corner of the document (your `AutoScrollPosition` property, that is, the vector from B to A in the diagram). The `Graphics` device will now work out all its coordinates, taking into account where the client area is relative to the document.

If we translate this long explanation into code, all you typically need to do is add the following line to your drawing code:

```
dc.TranslateTransform(this.AutoScrollPosition.X, this.AutoScrollPosition.Y);
```

However, in this example, it is a little more complicated because you are also separately testing whether you need to do any drawing by looking at the clipping region. You need to adjust this test to take the scroll position into account, too. When you have done that, the full drawing code for the sample looks like this:

```
protected override void OnPaint( PaintEventArgs e )
{
   base.OnPaint(e);
   Graphics dc = e.Graphics;
   Size scrollOffset = new Size(this.AutoScrollPosition);
   if (e.ClipRectangle.Top+scrollOffset.Width < 350 ||
      e.ClipRectangle.Left+scrollOffset.Height < 250)
   {
      Rectangle rectangleArea = new Rectangle
         (rectangleTopLeft+scrollOffset, rectangleSize);
      Rectangle ellipseArea = new Rectangle
         (ellipseTopLeft+scrollOffset, ellipseSize);
      dc.DrawRectangle(bluePen, rectangleArea);
      dc.DrawEllipse(redPen, ellipseArea);
   }
}
```

Now you have your scroll code working perfectly. You can at last obtain a correctly scrolled screenshot (see Figure 48-12).

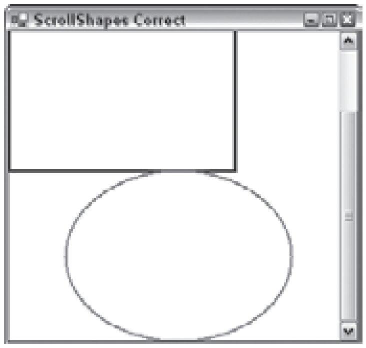

FIGURE 48-12

WORLD, PAGE, AND DEVICE COORDINATES

The distinction between measuring position relative to the top-left corner of the document and measuring it relative to the top-left corner of the screen (desktop) is so important that GDI+ has special names for these coordinate systems:

- **World coordinates** specify the position of a point measured in pixels from the top-left corner of the document.
- **Page coordinates** specify the position of a point measured in pixels from the top-left corner of the client area.

Developers familiar with GDI will note that world coordinates correspond to what in GDI were known as logical coordinates. Page coordinates correspond to what were known as device coordinates. As a developer familiar with GDI, you should also note that the way you code conversion between logical and device coordinates has changed in GDI+. In GDI, conversions took place via the device context, using the `LPtoDP()` *and* `DPtoLP()` *Windows API functions. In GDI+, it is the* `Control` *class, from which both* `Form` *and all the various Windows Forms controls derive, that maintains the information needed to carry out the conversion.*

GDI+ also distinguishes a third coordinate system, which is now known as *device coordinates*. Device coordinates are similar to page coordinates, except that you do not use pixels as the unit of measurement. Instead, you use some other unit that can be specified by the user by calling the `Graphics.PageUnit` property. Possible units, besides the default of pixels, include inches and millimeters. Although you will not use the `PageUnit` property in this chapter, you might find it useful as a way of getting around the different pixel densities of devices. For example, 100 pixels on most monitors will occupy approximately an inch. However, laser printers can have 1,200 or more dpi (dots per inch), which means that a shape specified as 100 pixels wide will look a lot smaller when printed. By setting the units to, say, inches and specifying that the shape should be 1 inch wide, you can ensure that the shape will look the same size on the different devices. This is illustrated in the following:

```
Graphics dc = this.CreateGraphics();
dc.PageUnit = GraphicsUnit.Inch;
```

Possible units available via the `GraphicsUnit` enumeration include the following:

- **Display** — Defines the display's unit measure.
- **Document** — Defines the document unit (1⁄300 inch) as the unit of measure.
- **Inch** — Defines the inch measurement as the unit of measure.
- **Millimeter** — Defines the millimeter measurement as the unit of measure.
- **Pixel** — Defines the pixel measurement as the unit of measure.
- **Point** — Defines the printer point (1⁄72 inch) as the unit of measure.
- **World** — Defines the world coordinate system as the unit of measure.

COLORS

This section discusses the ways that you can specify what color you want something to be drawn in.

Colors in GDI+ are represented by instances of the `System.Drawing.Color` struct. Generally, after you have instantiated this struct, you won't do much with the corresponding `Color` instance — you just pass it to whatever other method you are calling that requires a `Color`. You have encountered this struct before, when you set the background color of the client area of the window in each of the examples, as well as when you set the colors of the various shapes you were displaying. The `Form.BackColor` property actually returns a `Color` instance. This section looks at this struct in more detail. In particular, it examines several different ways that you can construct a `Color`.

Red-Green-Blue Values

The total number of colors that can be displayed by a monitor is huge — more than 16 million. To be exact, the number is 2 to the power of 24, which works out to 16,777,216. Obviously, you need some way of indexing those colors so that you can indicate which one is the color you want to display at any given pixel.

The most common way of indexing colors is by dividing them into the red, green, and blue components. This idea is based on the theory that any color that the human eye can distinguish can be constructed from a certain amount of red light, a certain amount of green light, and a certain amount of blue light. These colors are known as *components*. In practice, dividing the amount of each component light into 256 possible intensities yields a sufficiently fine gradation to be able to display images that are perceived by the human eye to be of photographic quality. You, therefore, specify colors by giving the amounts of these components on a scale of 0 to 255 where 0 means that the component is not present and 255 means that it is at its maximum intensity.

This gives you your first way of telling GDI+ about a color. You can indicate a color's red, green, and blue values by calling the static function `Color.FromArgb()`. Microsoft has chosen not to supply a constructor to do this task. The reason is that there are other ways, besides the usual RGB components, to indicate a color. Because of this, Microsoft felt that the meaning of parameters passed to any constructor they defined would be open to misinterpretation:

```
Color redColor = Color.FromArgb(255,0,0);
Color funnyOrangyBrownColor = Color.FromArgb(255,155,100);
Color blackColor = Color.FromArgb(0,0,0);
Color whiteColor = Color.FromArgb(255,255,255);
```

The three parameters are, respectively, the quantities of red, green, and blue. This function has a number of other overloads, some of which also allow you to specify something called an alpha-blend (that is the `A` in the name of the method, `FromArgb()`). Alpha blending is beyond the scope of this chapter, but it allows you to paint a color semi-transparently by combining it with whatever color was already on the screen. This can give some beautiful effects and is often used in games.

The Named Colors

Constructing a `Color` using `FromArgb()` is the most flexible technique because it literally means you can specify any color that the human eye can see. However, if you want a simple, standard, well-known color such as red or blue, it is a lot easier to name the color you want. Hence, Microsoft has also provided a large number of static properties in `Color`, each of which returns a named color. It was one of these properties that you used when you set the background color of your windows to white in the examples:

```
this.BackColor = Color.White;
// has the same effect as:
// this.BackColor = Color.FromArgb(255, 255, 255);
```

Several hundred such colors exist. The full list is given in the SDK documentation. They include all the simple colors: `Red`, `White`, `Blue`, `Green`, `Black`, and so on, as well as such delights as `MediumAquamarine`, `LightCoral`, and `DarkOrchid`. There is also a `KnownColor` enumeration, which lists the named colors.

Graphics Display Modes and the Safety Palette

Although in principle monitors can display any of the more than 16 million RGB colors, in practice this depends on how you have set the display properties on your computer. In Windows, there are traditionally three main color options (although some machines might provide other options depending on the hardware): true color (24 bit), high color (16 bit), and 256 colors. (On some graphics cards these days, true color is actually marked as 32 bit. This has to do with optimizing the hardware, though in that case only 24 bits of the 32 bits are used for the color itself.)

Only true color mode allows you to display all the RGB colors simultaneously. This sounds like the best option, but it comes at a cost: 3 bytes are needed to hold a full RGB value, which means that 3 bytes of graphics card memory are needed to hold each pixel that is displayed. If graphics card memory is at a premium (a restriction that is less common now than it used to be), then you might want to choose one of the other modes. High color mode gives you 2 bytes per pixel, which is enough to give 5 bits for each RGB component. Therefore, instead of 256 gradations of red intensity, you get just 32 gradations. The same applies to blue and green, which produce a total of 65,536 colors. That is just about enough to give apparent photographic quality on a casual inspection, although areas of subtle shading tend to be broken up a bit.

The 256-color mode gives you even fewer colors. However, in this mode, you get to choose the colors. The system sets up something known as a *palette*. This is a list of 256 colors chosen from the 16 million RGB colors. After you have specified the colors in the palette, the graphics device will be able to display just those colors. The palette can be changed at any time, but the graphics device can only display 256 different colors on the screen at any one time. The 256-color mode is used only when high performance is necessary and video memory is at a premium. Most computer games use this mode. They can still achieve decent-looking graphics because of a very careful choice of palette.

In general, if a display device is in high-color or 256-color mode and a particular RGB color is requested, then it will pick the nearest mathematical match from the pool of colors that it is able to display. It is for this reason that it is important to be aware of the color modes. If you are drawing something that involves subtle shading or photographic-quality images, and the user does not have 24-bit color mode selected, she might not see the image the same way you intended it. Therefore, if you are doing that kind of work with GDI+, then you should test your application in different color modes. (It is also possible for your application to programmatically set a given color mode, although that is not discussed in this chapter for lack of space.)

The Safety Palette

For reference, this section quickly mentions the safety palette, which is a commonly used default palette. To use the safety palette, you set six equally spaced possible values for each color component: 0, 51, 102, 153, 204, and 255. In other words, the red component can have any of these values. The green component can have any of these values and so can the blue component. Possible colors from the safety palette include (0, 0, 0), black; (153, 0, 0), a fairly dark shade of red; (0, 255, 102), green with a smattering of blue added; and so on. This gives you a total of 6 cubed = 216 colors. The idea is that this provides an easy way of creating a palette that contains colors from right across the spectrum and of all degrees of brightness. In practice, however, this does not actually work that well because equal mathematical spacing of color components does not mean equal perception of color differences by the human eye.

If you set Windows to 256-color mode, you will find that the default palette is the safety palette, with 20 Windows-standard colors added to it, and 20 spare colors.

PENS AND BRUSHES

This section reviews two helper classes that are needed to draw shapes. You have already encountered the `Pen` class, which you used to instruct the graphics instance how to draw lines. A related class is `System.Drawing.Brush`, which instructs the graphics instance how to fill regions. For example, the `Pen` is needed to draw the outlines of the rectangle and ellipse in the previous examples. If you had needed to draw these shapes as solid, you would have used a brush to specify how to fill them. One aspect of both of these classes is that you will hardly ever call any methods on them. You simply construct a `Pen` or `Brush` instance with the required color and other properties, and then pass it to drawing methods that require a `Pen` or `Brush`.

Brushes

GDI+ has several different kinds of brushes — more than there is space to go into in this chapter, so this section just explains the simpler ones to give you an idea of the principles. Each type of brush is represented by an instance of a class derived from the abstract class `System.Drawing.Brush`. The simplest brush, `System.Drawing.SolidBrush`, indicates that a region is to be filled with a solid color:

```
Brush solidBeigeBrush = new SolidBrush(Color.Beige);
Brush solidFunnyOrangyBrownBrush = new SolidBrush(Color.FromArgb(255,155,100));
```

Alternatively, if the brush is one of the web-safe colors, then you can construct the brush using another class, `System.Drawing.Brushes`. `Brushes` is one of those classes that you never actually instantiate (it has a private constructor to stop you from doing that). It simply has a large number of static properties, each of which returns a brush of a specified color. You can use `Brushes` like this:

```
Brush solidAzureBrush = Brushes.Azure;
Brush solidChocolateBrush = Brushes.Chocolate;
```

The next level of complexity is a hatch brush, which fills a region by drawing a pattern. This type of brush is considered more advanced, so it is in the `Drawing2D` namespace, represented by the class `System.Drawing.Drawing2D.HatchBrush`. The `Brushes` class cannot help you with hatch brushes; you will need to construct one explicitly by supplying the hatch style and two colors — the foreground color followed by the background color. (Note, you can omit the background color, in which case it defaults to black). The hatch style comes from an enumeration, `System.Drawing.Drawing2D.HatchStyle`. You can choose from a large number of `HatchStyle` values (see the SDK documentation for the full list). To give you an idea, typical styles include `ForwardDiagonal`, `Cross`, `DiagonalCross`, `SmallConfetti`, and `ZigZag`. Examples of constructing a hatch brush include these:

```
Brush crossBrush = new HatchBrush(HatchStyle.Cross, Color.Azure);
// background color of CrossBrush is black
Brush brickBrush = new HatchBrush(HatchStyle.DiagonalBrick,
                                  Color.DarkGoldenrod, Color.Cyan);
```

Solid and hatch brushes are the only brushes available with GDI. GDI+ has added a couple of new styles of brushes:

- `System.Drawing.Drawing2D.LinearGradientBrush` fills in an area with a color that varies across the screen.
- `System.Drawing.Drawing2D.PathGradientBrush` is similar, but in this case, the color varies along a path around the region to be filled.

Note that both brushes can render some spectacular effects if used carefully.

Pens

Unlike brushes, pens are represented by just one class: `System.Drawing.Pen`. However, the pen is slightly more complex than the brush because it needs to indicate how thick lines should be (how many pixels wide) and, for a wide line, how to fill the area inside the line. Pens can also specify a number of other properties, which are beyond the scope of this chapter, but which include the `Alignment` property mentioned earlier. This property indicates where in relation to the border of a shape a line should be drawn, as well as what shape to draw at the end of a line (whether to round off the shape).

The area inside a thick line can be filled with a solid color or by using a brush. Hence, a `Pen` instance might contain a reference to a `Brush` instance. This is quite powerful because it means that you can draw lines that are colored in by using, say, hatching or linear shading. There are four different ways to construct a `Pen` instance that you have designed yourself. One is by passing a color; a second is by passing in a brush. Both of these constructors will produce a pen with a width of one pixel. Alternatively, a third way is to pass in a color or a brush, and additionally a `float`, which represents the width of the pen. (It needs to be a `float` in case you are using non-default units such as millimeters or inches for the `Graphics` object that will do the drawing, so you can, for example, specify fractions of an inch.) For example, you can construct pens similar to this:

```
Brush brickBrush = new HatchBrush(HatchStyle.DiagonalBrick,
                                   Color.DarkGoldenrod, Color.Cyan);
Pen solidBluePen = new Pen(Color.FromArgb(0,0,255));
Pen solidWideBluePen = new Pen(Color.Blue, 4);
Pen brickPen = new Pen(brickBrush);
Pen brickWidePen = new Pen(brickBrush, 10);
```

Additionally, a fourth way offers the quick construction of pens by using the class `System.Drawing.Pens`, which, like the `Brushes` class, contains a number of stock pens. These pens all have a 1-pixel width and come in the usual sets of web-safe colors. This allows you to construct pens in this way:

```
Pen solidYellowPen = Pens.Yellow;
```

DRAWING SHAPES AND LINES

You have almost finished the first part of the chapter, and you have seen all the basic classes and objects required to draw specified shapes and so on to the screen. This section starts by reviewing some of the drawing methods the `Graphics` class makes available and presents a short example that illustrates the use of several brushes and pens.

`System.Drawing.Graphics` has a large number of methods that allow you to draw various lines, outline shapes, and solid shapes. Again, there are too many to provide a comprehensive list here, but the following table lists the main ones and should give you some idea of the variety of shapes you can draw.

METHOD	TYPICAL PARAMETERS	WHAT IT DRAWS
`DrawLine`	Pen, start and end points	A single straight line.
`DrawRectangle`	Pen, position, and size	Outline of a rectangle.
`DrawEllipse`	Pen, position, and size	Outline of an ellipse.
`FillRectangle`	Brush, position, and size	Solid rectangle.
`FillEllipse`	Brush, position, and size	Solid ellipse.
`DrawLines`	Pen, array of points	Series of lines, connecting each point to the next one in the array.
`DrawBezier`	Pen, four points	A smooth curve through the two endpoints, with the remaining two points used to control the shape of the curve.
`DrawCurve`	Pen, array of points	A smooth curve through the points.
`DrawArc`	Pen, rectangle, two angles	Portion of circle within the rectangle defined by the angles.
`DrawClosedCurve`	Pen, array of points	Like `DrawCurve` but also draws a straight line to close the curve.
`DrawPie`	Pen, rectangle, two angles	Wedge-shaped outline within the rectangle.
`FillPie`	Brush, rectangle, two angles	Solid wedge-shaped area within the rectangle.
`DrawPolygon`	Pen, array of points	Like `DrawLines` but also connects first and last points to close the figure drawn.

Before we leave the subject of drawing simple objects, this section rounds off with a simple example that demonstrates the kinds of visual effects you can achieve using brushes. The example is called `ScrollMoreShapes`, and it is essentially a revision of `ScrollShapes`. Besides the rectangle and ellipse, you will add a thick line and fill in the shapes with various custom brushes. You have already learned the principles of drawing, so the code speaks for itself. First, because of your new brushes, you need to indicate that you are using the `System.Drawing.Drawing2D` namespace:

```
using System;
using System.Collections.Generic;
using System.ComponentModel;
using System.Data;
using System.Drawing;
using System.Drawing.Drawing2D;
using System.Text;
using System.Windows.Forms;
```

Next are some extra fields in your `Form1` class, which contain details of the locations where the shapes are to be drawn, as well as various pens and brushes you will use:

```
private Rectangle rectangleBounds = new Rectangle(new Point(0,0),
                                                  new Size(200,200));
private Rectangle ellipseBounds = new Rectangle(new Point(50,200),
                                                new Size(200,150));
private readonly Pen bluePen = new Pen(Color.Blue, 3);
private readonly Pen redPen = new Pen(Color.Red, 2);
private readonly Brush solidAzureBrush = Brushes.Azure;
private readonly Brush solidYellowBrush = new SolidBrush(Color.Yellow);
private static readonly Brush brickBrush = new
   HatchBrush(HatchStyle.DiagonalBrick, Color.DarkGoldenrod, Color.Cyan);
private readonly Pen brickWidePen = new Pen(brickBrush, 10);
```

code download ScrollMoreShapes.sln

The `brickBrush` field has been declared as static so that you can use its value to initialize the `brickWidePen` field. C# will not let you use one instance field to initialize another instance field because it has not defined which one will be initialized first. However, declaring the field as static solves the problem. Because only one instance of the `Form1` class will be instantiated, it is immaterial whether the fields are static or instance fields.

The following is the `OnPaint()` override:

```
protected override void OnPaint( PaintEventArgs e )
{
   base.OnPaint(e);
   Graphics dc = e.Graphics;
   Point scrollOffset = AutoScrollPosition;
   dc.TranslateTransform(scrollOffset.X, scrollOffset.Y);
   if (e.ClipRectangle.Top+scrollOffset.X < 350 ||
       e.ClipRectangle.Left+scrollOffset.Y < 250)
   {
      dc.DrawRectangle(bluePen, rectangleBounds);
      dc.FillRectangle(solidYellowBrush, rectangleBounds);
      dc.DrawEllipse(redPen, ellipseBounds);
      dc.FillEllipse(solidAzureBrush, ellipseBounds);
      dc.DrawLine(brickWidePen, rectangleBounds.Location,
                               ellipseBounds.Location+ellipseBounds.Size);
   }
}
```

code download ScrollMoreShapes.sln

As before, you also set the `AutoScrollMinSize` to (250,350). Figure 48-13 shows the new results.

Notice that the thick diagonal line has been drawn on top of the rectangle and ellipse because it was the last item to be painted.

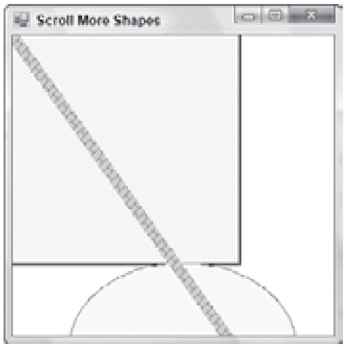

FIGURE 48-13

DISPLAYING IMAGES

One of the most common things you might want to do with GDI+ is display an image that already exists in a file. This is actually a lot simpler than drawing your own user interface because the image is already pre-drawn. Effectively, all you have to do is load the file and instruct GDI+ to display it. The image can be a simple line drawing, an icon, or a complex image such as a photograph. You can also manipulate the image by stretching or rotating it, or simply displaying only a portion of it.

This section, just for a change, presents the sample first. Then it discusses some of the issues you need to be aware of when displaying images. Presenting it this way is possible because the code needed to display an image is so simple.

The class you need is the .NET base class, `System.Drawing.Image`. An instance of `Image` represents one image. Reading in an image simply takes one line of code:

```
Image myImage = Image.FromFile("FileName");
```

`FromFile()` is a static member of `Image` and is the usual way of instantiating an image. The file can be any of the commonly supported graphics file formats, including `.bmp`, `.jpg`, `.gif`, and `.png`.

Displaying an image is also very simple, assuming that you have a suitable `Graphics` instance at hand — a call to either `Graphics.DrawImageUnscaled()` or `Graphics.DrawImage()` suffices. There are quite a few overloads of these methods, allowing you a lot of flexibility in the information you supply in terms of where the image is located and how big it is to be drawn. However, this example uses `DrawImage()`, like this:

```
dc.DrawImage(myImage, points);
```

In this line of code, `dc` is assumed to be a `Graphics` instance, and `myImage` is the `Image` to be displayed. `points` is an array of `Point` structs, where `points[0]`, `points[1]`, and `points[2]` are the coordinates of the top-left, top-right, and bottom-left corner of the image.

The process of displaying an image is illustrated with an example called `DisplayImage`. The example simply displays a `.jpg` file in the application's main window. To keep things simple, the path of the `.jpg` file is hard-coded into the application (so if you run the example, then you need to change it to reflect the location of the file in your system). The `.jpg` file you will display is a sunset picture in St. Petersburg.

As with the other examples, the `DisplayImage` project is a standard C# Visual Studio 2010-generated Windows application. You add the following fields to your `Form1` class:

```
readonly Image piccy;
private readonly Point [] piccyBounds;
```

You then load the file in the `Form1()` constructor:

```
public Form1()
{
   InitializeComponent();
   piccy =
      Image.FromFile(@"C:\ProCSharp\GdiPlus\Images\London.jpg");
   AutoScrollMinSize = piccy.Size;
   piccyBounds = new Point[3];
   piccyBounds[0] = new Point(0,0);      // top left
   piccyBounds[1] = new Point(piccy.Width,0);   // top right
   piccyBounds[2] = new Point(0,piccy.Height);   // bottom left
}
```

code download DisplayPicture.sln

Note that the size in pixels of the image is obtained as its `Size` property, which you use to set the document area. You also set up the `piccyBounds` array, which is used to identify the position of the image on the screen. You have chosen the coordinates of the three corners to draw the image in its actual size and shape here, but if you had wanted the image to be resized, stretched, or even sheared into a nonrectangular parallelogram, then you could do so simply by changing the values of the `Points` in the `piccyBounds` array.

The image is displayed in the `OnPaint()` override:

```
protected override void OnPaint(PaintEventArgs e)
{
   base.OnPaint(e);
   Graphics dc = e.Graphics;
   dc.ScaleTransform(1.0f, 1.0f);
   dc.TranslateTransform(AutoScrollPosition.X, AutoScrollPosition.Y);
   dc.DrawImage(piccy, piccyBounds);
}
```

code download DisplayPicture.sln

Finally, note the modification made to the IDE-generated `Form1.Dispose()` method:

```
protected override void Dispose(bool disposing)
{
   piccy.Dispose();
   if (disposing && (components != null))
   {
      components.Dispose();
   }
   base.Dispose(disposing);
}
```

code download DisplayPicture.sln

Disposing of the image as soon as possible when it is no longer needed is important because images generally take up a lot of memory while in use. After `Image.Dispose()` has been called, the `Image` instance no longer refers to any actual image, and so it can no longer be displayed (unless you load a new image).

Figure 48-14 shows the result of running this code.

FIGURE 48-14

ISSUES WHEN MANIPULATING IMAGES

Although displaying images is very simple, it still pays to have some understanding of what is going on behind the scenes.

The most important point to understand about images is that they are always rectangular. That is not just a convenience; it is because of the underlying technology. All modern graphics cards have hardware built in that can efficiently copy blocks of pixels from one area of memory to another area of memory, provided that the block of pixels represents a rectangular region. This hardware-accelerated operation can occur virtually as one single operation, and as such, is extremely fast. Indeed, it is the key to modern high-performance graphics. This operation is known as a *bitmap block transfer* (or *BitBlt*). `Graphics.DrawImageUnscaled()` internally uses a `BitBlt`, which is why you can see a huge image, perhaps containing as many as a million pixels, appearing almost instantly. If the computer had to copy the image to the screen pixel by pixel, you would see the image gradually being drawn over a period of up to several seconds.

`BitBlt`s are very efficient; therefore, almost all drawing and manipulation of images is carried out using them. Even some editing of images will be done by manipulating portions of images with `BitBlts` between DCs that represent areas of memory. In the days of GDI, the Windows 32 API function `BitBlt()` was arguably the most important and widely used function for image manipulation, although with GDI+, the `BitBlt` operations are largely hidden by the GDI+ object model.

It's not possible to `BitBlt` areas of images that are not rectangular, although similar effects can be easily simulated. One way is to mark a certain color as transparent for the purposes of a `BitBlt`, so that areas of that color in the source image will not overwrite the existing color of the corresponding pixel in the destination device. It is also possible to specify that in the process of a `BitBlt`, each pixel of the resultant image will be formed by some logical operation (such as a bitwise `AND`) on the colors of that pixel in the source image and in the destination device before the `BitBlt`. Such operations are supported by hardware acceleration and can be used to give a variety of subtle effects. Note that the `Graphics` object implements another method, `DrawImage()`. This is similar to `DrawImageUnscaled()` but comes in a large number of overloads that allow you to specify more complex forms of `BitBlt` be used in the drawing process. `DrawImage()` also allows you to draw (using `BitBlt`) only a specified part of the image, or to perform certain other operations on it such as scaling it (expanding or reducing it in size) as it is drawn.

DRAWING TEXT

We have chosen to cover the very important topic of displaying text late in this chapter because drawing text to the screen is (in general) more complex than drawing simple graphics. Although displaying a line or two of text when you don't care about the appearance is extremely easy (it takes one single call to the `Graphics.DrawString()` method), if you are trying to display a document that has a fair amount of text in it, then you will rapidly find that things become a lot more complex. This is for two reasons:

- If you are concerned about getting the appearance just right, then you must understand fonts. Whereas shape drawing requires brushes and pens as helper objects, the process of drawing text requires fonts as helper objects. Moreover, understanding fonts is not a trivial undertaking.
- Text needs to be very carefully laid out in the window. Users generally expect words to follow naturally from one word to another and to be lined up with clear spaces in between. Doing that is harder than you might think. For starters, you do not usually know in advance how much space on the screen a word is going to take up. That has to be calculated (using the `Graphics.MeasureString()` method). In addition, the space a word occupies on the screen affects where in the document every subsequent word is placed. If your application does any line wrapping, then it will need to assess word sizes carefully before deciding where to place the line break. The next time you run Microsoft Word, look carefully at the way Word is continually repositioning text as you do your work; there is a lot of complex processing going on there. Chances are that any GDI+ application you work on will not be nearly as complex as Word. However, if you need to display any text, many of the same considerations apply.

In short, high-quality text processing is tricky to get right. However, putting a line of text on the screen, assuming that you know the font and where you want it to go, is actually very simple. Therefore, the next section presents a quick example that shows you how to display some text, followed by a short review of the principles of fonts and font families and a more realistic (and involved) text-processing example, `CapsEditor`.

SIMPLE TEXT EXAMPLE

This example, `DisplayText`, is your usual Windows Forms effort. This time you override `OnPaint()` and add member fields as follows:

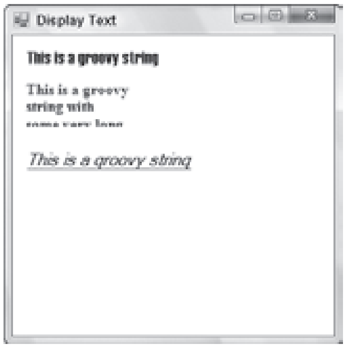
```
private readonly Brush blackBrush = Brushes.Black;
private readonly Brush blueBrush = Brushes.Blue;
private readonly Font haettenschweilerFont = new Font("Haettenschweiler", 12);
private readonly Font boldTimesFont = new Font("Times New Roman", 10,
   FontStyle.Bold);
private readonly Font italicCourierFont = new Font("Courier", 11,
   FontStyle.Italic | FontStyle.Underline);

protected override void OnPaint(PaintEventArgs e)
{
   base.OnPaint(e);
   Graphics dc = e.Graphics;
   dc.DrawString("This is a groovy string", haettenschweilerFont, blackBrush,
                 10, 10);
   dc.DrawString("This is a groovy string " +
                 "with some very long text that will never fit in the box",
                 boldTimesFont, blueBrush,
                 new Rectangle(new Point(10, 40), new Size(100, 40)));
   dc.DrawString("This is a groovy string", italicCourierFont, blackBrush,
                 new Point(10, 100));
}
```

code download DisplayText.sln

Figure 48-15 shows the result of running this example.

The example demonstrates the use of the `Graphics.DrawString()` method to draw items of text. The method `DrawString()` comes in a number of overloads, three of which are demonstrated here. The different overloads require parameters that indicate the text to be displayed, the font that the string should be drawn in, and the brush that should be used to construct the various lines and curves that make up each character of text. A few alternatives exist for the remaining parameters. In general, however, it is possible to specify either a `Point` (or equivalently, two numbers) or a `Rectangle`.



This is a groovy string

This is a groovy
string with
some very long

This is a groovy string

FIGURE 48-15

If you specify a `Point`, then the text will start with its top-left corner at that `Point` and simply stretch out to the right. If you specify a `Rectangle`, then the `Graphics` instance will lay out the string inside that rectangle. If the text does not fit within the boundaries of the rectangle, it will be cut off (see the fourth line of text in Figure 48-15). Passing a rectangle to `DrawString()` means that the drawing process will take longer because `DrawString()` will need to figure out where to put line breaks, but the result may look nicer — provided the string fits in the rectangle!

This example also shows a few ways to construct fonts. You always need to include the name of the font and its size (height). You can also optionally pass in various styles that modify how the text is to be drawn (bold, underline, and so on).

FONTS AND FONT FAMILIES

A font describes exactly how each letter should be displayed. Selection of the appropriate font and providing a reasonable variety of fonts within a document are important factors in improving readability.

Most people, if asked to name a font, might mention Arial or Times New Roman (if they are Windows users) or Times or Helvetica (if they are Mac OS users). In fact, these are not fonts at all — they are *font families*. The font family tells you, in generic terms, the visual style of the text and is a key factor in the overall appearance of your application. Most of us recognize the styles of the most common font families, even if we are not consciously aware of it.

An actual *font* would be something like Arial 9-point italic. In other words, the size and other modifications to the text are specified as well as the font family. These modifications might include whether text is **bold**, *italic*, underlined, or displayed in SMALL CAPS or as $_{\text{subscript}}$; this is technically referred to as the *style*, although in some ways, the term is misleading because the visual appearance is determined as much by the font family.

The size of the text is measured by specifying its height. The height is measured in *points* — a traditional unit that represents $\frac{1}{72}$ of an inch (0.351 mm). So letters in a 10-point font are roughly $\frac{1}{7}$ of an inch, or 3.5 mm high. However, you will not get seven lines of 10-point text into one inch of vertical screen or paper space, as you need to allow for the spacing between the lines as well.

When you are dealing with fonts, you might also encounter some other terms commonly used to describe certain font families:

- **Serif** font families have feet at the ends of many of the lines that make up the characters (these ticks are known as serifs). Times New Roman is a classic example of this.
- **Sans serif** font families, by contrast, do not have these feet. Good examples of sans serif fonts are Arial and Verdana. The lack of feet often gives text a blunt, in-your-face appearance, so sans serif fonts are often used for important text.
- A **TrueType** font family is one that is defined by expressing the shapes of the curves that make up the characters in a precise mathematical manner. This means that the same definition can be used to calculate how to draw fonts of any size within the family. These days, virtually all the fonts you might use are TrueType fonts. Some older font families from the days of Windows 3.1 were defined by individually specifying the bitmap for each character separately for each font size, but the use of these fonts is now discouraged.

Microsoft has provided two main classes that you need to deal with when selecting or manipulating fonts:

- `System.Drawing.Font`
- `System.Drawing.FontFamily`

You have already seen the main use of the `Font` class. When you want to draw text, you instantiate an instance of `Font` and pass it to the `DrawString()` method to indicate how the text should be drawn. A `FontFamily` instance is used to represent a family of fonts.

You can use the `FontFamily` class, for example, if you know you want a font of a particular type (serif, sans serif, or TrueType), but do not have a preference for which font. The static properties `GenericSerif`, `GenericSansSerif`, and `GenericMonospace` return default fonts that satisfy these criteria:

```
FontFamily sansSerifFont = FontFamily.GenericSansSerif;
```

However, if you are writing a professional application, then you need to choose your font in a more sophisticated way. Most likely, you will implement your drawing code so that it checks the font families available and selects the appropriate one, perhaps by taking the first available one on a list of preferred fonts. Moreover, if you want your application to be very user-friendly, then the first choice on the list will probably be the one that users selected the last time they ran your software. Usually, if you are dealing with the most popular font families, such as Arial and Times New Roman, you are safe. However, if you try to display text using a font that does not exist, the results are not always predictable. You are quite likely to find that Windows just substitutes the standard system font, which is very easy for the system to draw, but that it does not look very pleasant — and if it does appear in your document, then it is likely to give the impression of software that is of poor quality.

You can find out what fonts are available on your system using a class called `InstalledFontCollection`, which is in the `System.Drawing.Text` namespace. This class implements a property, `Families`, which is an array of all the fonts that are available to use on your system:

```
InstalledFontCollection insFont = new InstalledFontCollection();
FontFamily [] families = insFont.Families;

foreach (FontFamily family in families)
{
   // do processing with this font family
}
```

ENUMERATING FONT FAMILIES EXAMPLE

In this section, you work through a quick example, `EnumFontFamilies`, which lists all the font families available on the system and illustrates them by displaying the name of each family using an appropriate font (the 12-point regular version of that font family). Figure 48-16 shows the result of running `EnumFontFamilies`.

Of course, the results that you get will depend on the fonts you have installed on your computer.

FIGURE 48-16

For this example, you create a standard C# Windows application, `ListFonts`. You start by adding an extra namespace to be searched. You will be using the `InstalledFontCollection` class, which is defined in `System.Drawing.Text`.

```
using System.Drawing;
using System.Drawing.Text;
using System.Windows.Forms;
```

You then add the following constant to the `Form1` class:

```
private const int margin = 10;
```

`margin` is the size of the left and top margin between the text and the edge of the document — it stops the text from appearing right at the edge of the client area.

This is designed as a quick-and-easy way of showing off font families; therefore, the code is crude and in many instances does not do things the way you ought to in a real application. For example, here you hard-code an estimated value for the document size of (200, 1500) and set the `AutoScrollMinSize` property to this value using the Visual Studio 2010 properties window. Typically, you would have to examine the text to be displayed to work out the document size. You do that in the next section.

Here is the `OnPaint()` method:

```
protected override void OnPaint(PaintEventArgs e)
{
   base.OnPaint(e);
   int verticalCoordinate = margin;
   InstalledFontCollection insFont = new InstalledFontCollection();
   FontFamily [] families = insFont.Families;
   e.Graphics.TranslateTransform(AutoScrollPosition.X,
                                 AutoScrollPosition.Y);
   foreach (FontFamily family in families)
   {
      if (family.IsStyleAvailable(FontStyle.Regular))
      {
         Font f = new Font(family.Name, 10);
         Point topLeftCorner = new Point(margin, verticalCoordinate);
         verticalCoordinate += f.Height;
         e.Graphics.DrawString (family.Name, f,
                                Brushes.Black,topLeftCorner);
         f.Dispose();
      }
   }
}
```

code download ListFonts.sln

In this code, you start by using an `InstalledFontCollection` object to obtain an array that contains details of all the available font families. For each family, you instantiate a 10-point `Font`. You use a simple constructor for Font — there are many more that allow additional options to be specified. The constructor takes two parameters, the name of the family and the size of the font:

```
Font f = new Font(family.Name, 10);
```

This constructor builds a font that has the regular style. To be on the safe side, however, you first check that this style is available for each font family before attempting to display anything using that font. This is done using the `FontFamily.IsStyleAvailable()` method. This check is important because not all fonts are available in all styles:

```
if (family.IsStyleAvailable(FontStyle.Regular))
```

`FontFamily.IsStyleAvailable()` takes one parameter, a `FontStyle` enumeration. This enumeration contains a number of flags that might be combined with the bitwise `OR` operator. The possible flags are `Bold`, `Italic`, `Regular`, `Strikeout`, and `Underline`.

Finally, note that you use a property of the `Font` class, `Height`, which returns the height needed to display text of that font, to work out the line spacing:

```
Font f =  new Font(family.Name, 10);
Point topLeftCorner = new Point(margin, verticalCoordinate);
verticalCoordinate += f.Height;
```

Again, to keep things simple, this version of `OnPaint()` reveals some bad programming practices. For example, you have not bothered to check what area of the document actually needs drawing — you just tried to display everything. Also, instantiating a `Font` is, as remarked earlier, a computationally intensive process, so you really ought to save the fonts rather than instantiating new copies every time `OnPaint()` is called. Because of the way the code has been designed, you might note that this example actually takes a noticeable amount of time to paint itself. To try to conserve memory and help the garbage collector, you do, however, call `Dispose()` on each font instance after you have finished with it. If you did not, after 10 or 20 paint operations, there would be a lot of wasted memory storing fonts that are no longer needed.

EDITING A TEXT DOCUMENT: THE CAPSEDITOR EXAMPLE

You now come to the extended example in this chapter. The `CapsEditor` example is designed to demonstrate how the principles of drawing that you have learned so far have to be applied in a more realistic context. The `CapsEditor` example does not require any new material, apart from responding to user input via the mouse, but it shows how to manage the drawing of text so that the application maintains performance while ensuring that the contents of the client area of the main window are always kept up-to-date.

The `CapsEditor` program allows the user to read in a text file, which is then displayed line by line in the client area. If the user double-clicks any line, then that line will be changed to all uppercase. That is literally all the example does. Even with this limited set of features, you will find that the work involved in making sure everything is displayed in the right place while considering performance issues is quite complex. In particular, you have a new element here: the contents of the document can change — either when the user selects the menu option to read a new file, or when she double-clicks to capitalize a line. In the first case, you need to update the document size so the scrollbars still work correctly, and you have to redisplay everything. In the second case, you need to check carefully whether the document size has changed, and what text needs to be redisplayed.

This section starts by reviewing the appearance of `CapsEditor`. When the application is first run, it has no document loaded and resembles Figure 48-17.

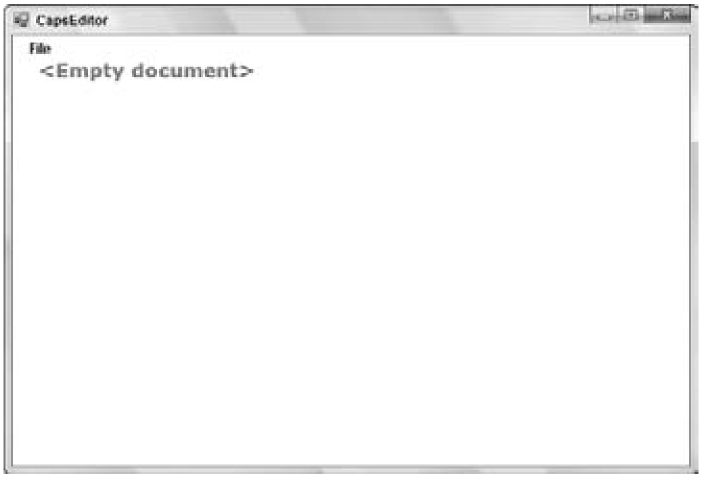

FIGURE 48-17

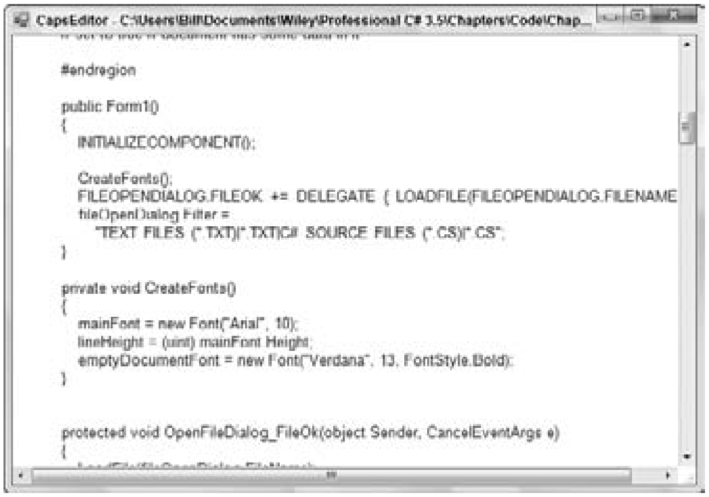
The File menu has two options: Open, which evokes `OpenFileDialog` when selected and reads in whatever file the user clicks, and Exit, which closes the application when clicked. Figure 48-18 shows `CapsEditor` displaying its own source file, `Form1.cs`. (A few lines have been double-clicked in this image to convert them to uppercase.)



CapsEditor - C:\Users\Bill\Documents\Wiley\Professional C# 3.5\Chapters\Code\Chap...

```
#endregion

public Form1()
{
   INITIALIZECOMPONENT();

   CreateFonts();
   FILEOPENDIALOG.FILEOK += DELEGATE { LOADFILE(FILEOPENDIALOG.FILENAME
   fileOpenDialog.Filter =
      "TEXT FILES (*.TXT)|*.TXT|C# SOURCE FILES (*.CS)|*.CS";
}

private void CreateFonts()
{
   mainFont = new Font("Arial", 10);
   lineHeight = (uint) mainFont.Height;
   emptyDocumentFont = new Font("Verdana", 13, FontStyle.Bold);
}

protected void OpenFileDialog_FileOk(object Sender, CancelEventArgs e)
{
```

FIGURE 48-18

The sizes of the horizontal and vertical scrollbars are correct. The client area will scroll just enough to view the entire document. `CapsEditor` does not try to wrap lines of text — the example is already complicated enough as is. It just displays each line of the file exactly as it is read in. There are no limits to the size of the file, but you are assuming that it is a text file and does not contain any nonprintable characters.

Begin by adding a `using` command:

```
using System;
using System.Collections;
using System.ComponentModel;
using System.Drawing;
using System.IO;
using System.Windows.Forms;
```

You will be using the `StreamReader` class, which is in the `System.IO` namespace. Next, you add some fields to the `Form1` class:

```
#region Constant fields
private const string standardTitle = "CapsEditor";
                                              // default text in titlebar
private const uint margin = 10;
                        // horizontal and vertical margin in client area
#endregion
#region Member fields
// The 'document'
private readonly List<TextLineInformation> documentLines =
   new List<TextLineInformation>();
private uint lineHeight;        // height in pixels of one line
private Size documentSize;      // how big a client area is needed to
                                // display document
private uint nLines;            // number of lines in document
private Font mainFont;          // font used to display all lines
private Font emptyDocumentFont; // font used to display empty message
private readonly Brush mainBrush = Brushes.Blue;
                                // brush used to display document text
private readonly Brush emptyDocumentBrush = Brushes.Red;
                       // brush used to display empty document message
private Point mouseDoubleClickPosition;
      // location mouse is pointing to when double-clicked
private readonly OpenFileDialog fileOpenDialog = new OpenFileDialog();
      // standard open file dialog
private bool documentHasData = false;
      // set to true if document has some data in it
#endregion
```

code download CapsEditor.sln

Most of these fields should be self-explanatory. The `documentLines` field is a `List<TextLineInformation>` that contains the actual text of the file that has been read in. Actually, this is the field that contains the data in the document. Each element of `documentLines` contains information for one line of text that has been read in. Because it is a `List<TextLineInformation>` rather than a plain array, you can dynamically add elements to it as you read in a file.

As previously mentioned, each `documentLines` element contains information about a line of text. This information is actually an instance of another class, `TextLineInformation`:

```
class TextLineInformation
{
   public string Text;
   public uint Width;
}
```

`TextLineInformation` looks like a classic case where you would normally use a struct rather than a class because it is just there to group a couple of fields. However, its instances are always accessed as elements of a `List<TextLineInformation>`, which expects its elements to be stored as reference types.

Each `TextLineInformation` instance stores a line of text — and that can be thought of as the smallest item that is displayed as a single item. In general, for each similar item in a GDI+ application, you would probably want to store the text of the item, as well as the world coordinates of where it should be displayed and its size. (The page coordinates will change frequently, whenever the user scrolls, whereas world coordinates will normally change only when other parts of the document are modified in some way.) In this case, you have stored only the `Width` of the item because the height in this case is just the height of whatever your selected font is. It is the same for all lines of text so there is no point storing the height separately for each one; you store it once, in the `Form1.lineHeight` field. As for the position, well, in this case, the x coordinate is just equal to the margin, and the y coordinate is easily calculated here:

```
margin + lineHeight*(however many lines are above this one)
```

If you had been trying to display and manipulate, say, individual words instead of complete lines, then the x position of each word would have to be calculated using the widths of all the previous words on that line of text, but the intent is to keep it simple here, which is why you are treating each line of text as one single item.

Let's turn to the main menu now. This part of the application is more the realm of Windows Forms (see Chapter 39) than of GDI+. Add the menu options using the design view in Visual Studio 2010, but rename them `menuFile`, `menuFileOpen`, and `menuFileExit`. Next, add event handlers for the File Open and File Exit menu options using the Visual Studio 2010 properties window. The event handlers have their Visual Studio 2010-generated names of `menuFileOpen_Click()` and `menuFileExit_Click()`.

Add some extra initialization code in the `Form1()` constructor:

```
public Form1()
{
   InitializeComponent();
   CreateFonts();
   fileOpenDialog.FileOk += delegate { LoadFile(fileOpenDialog.FileName); };
   fileOpenDialog.Filter =
      "Text files (*.txt)|*.txt|C# source files (*.cs)|*.cs";

}
```

code download CapsEditor.sln

You add the event handler here for instances when the user clicks OK in the File Open dialog box. You have also set the filter for the Open File dialog box, so that you can load text files only. The example in this case only uses `.txt` files, in addition to the C# source files, so you can use the application to examine the source code for the samples.

`CreateFonts()` is a helper method that sorts out the fonts you intend to use:

```
private void CreateFonts()
{
   mainFont = new Font("Arial", 10);
   lineHeight = (uint)mainFont.Height;
   emptyDocumentFont = new Font("Verdana", 13, FontStyle.Bold);
}
```

The actual definitions of the handlers are pretty standard:

```
protected void menuFileOpen_Click(object sender, EventArgs e)
{
   fileOpenDialog.ShowDialog();
}
protected void menuFileExit_Click(object sender, EventArgs e)
{
   Close();
}
```

Next, take a look at the `LoadFile()` method. It handles the opening and reading of a file (as well as ensuring a `Paint` event is raised to force a repaint with the new file):

```
private void LoadFile(string FileName)
{
   StreamReader sr = new StreamReader(FileName);
   string nextLine;
   documentLines.Clear();
```

```
      nLines = 0;
      TextLineInformation nextLineInfo;
      while ( (nextLine = sr.ReadLine()) != null)
      {
         nextLineInfo = new TextLineInformation();
         nextLineInfo.Text = nextLine;
         documentLines.Add(nextLineInfo);
         ++nLines;
      }
      sr.Close();
      documentHasData = (nLines>0) ? true: false;
      CalculateLineWidths();
      CalculateDocumentSize();
      Text = standardTitle + "-" + FileName;
      Invalidate();
   }
```

code download CapsEditor.sln

Most of this function is just standard file-reading (see Chapter 29, "Manipulating Files and the Registry"). Note that as the file is read, you progressively add lines to `documentLines ArrayList`, so this array ends up containing information for each of the lines in order. After you have read in the file, you set the `documentHasData` flag, which indicates whether there is actually anything to display. Your next task is to work out where everything is to be displayed, and, having done that, how much client area you need to display the file as well as the document size that will be used to set the scrollbars. Finally, you set the title bar text and call `Invalidate()`. `Invalidate()` is an important method supplied by Microsoft, so the next section discusses its use first, before examining the code for the `CalculateLineWidths()` and `CalculateDocumentSize()` methods.

The Invalidate() Method

`Invalidate()` is a member of `System.Windows.Forms.Form`. It marks an area of the client window as invalid and, therefore, in need of repainting, and then makes sure a `Paint` event is raised. `Invalidate()` has a couple of overrides: you can pass it a rectangle that specifies (in page coordinates) precisely which area of the window needs repainting. If you do not pass any parameters, it just marks the entire client area as invalid.

If you know that something needs painting, why don't you just call `OnPaint()` or some other method to do the painting directly? The answer is that, in general, calling painting routines directly is regarded as bad programming practice — if your code decides it wants some painting done, you should call `Invalidate()`. Here is why:

- Drawing is almost always the most processor-intensive task a GDI+ application will carry out, so doing it in the middle of other work holds up the other work. With the example, if you had directly called a method to do the drawing from the `LoadFile()` method, then the `LoadFile()` method would not return until that drawing task was complete. During that time, your application cannot respond to any other events. However, by calling `Invalidate()`, you are simply getting Windows to raise a `Paint` event before immediately returning from `LoadFile()`. Windows is then free to examine the events that are in line to be handled. How this works internally is that the events sit as what are known as *messages* in a *message queue*. Windows periodically examines the queue, and if there are events in it, then it picks one and calls the corresponding event handler. Although the `Paint` event might be the only one sitting in the queue (so `OnPaint()` is called immediately anyway), in a more complex application there might be other events that ought to get priority over your `Paint` event. In particular, when the user has decided to quit the application, this will be marked by a message known as `WM_QUIT`.
- If you have a more complicated, multithreaded application, then you will probably want just one thread to handle all the drawing. Using `Invalidate()` to route all drawing through the message

queue provides a good way of ensuring that the same thread does all the drawing, no matter what other thread requested the drawing operation. (Whatever thread is responsible for the message queue will be the thread that called `Application.Run()`.)

- There is an additional performance-related reason. Suppose that a couple of different requests to draw part of the screen come in at about the same time. Maybe your code has just modified the document and wants to ensure the updated document is displayed, while at the same time the user has just moved another window that was covering part of the client area out of the way. By calling `Invalidate()`, you are giving Windows a chance to notice that this has occurred. Windows can then merge the `Paint` events if appropriate, combining the invalidated areas, so that the painting is only done once.
- The code to do the painting is probably going to be one of the most complex parts of the code in your application, especially if you have a very sophisticated user interface. The people who have to maintain your code in a couple of years time will thank you for having kept your painting code all in one place and as simple as you reasonably can — something that is easier to do if you do not have too many pathways into it from other parts of the program.

The bottom line from all this is that it is good practice to keep all your painting in the `OnPaint()` routine, or in other methods called from that method. However, you have to strike a balance; if you want to replace just one character on the screen and you know perfectly well that it won't affect anything else that you have drawn, then you might decide that it's not worth the overhead of going through `Invalidate()` and just write a separate drawing routine.

Calculating Item Sizes and Document Size

This section returns to the `CapsEditor` example and examines the `CalculateLineWidths()` and `CalculateDocumentSize()` methods called from `LoadFile()`:

```
private void CalculateLineWidths()
{
   Graphics dc = this.CreateGraphics();
   foreach (TextLineInformation nextLine in documentLines)
   {
      nextLine.Width = (uint)dc.MeasureString(nextLine.Text,
         mainFont).Width;
   }
}
```

code download CapsEditor.sln

This method simply runs through each line that has been read in and uses the `Graphics.MeasureString()` method to work out and store how much horizontal screen space the string requires. You store the value because `MeasureString()` is computationally intensive. If the `CapsEditor` sample had not been simple enough to easily work out the height and location of each item, then this method would almost certainly have needed to be implemented in such a way as to compute all those quantities, too.

Now that you know how big each item on the screen is and you can calculate where each item goes, you are in a position to work out the actual document size. The height is the number of lines multiplied by the height of each line. The width will need to be worked out by iterating through the lines to find the longest. For both height and width, you will also want to make an allowance for a small margin around the displayed document to make the application look more attractive.

The following is the method that calculates the document size:

```
private void CalculateDocumentSize()
{
   if (!documentHasData)
   {
      documentSize = new Size(100, 200);
   }
   else
   {
      documentSize.Height = (int)(nLines*lineHeight) + 2*(int)margin;
      uint maxLineLength = 0;
      foreach (TextLineInformation nextWord in documentLines)
      {
         uint tempLineLength = nextWord.Width;
         if (tempLineLength > maxLineLength)
         {
            maxLineLength = tempLineLength;
         }
      }
      maxLineLength += 2*margin;
      documentSize.Width = (int)maxLineLength;
   }
   AutoScrollMinSize = documentSize;
}
```

code download CapsEditor.sln

This method first checks whether there is any data to be displayed. If there is not, then you cheat a bit and use a hard-coded document size, which is big enough to display the big red `<Empty Document>` warning. If you had wanted to really do it properly, you would have used `MeasureString()` to check how big that warning actually is.

When you have worked out the document size, you tell the `Form` instance what the size is by setting the `Form.AutoScrollMinSize` property. When you do this, something interesting happens behind the scenes. In the process of setting this property, the client area is invalidated and a `Paint` event is raised, for the very sensible reason that changing the size of the document means scrollbars will need to be added or modified and the entire client area will almost certainly be repainted. Why is that interesting? If you look back at the code for `LoadFile()`, you will realize that the call to `Invalidate()` in that method is actually redundant. The client area will be invalidated anyway when you set the document size. The explicit call to `Invalidate()` was left in the `LoadFile()` implementation to illustrate how you should normally do things. In fact, in this case, calling `Invalidate()` again will only needlessly request a duplicate `Paint` event. However, this in turn illustrates how `Invalidate()` gives Windows the chance to optimize performance. The second `Paint` event will not, in fact, get raised: Windows will see that there is a `Paint` event already sitting in the queue and will compare the requested invalidated regions to see if it needs to do anything to merge them. In this case, both `Paint` events will specify the entire client area, so nothing needs to be done, and Windows will quietly drop the second `Paint` request. Of course, going through that process will take up a little bit of processor time, but it will be a negligible amount of time compared to how long it takes to actually do some painting.

OnPaint()

Now that you have seen how `CapsEditor` loads the file, it's time to look at how the painting is done:

```
protected override void OnPaint(PaintEventArgs e)
{
   base.OnPaint(e);
   Graphics dc = e.Graphics;
```

```
         int scrollPositionX = AutoScrollPosition.X;
         int scrollPositionY = AutoScrollPosition.Y;
         dc.TranslateTransform(scrollPositionX, scrollPositionY);
         if (!documentHasData)
         {
            dc.DrawString("<Empty document>", emptyDocumentFont,
               emptyDocumentBrush, new Point(20,20));
            base.OnPaint(e);
            return;
         }
         // work out which lines are in clipping rectangle
         int minLineInClipRegion =
                       WorldYCoordinateToLineIndex(e.ClipRectangle.Top -
                                                   scrollPositionY);
         if (minLineInClipRegion == -1)
         {
            minLineInClipRegion = 0;
         }
         int maxLineInClipRegion =
                       WorldYCoordinateToLineIndex(e.ClipRectangle.Bottom -
                                                   scrollPositionY);
         if (maxLineInClipRegion >= documentLines.Count ||
            maxLineInClipRegion == -1)
         {
            maxLineInClipRegion = documentLines.Count-1;
         }
         TextLineInformation nextLine;
         for (int i=minLineInClipRegion; i<=maxLineInClipRegion; i++)
         {
            nextLine = (TextLineInformation)documentLines[i];
            dc.DrawString(nextLine.Text, mainFont, mainBrush,
                         LineIndexToWorldCoordinates(i));
         }
      }
```

code download CapsEditor.sln

At the heart of this `OnPaint()` override is a loop that goes through each line of the document, calling `Graphics.DrawString()` to paint each one. The rest of this code is mostly concerned with optimizing the painting — figuring out what exactly needs painting instead of rushing in and telling the graphics instance to redraw everything.

You begin by checking if there is any data in the document. If there is not, then you draw a quick message saying so, call the base class's `OnPaint()` implementation, and exit. If there is data, then you start looking at the clipping rectangle by calling another method, `WorldYCoordinateToLineIndex()`. This method is examined next, but essentially it takes a given y position relative to the top of the document, and works out what line of the document is being displayed at that point.

The first time you call the `WorldYCoordinateToLineIndex()` method, you pass it the coordinate value `(e.ClipRectangle.Top – scrollPositionY)`. This is just the top of the clipping region, converted to world coordinates. If the return value is `-1`, you play it safe and assume that you need to start at the beginning of the document (this is the case if the top of the clipping region is within the top margin).

After you have done all that, you essentially repeat the same process for the bottom of the clipping rectangle to find the last line of the document that is inside the clipping region. The indices of the first and last lines are respectively stored in `minLineInClipRegion` and `maxLineInClipRegion`, so then you can just run a `for` loop between these values to do your painting. Inside the painting loop, you actually need to do roughly the reverse transformation to the one performed by `WorldYCoordinateToLineIndex()`. You are given the index of a line of text, and you need to check where it should be drawn. This calculation is actually quite simple, but you have wrapped it up in another method, `LineIndexToWorldCoordinates()`, which returns the required coordinates of the top-left corner of the item. The returned coordinates are world coordinates, but that is fine because you have already called `TranslateTransform()` on the `Graphics` object so that you need to pass it as a world coordinate, rather than a page, when asking it to display items.

Coordinate Transforms

This section examines the implementation of the helper methods that are written in the `CapsEditor` sample to help you with coordinate transforms. These are the `WorldYCoordinateToLineIndex()` and `LineIndexToWorldCoordinates()` methods referred to in the previous section, as well as a couple of other methods.

First, `LineIndexToWorldCoordinates()` takes a given line index, and works out the world coordinates of the top-left corner of that line, using the known margin and line height:

```
private Point LineIndexToWorldCoordinates(int index)
{
   Point TopLeftCorner = new Point(
      (int)margin, (int)(lineHeight*index + margin));
   return TopLeftCorner;
}
```

code download CapsEditor.sln

You also use a method that roughly does the reverse transform in `OnPaint()`. `WorldYCoordinateToLineIndex()` works out the line index, but it takes into account only a vertical world coordinate because it is used to work out the line index corresponding to the top and bottom of the clip region:

```
private int WorldYCoordinateToLineIndex(int y)
{
   if (y < margin)
   {
      return -1;
   }
   return (int)((y-margin)/lineHeight);
}
```

There are three more methods, which will be called from the handler routine that responds to the user double-clicking the mouse. First, you have a method that works out the index of the line being displayed at given world coordinates. Unlike `WorldYCoordinateToLineIndex()`, this method takes into account the x and y positions of the coordinates. It returns `-1` if there is no line of text covering the coordinates passed in:

```
private int WorldCoordinatesToLineIndex(Point position)
{
   if (!documentHasData)
   {
      return -1;
   }
   if (position.Y < margin || position.X < margin)
   {
      return -1;
   }
   int index = (int)(position.Y-margin)/(int)this.lineHeight;
   // check position is not below document
   if (index >= documentLines.Count)
   {
      return -1;
   }
   // now check that horizontal position is within this line
   TextLineInformation theLine =
                          (TextLineInformation)documentLines[index];
```

```
            if (position.X > margin + theLine.Width)
            {
               return -1;
            }
            // all is OK. We can return answer
            return index;
         }
```

Finally, on occasion, you also need to convert between line index and page, rather than world, coordinates. The following methods achieve this:

```
         private Point LineIndexToPageCoordinates(int index)
         {
            return LineIndexToWorldCoordinates(index) +
                                                new Size(AutoScrollPosition);
         }
         private int PageCoordinatesToLineIndex(Point position)
         {
            return WorldCoordinatesToLineIndex(position-new
                                                Size(AutoScrollPosition));
         }
```

Note that when converting to page coordinates, you add the `AutoScrollPosition`, which is negative.

Although these methods by themselves do not look particularly interesting, they do illustrate a general technique that you will probably need to use often. With GDI+, you will often find yourself in a situation where you have been given specific coordinates (for example the coordinates of where the user has clicked the mouse), and you will need to figure out what item is being displayed at that point. Or it could happen the other way around — where should a particular display item be displayed? Hence, if you are writing a GDI+ application, you will probably find it useful to write methods that do the equivalent of the coordinate transformation methods illustrated here.

Responding to User Input

So far, with the exception of the File menu in the `CapsEditor` sample, everything you have done in this chapter has been one way: the application has talked to the user by displaying information on the screen. Almost all software of course works both ways: the user can talk to the software as well. You are now going to add that functionality to `CapsEditor`.

Getting a GDI+ application to respond to user input is actually a lot simpler than writing the code to draw to the screen. (Chapter 39 covers how to handle user input.) Essentially, you override methods from the `Form` class that are called from the relevant event handler, in much the same way that `OnPaint()` is called when a `Paint` event is raised.

The following table lists the methods you might want to override when the user clicks or moves the mouse.

METHOD	CALLED WHEN …
`OnClick(EventArgs e)`	Mouse is clicked.
`OnDoubleClick(EventArgs e)`	Mouse is double-clicked.
`OnMouseDown(MouseEventArgs e)`	Left mouse button is pressed.
`OnMouseHover(MouseEventArgs e)`	Mouse stays still somewhere after moving.
`OnMouseMove(MouseEventArgs e)`	Mouse is moved.
`OnMouseUp(MouseEventArgs e)`	Left mouse button is released.

If you want to detect when the user types in any text, then you will probably want to override the methods listed in the following table.

METHOD	CALLED WHEN ...
`OnKeyDown(KeyEventArgs e)`	A key is pressed.
`OnKeyPress(KeyPressEventArgs e)`	A key is pressed and released.
`OnKeyUp(KeyEventArgs e)`	A pressed key is released.

Note that some of these events overlap. For example, when the user presses a mouse button, the `MouseDown` event is raised. If the button is immediately released again, then this will raise the `MouseUp` event and the `Click` event. In addition, some of these methods take an argument that is derived from `EventArgs` rather than an instance of `EventArgs` itself. These instances of derived classes can be used to give more information about a particular event. `MouseEventArgs` has two properties, `X` and `Y`, which give the device coordinates of the mouse at the time it was pressed. Both `KeyEventArgs` and `KeyPressEventArgs` have properties that indicate which key or keys the event concerns.

That is all there is to it. It is up to you to think about the logic of precisely what you want to do. The only point to note is that you will probably find yourself doing a bit more logic work with a GDI+ application than you would have with a `Windows.Forms` application. That is because in a `Windows.Forms` application you are typically responding to high-level events (`TextChanged` for a text box, for example). By contrast, with GDI+, the events tend to be more elementary — the user clicks the mouse or presses the H key. The action your application takes is likely to depend on a sequence of events rather than on a single event. For example, say your application works similar to Microsoft Word for Windows: to select some text, the user clicks the left mouse button, and then moves the mouse and releases the left mouse button. Your application receives the `MouseDown` event, but there is not much you can do with this event except record that the mouse was clicked with the cursor in a certain position. Then, when the `MouseMove` event is received, you need to check from the record whether the left button is currently down, and if so, highlight text as the user selects it. When the user releases the left mouse button, your corresponding action (in the `OnMouseUp()` method) will need to check whether any dragging took place while the mouse button was down and act accordingly within the method. Only at this point is the sequence complete.

Another point to consider is that, because certain events overlap, you will often have a choice of which event you want your code to respond to.

The golden rule is to think carefully about the logic of every combination of mouse movement or click and keyboard event that the user might initiate, and ensure that your application responds in a way that is intuitive and in accordance with the expected behavior of applications in *every* case. Most of your work here will be in thinking rather than in coding, although the coding you do will be tricky because you might need to take into account many combinations of user input. For example, what should your application do if the user starts typing in text while one of the mouse buttons is held down? It might sound like an improbable combination, but eventually some user is going to try it!

The `CapsEditor` example keeps things very simple, so you do not really have any combinations to think about. The only thing you are going to respond to in the example is when the user double-clicks, in which case you capitalize whatever line of text the mouse pointer is hovering over.

This should be a simple task, but there is one snag. You need to trap the `DoubleClick` event, but the previous table shows that this event takes an `EventArgs` parameter, not a `MouseEventArgs` parameter. The trouble is that you need to know where the mouse is when the user double-clicks if you are to correctly identify the line of text to be capitalized — and you need a `MouseEventArgs` parameter to do that. There are two workarounds. One is to use a static method implemented by the `Form1` object `Control.MousePosition` to find the mouse position:

```
protected override void OnDoubleClick(EventArgs e)
{
   Point MouseLocation = Control.MousePosition;
   // handle double click
}
```

code download CapsEditor.sln

In most cases, this will work. However, there could be a problem if your application (or even some other application with a high priority) is doing some computationally intensive work at the moment the user double-clicks. It just might happen in that case that the `OnDoubleClick()` event handler does not get called until perhaps half a second or so *after* the user has double-clicked. You do not want such delays because they usually annoy users intensely, but even so, occasionally it does happen and sometimes for reasons beyond the control of your application (a slow computer, for instance). The trouble is that half a second is easily enough time for the mouse to be moved halfway across the screen, in which case your call to `Control.MousePosition` will return the completely wrong location!

A better approach here is to rely on one of the many overlaps between mouse event meanings. The first part of double-clicking a mouse involves pressing the left button down. This means that if `OnDoubleClick()` is called, you know that `OnMouseDown()` has also just been called, with the mouse at the same location. You can use the `OnMouseDown()` override to record the position of the mouse, ready for `OnDoubleClick()`. This is the approach taken in `CapsEditor`:

```
protected override void OnMouseDown(MouseEventArgs e)
{
   base.OnMouseDown(e);
   mouseDoubleClickPosition = new Point(e.X, e.Y);
}
```

Now look at the `OnDoubleClick()` override. There is quite a bit more work to do here:

```
protected override void OnDoubleClick(EventArgs e)
{
   int i = PageCoordinatesToLineIndex(mouseDoubleClickPosition);
   if (i >= 0)
   {
      TextLineInformation lineToBeChanged =
                         (TextLineInformation)documentLines[i];
      lineToBeChanged.Text = lineToBeChanged.Text.ToUpper();
      Graphics dc = this.CreateGraphics();
      uint newWidth =(uint)dc.MeasureString(lineToBeChanged.Text,
                                      mainFont).Width;
      if (newWidth > lineToBeChanged.Width)
         lineToBeChanged.Width = newWidth;
      if (newWidth+2*margin > this.documentSize.Width)
      {
         documentSize.Width = (int)newWidth;
         AutoScrollMinSize = this.documentSize;
      }
      Rectangle changedRectangle = new Rectangle(
                                  LineIndexToPageCoordinates(i),
                                  new Size((int)newWidth,
                                  (int)this.lineHeight));
      Invalidate(changedRectangle);
   }
   base.OnDoubleClick(e);
}
```

code download CapsEditor.sln

You start off by calling `PageCoordinatesToLineIndex()` to work out which line of text the mouse pointer was hovering over when the user double-clicked. If this call returns `-1`, then you weren't over any text, so there is nothing to do — except, of course, call the base class version of `OnDoubleClick()` to let Windows do any default processing.

Assuming that you have identified a line of text, you can use the `string.ToUpper()` method to convert it to uppercase. That was the easy part. The hard part is figuring out what needs to be redrawn where. Fortunately, because this example is simple, there are not too many combinations. You can assume that converting to uppercase will always either leave the width of the line on the screen unchanged or increase it. Capital letters are bigger than lowercase letters; therefore, the width will never go down. You also know that because you are not wrapping lines, your line of text will not overflow to the next line and push out other text below. Your action of converting the line to uppercase will not, therefore, actually change the locations of any of the other items being displayed. That is a big simplification!

The next thing the code does is use `Graphics.MeasureString()` to work out the new width of the text. There are now just two possibilities:

- ➤ The new width might make your line the longest line and cause the width of the entire document to increase. If that is the case, then you will need to set `AutoScrollMinSize` to the new size so that the scrollbars are correctly placed.
- ➤ The size of the document might be unchanged.

In either case, you need to get the screen redrawn by calling `Invalidate()`. Only one line has changed; therefore, you do not want to have the entire document repainted. Rather, you need to work out the bounds of a rectangle that contains just the modified line, so that you can pass this rectangle to `Invalidate()`, ensuring that just that line of text is repainted. That is precisely what the previous code does. Your call to `Invalidate()` initiates a call to `OnPaint()` when the mouse event handler finally returns. Keeping in mind the earlier comments about the difficulty in setting a break point in `OnPaint()`, if you run the sample and set a break point in `OnPaint()` to trap the resultant painting action, then you will find that the `PaintEventArgs` parameter to `OnPaint()` does indeed contain a clipping region that matches the specified rectangle. And because you have overloaded `OnPaint()` to take careful account of the clipping region, only one required line of text will be repainted.

PRINTING

So far, the chapter has focused exclusively on drawing to the screen. However, at some point you will probably also want to be able to produce a hard copy of the data. That is the topic of this section. You are going to extend the `CapsEditor` sample so that it is able to print preview and print the document that is being edited.

Unfortunately, there is not enough space to go into too much detail about printing here, so the printing functionality you will implement is very basic. Typically, when you are implementing the ability for an application to print data, you will need to add three items to the application's main File menu:

- ➤ **Page Setup**, which allows the user to choose options such as which pages to print, which printer to use, and so on.
- ➤ **Print Preview**, which opens a new Form that displays a mock-up of what the printed copy should look like.
- ➤ **Print**, which prints the document.

In this case, to keep things simple, you will not implement a Page Setup menu option. Printing will only be possible using default settings. Note, however, that if you want to implement Page Setup, Microsoft has already written a page setup dialog class for you to use: `System.Windows.Forms.PrintDialog`. You will normally want to write an event handler that displays this form and saves the settings chosen by the user.

In many ways, printing is just the same as displaying to a screen. You will be supplied with a device context (`Graphics` instance) and call all the usual display commands against that instance. Microsoft has written a number of classes to assist you in doing this; the two main ones are `System.Drawing.Printing.PrintDocument` and `System.Windows.Forms.PrintPreviewDialog`. These two classes handle the process of making sure that drawing instructions passed to a device context are handled appropriately for printing, leaving you to think about the logic of what to print where.

Some important differences exist between printing or print previewing on the one hand, and displaying to the screen on the other hand. Printers cannot scroll; instead, they turn out pages. Therefore, you will need to make sure that you find a sensible way of dividing your document into pages and draw each page as requested. Among other things, that means calculating how much of your document will fit onto a single page and, therefore, how many pages you will need and which page each part of the document needs to be written to.

Despite these complications, the process of printing is quite simple. Programmatically, the steps you need to go through look roughly like this:

- **Printing** — You instantiate a `PrintDocument` object and call its `Print()` method. This method signals the `PrintPage` event to print the first page. `PrintPage` takes a `PrintPageEventArgs` parameter, which supplies information concerning paper size and setup, as well as a `Graphics` object used for the drawing commands. You should therefore have written an event handler for this event, and have implemented this handler to print a page. This event handler should also set a Boolean property of the `PrintPageEventArgs` called `HasMorePages` to either `true` or `false` to indicate whether there are more pages to be printed. The `PrintDocument.Print()` method will repeatedly raise the `PrintPage` event until it sees that `HasMorePages` has been set to `false`.
- **Print Previewing** — In this case, you instantiate both a `PrintDocument` object and a `PrintPreviewDialog` object. You attach the `PrintDocument` to the `PrintPreviewDialog` (using the property `PrintPreviewDialog.Document`) and then call the dialog's `ShowDialog()` method. This method modally displays the dialog, which turns out to be a standard Windows print preview form and which displays pages of the document. Internally, the pages are displayed again by repeatedly raising the `PrintPage` event until the `HasMorePages` property is `false`. There is no need to write a separate event handler for this; you can use the same event handler as used for printing each page because the drawing code ought to be identical in both cases. (After all, whatever is print previewed ought to look identical to the printed version!)

Implementing Print and Print Preview

Now that this process has been outlined in broad strokes, in this section you see how this works in code terms. You can download the code as the `PrintingCapsEdit` project at `www.wrox.com`; it consists of the `CapsEditor` project with the changes displayed in the following snippet.

You begin by using the Visual Studio 2010 design view to add two new items to the File menu: Print and Print Preview. You also use the properties window to name these items `menuFilePrint` and `menuFilePrintPreview`, and to set them to be disabled when the application starts up (you cannot print anything until a document has been opened!). You arrange for these menu items to be enabled by adding the following code to the main form's `LoadFile()` method, which is responsible for loading a file into the `CapsEditor` application:

```
private void LoadFile(string FileName)
{
   StreamReader sr = new StreamReader(FileName);
   string nextLine;
   documentLines.Clear();
   nLines = 0;
   TextLineInformation nextLineInfo;
   while ( (nextLine = sr.ReadLine()) != null)
   {
      nextLineInfo = new TextLineInformation();
      nextLineInfo.Text = nextLine;
      documentLines.Add(nextLineInfo);
      ++nLines;
   }
   sr.Close();
```

```
      if (nLines > 0)
      {
         documentHasData = true;
         menuFilePrint.Enabled = true;
         menuFilePrintPreview.Enabled = true;
      }
      else
      {
         documentHasData = false;
         menuFilePrint.Enabled = false;
         menuFilePrintPreview.Enabled = false;
      }
      CalculateLineWidths();
      CalculateDocumentSize();
      Text = standardTitle + "-" + FileName;
      Invalidate();
   }
```

code download Printing.sln

The above code is the new code added to this method. Next, you add a member field to the `Form1` class:

```
      public partial class Form1: Form
      {
         private int pagesPrinted = 0;
```

This field will be used to indicate which page you are currently printing. You are making it a member field because you will need to remember this information between calls to the `PrintPage` event handler.

Next, you will find the event handlers that handle the selection of the Print or Print Preview menu options:

```
   private void menuFilePrintPreview_Click(object sender, System.EventArgs e)
   {
      this.pagesPrinted = 0;
      PrintPreviewDialog ppd = new PrintPreviewDialog();
      PrintDocument pd = new PrintDocument();
      pd.PrintPage += this.pd_PrintPage;
      ppd.Document = pd;
      ppd.ShowDialog();
   }
   private void menuFilePrint_Click(object sender, System.EventArgs e)
   {
      this.pagesPrinted = 0;
      PrintDocument pd = new PrintDocument();
      pd.PrintPage += new PrintPageEventHandler
         (this.pd_PrintPage);
      pd.Print();
   }
```

code download Printing.sln

You have already seen the steps involved in printing, and you can see that these event handlers are simply implementing that procedure. In both cases, you are instantiating a `PrintDocument` object and attaching an event handler to its `PrintPage` event. In the case of printing, you call `PrintDocument.Print()`, whereas for print previewing, you attach the `PrintDocument` object to a `PrintPreviewDialog` and call the preview dialog box object's `ShowDialog()` method. The real work to the `PrintPage` event is done in the event handler. Here is how this handler looks:

```
   private void pd_PrintPage(object sender, PrintPageEventArgs e)
   {
      float yPos = 0;
      float leftMargin = e.MarginBounds.Left;
      float topMargin = e.MarginBounds.Top;
      string line = null;
      // Calculate the number of lines per page.
      int linesPerPage = (int)(e.MarginBounds.Height /
         mainFont.GetHeight(e.Graphics));
      int lineNo = pagesPrinted * linesPerPage;
      // Print each line of the file.
      int count = 0;
      while(count < linesPerPage && lineNo < this.nLines)
      {
         line = ((TextLineInformation)this.documentLines[lineNo]).Text;
         yPos = topMargin + (count * mainFont.GetHeight(e.Graphics));
         e.Graphics.DrawString(line, mainFont, Brushes.Blue,
            leftMargin, yPos, new StringFormat());
         lineNo++;
         count++;
      }
      // If more lines exist, print another page.
      if(this.nLines > lineNo)
         e.HasMorePages = true;
      else
         e.HasMorePages = false;
      pagesPrinted++;
   }
```

code download Printing.sln

After declaring a couple of local variables, the first thing you do is work out how many lines of text can be displayed on one page, which will be the height of a page divided by the height of a line and rounded down. The height of the page can be obtained from the `PrintPageEventArgs.MarginBounds` property. This property is a `RectangleF` struct that has been initialized to give the bounds of the page. The height of a line is obtained from the `Form1.mainFont` field, which is the font used for displaying the text. There is no reason here for not using the same font for printing too. Note that for the `PrintingCapsEditor` sample, the number of lines per page is always the same, so you arguably could have cached the value the first time you calculated it. However, the calculation is not too hard, and in a more sophisticated application, the value might change, so it is not bad practice to recalculate it every time you print a page.

You also initialize a variable called `lineNo`. This gives the zero-based index of the line of the document that will be the first line of this page. This information is important because, in principle, the `pd_PrintPage()` method could have been called to print any page, not just the first page. `lineNo` is computed as the number of lines per page times the number of pages that have so far been printed.

Next, you run through a loop, printing each line. This loop will terminate either when you find that you have printed all the lines of text in the document, or when you find that you have printed all the lines that will fit on this page, whichever condition occurs first. Finally, you check whether there is any more of the document to be printed, and set the `HasMorePages` property of your `PrintPageEventArgs` accordingly. You also increment the `pagesPrinted` field so that you know to print the correct page the next time the `PrintPage` event handler is invoked.

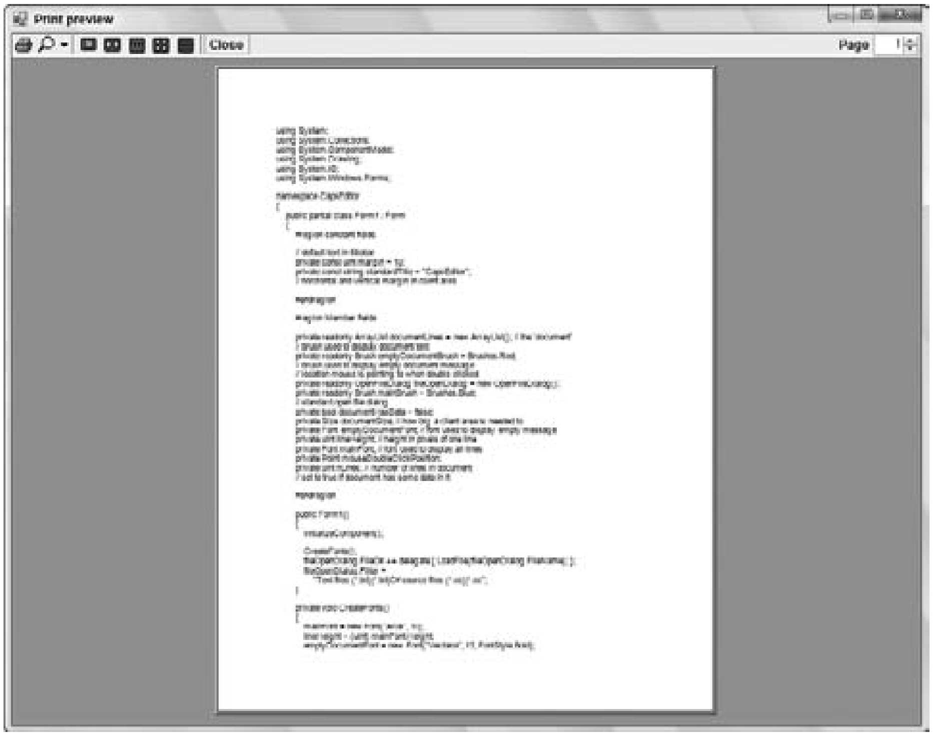
One point to note about this event handler is that you do not worry about where the drawing commands are being sent. You simply use the `Graphics` object that was supplied with the `PrintPageEventArgs`. The `PrintDocument` class that Microsoft has written will internally take care of making sure that, if you are printing, the `Graphics` object has been hooked up to the printer; if you are print previewing, then the `Graphics` object has been hooked up to the print preview form on the screen.

Finally, you need to ensure that the `System.Drawing.Printing` namespace is searched for type definitions:

```
using System;
using System.Collections.Generic;
using System.ComponentModel;
using System.Data;
using System.Drawing;
using System.Drawing.Printing;
using System.Text;
using System.Windows.Forms;
using System.IO;
```

All that remains is to compile the project and check that the code works. Figure 48-19 shows what happens when you run `CapsEdit`, load a text document (as before, you have picked the C# source file for the project), and select Print Preview.

In Figure 48-19, the document is scrolled to page 5 and the preview is set to display normal size. The `PrintPreviewDialog` has supplied quite a lot of features, as you can see by looking at the toolbar at the top of the form. The options available include printing the document, zooming in or out, and displaying two, three, four, or six pages together. These options are all fully functional, without your having to do any work. Figure 48-20 shows the result of changing the zoom to auto and clicking to display four pages (third toolbar button from the right).



```
using System;
using System.Collections;
using System.ComponentModel;
using System.Drawing;
using System.IO;
using System.Windows.Forms;

namespace CapsEditor
{
   public partial class Form1 : Form
   {
      #region constant fields

      [illegible]
```

FIGURE 48-19

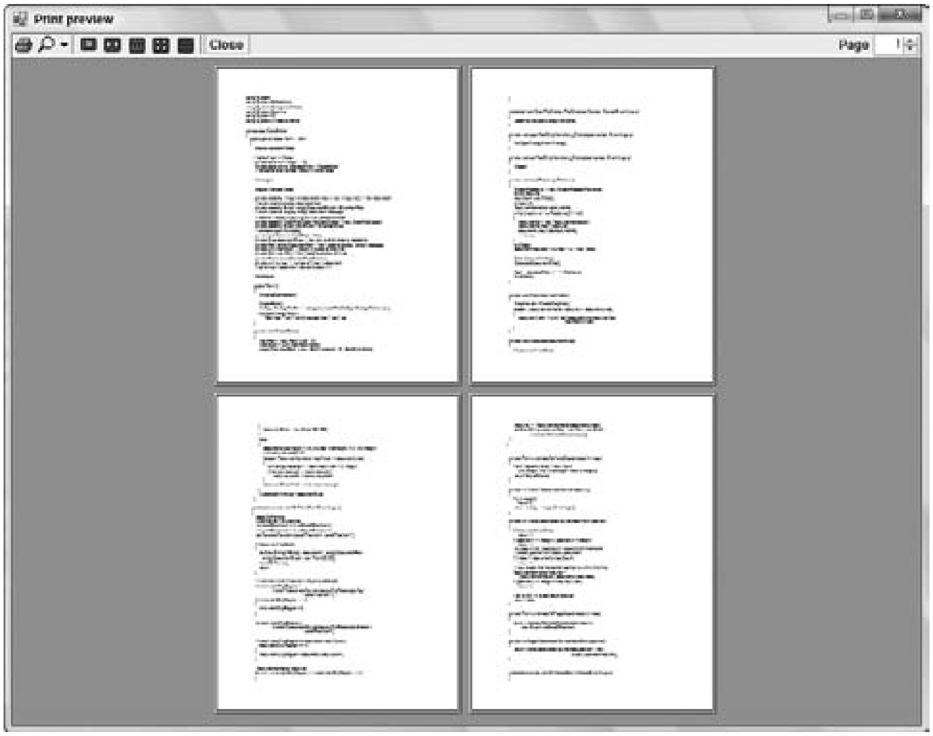


FIGURE 48-20

SUMMARY

This chapter covered the realm of GDI+ — the area of drawing to a display device, where the drawing is done by your code rather than by some predefined control or dialog box. GDI+ is a powerful tool, and there are many .NET base classes available to help you draw to a device. You have seen that the process of drawing is actually relatively simple. In most cases, you can draw text or sophisticated figures or display images with just a couple of C# statements. However, managing your drawing — the behind-the-scenes work involving working out what to draw, where to draw it, and what does or does not need repainting in any given situation — is far more complex and requires careful algorithm design. For this reason, it is also important to have a good understanding of how GDI+ works and what actions Windows takes to get something drawn. In particular, because of the architecture of Windows, it is important that, where possible, drawing should be done by invalidating areas of the window and relying on Windows to respond by issuing a `Paint` event.

Many more .NET classes can be used for drawing than there is space to cover in this chapter. However, if you have worked through it and understood the principles involved in drawing, then you will be in an excellent position to explore these classes by looking at their lists of methods in the SDK documentation and instantiating instances of them to see what they do. In the end, drawing, as with almost any other aspect of programming, requires logic, careful thought, and clear algorithms if you want to go beyond the standard controls. Your software will benefit in both user-friendliness and visual appearance if it is well thought out. Many applications out there rely entirely on controls for their user interface. Although this can be effective, such applications very quickly end up resembling each other. By adding some GDI+ code to do some custom drawing you can mark out your software as distinct and make it appear more original, which can only help increase your sales!

49

WHAT'S IN THIS CHAPTER?

- What types of projects you can create with VSTO and what capabilities you can include in these projects
- Fundamental techniques that apply to all types of VSTO solutions
- Using host items and host controls

In Visual Studio 2010, VSTO 4 extends and improves upon the previous version. It makes deployment easier, and there is no longer a requirement to install Primary Interop Assemblies (PIAs) on client PCs — this is instead achieved through CLR 4 type embedding. Support for Office 2010 is also included.

This chapter does not assume any prior knowledge of VSTO or its predecessors.

VSTO OVERVIEW

VSTO consists of the following components:

- A selection of project templates that you can use to create various types of Office solutions
- Designer support for visual layout of ribbons, action panes, and custom task panels
- Classes built on top of the Office object model that provide extensive capabilities

VSTO supports 2003, 2007, and 2010 versions of Office. The VSTO class library comes in multiple flavors for each of these Office versions, which use different sets of assemblies. For simplicity, this chapter focuses on the 2007 version.

The general architecture of VSTO solutions is shown in Figure 49-1.

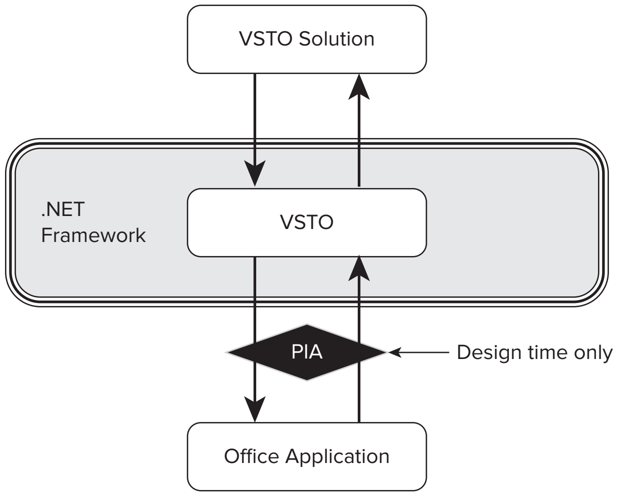

FIGURE 49-1

Note that the PIA shown in Figure 49-1 is only required at design time when targetting .NET 4, as type embedding is used when deployed to clients. This is not true for VSTO solutions that target .NET 3.5, which require PIAs on both the development and target machines.

Project Types

Figure 49-2 shows the project templates that are available in VS for Office 2007 (a similar list is available for Office 2010). In this chapter you'll concentrate on Office 2007.

FIGURE 49-2

The VSTO project templates can be divided into the following categories:

- Document-level customizations
- Application-level add-ins
- SharePoint workflow templates (not shown in Figure 49-2 as these are in a separate template category)

Note that the previous version of VSTO included a fourth category, InfoPath form templates, which is no longer available in VSTO 4.

This chapter concentrates on the most commonly used project types, which are document-level customizations and application-level add-ins.

Document-Level Customizations

When you create a project of this type, you will generate an assembly that will be linked to an individual document — for example a Word document, Word template, or Excel workbook. When you load the document, the associated Office application will detect the customization, load the assembly, and make the VSTO customization available.

You might use a project of this type to provide additional functionality to a particular line-of-business document, or to a whole class of documents by adding customizations to a document template. You can include code that manipulates the document and the content of the document, including any embedded objects. You can also provide custom menus, including ribbon menus that you can create using the VS Ribbon Designer.

When you create a document-level project, you can choose to create a new document or to copy an existing document as a starting point for your development. You can also choose the type of document to create. For a Word document, for example, you can choose to create `.docx` (the default), `.doc`, or `.docm` documents (`.docm` is a macro-enabled document). The dialog box for this is shown in Figure 49-3.

FIGURE 49-3

Application-Level Add-Ins

Application-level add-ins are different from document-level customizations in that they are available throughout their targeted Office application. You can access add-in code, which might include menus, document manipulations, and so on, regardless of what documents are loaded.

When you start an Office application such as Word, it will look for associated add-ins that have entries in the registry and will load any assemblies that it needs to.

SharePoint Workflow Templates

These projects provide a template to create SharePoint workflow applications. These are used to manage the flow of documents within SharePoint processes. By creating a project of this type, you can execute custom code at key times during the document lifecycle.

Project Features

There are several features that you can use in the various VSTO project types, such as interactive panes and controls. The project type you use determines the features that are available to you. The following tables list these features according to the projects in which they are available.

Document-Level Customization Features

FEATURE	DESCRIPTION
Actions pane	Actions panes are dialog boxes that are hosted inside the action pane of Word or Excel. You can display whatever controls you like here, which makes this an extremely versatile way of extending documents and applications.
Data cache	Data caching enables you to store data that is used in your documents externally to those documents in cached data islands. These data islands can be updated from data sources or manually, and enable the Office documents to access data when data sources are offline or unavailable.
Endpoints for VBA code	As discussed earlier, VSTO enables VBA interoperability. In document-level customizations, you can provide endpoint methods that can be called from VBA code.
Host controls	Host controls are extended wrappers around existing controls in the Office object model. You can manipulate and data-bind to these objects.
Smart Tags	Smart Tags are objects that are embedded in Office documents and that have typed content. They are automatically detected within the content of Office documents; for example, a stock quote Smart Tag is added automatically when the application detects appropriate text. You can create your own Smart Tag types and define operations that can be performed on them.

FEATURE	DESCRIPTION
Visual document designer	When you work with document customization projects, the Office object model is used to create a visual design surface that you can use to lay out controls interactively. The toolbars and menus shown in the designer are, as you will see later in this chapter, fully functional.

Application-Level Add-In Features

FEATURE	DESCRIPTION
Custom task pane	Task panes are typically docked to one edge of an Office application and provide a variety of functionality. For example, Word has a task pane used for manipulating styles. As with action panes, these give you a great deal of flexibility.
Cross-application communication	Once you have created an add-in for one Office application, you can expose that functionality to other add-ins. You could, for example, create a financial calculating service in Excel and then use that service from Word — without creating a separate add-in.
Outlook form regions	You can create form regions that can be used in Outlook.

Features Usable In All Project Types

FEATURE	DESCRIPTION
ClickOnce deployment	You can distribute any VSTO project that you create to end users through ClickOnce deployment methods. This enables users to stay up-to-date with updates to your document- and application-level solutions by detecting changes to the application manifest.
Ribbon menus	Ribbon menus are used in all Office applications, and VSTO includes two ways to create your own ribbon menus. You can either use XML to define a ribbon or use the Ribbon Designer. Typically, you will use the Ribbon Designer as it is much easier to use, although you may want the XML version for backwards compatibility.

VSTO PROJECT FUNDAMENTALS

Now that you have seen what is included in VSTO, it is time to look at the more practical side of things, and how you can build VSTO projects. The techniques demonstrated in this section are general ones that apply to all types of VSTO projects.

In this section, you will look at the following:

- Office object model
- VSTO namespaces
- Host items and host controls
- Basic VSTO project structure
- The Globals class
- Event handling

Office Object Model

The Office 2007 and 2010 suites of applications expose their functionality through a COM object model. You can use this object model directly from VBA to control just about any aspect of Office functionality. The Office object model was introduced in Office 97, and has evolved since then as functionality in Office has changed.

There are a huge number of classes in the Office object model, some of which are used across the suite of Office applications and some of which are specific to individual applications. For example, the Word 2007 object model includes a `Documents` collection representing the currently loaded objects, each of which is represented by a `Document` object. In VBA code, you can access documents by name or index and call methods to perform operations on them. For example, the following VBA code closes the document with the name `My Document` without saving changes:

```
Documents("My Document").Close SaveChanges:= wdDoNotSaveChanges
```

The Office object model includes named constants (such as `wdDoNotSaveChanges` in the preceding code) and enumerations to make it easier to use.

VSTO Namespaces

VSTO contains a collection of namespaces, which contain types that you can use to program against the Office object model. Many of the types in these namespaces map directly to types in the Office object model. These are accessed through Office PIAs at design time, and through embedded type information when solutions are deployed. Because of this type embedding, you will mostly use interfaces to access the Office object model. VSTO also contains types that do not map directly, or are unrelated to the Office object model. For example, there are a lot of classes that are used for designer support in VS.

The types that do wrap or communicate with objects in the Office object model are divided into namespaces. The namespaces that you will use for Office development are summarized in the following table.

NAMESPACE	DESCRIPTION
`Microsoft.Office.Core`, `Microsoft.Office.Interop.*`	These namespaces contain interfaces and thin wrappers around the office object model and, so, provide the base functionality for working with the Office classes. There are several nested namespaces in the `Microsoft.Office.Interop` namespace for each of the Office products.
`Microsoft.Office.Tools`	This namespace contains general types that provide VSTO functionality and base classes for many of the classes in nested namespaces. For example, this namespace includes the classes required to implement action panes in document-level customizations and the base class for application-level add-ins.
`Microsoft.Office.Tools.Excel`, `Microsoft.Office.Tools.Excel.*`	These namespaces contain the types required to interact with the Excel application and Excel documents.
`Microsoft.Office.Tools.Outlook`	These namespaces contain the types required to interact with the Outlook application.
`Microsoft.Office.Tools.Ribbon`	This namespace includes the types required to work with and create your own ribbon menus.
`Microsoft.Office.Tools.Word`, `Microsoft.Office.Tools.Word.*`	These namespaces contain the types required to interact with the Word application and Word documents.
`Microsoft.VisualStudio.Tools.*`	These namespaces provide the VSTO infrastructure that you work with when you develop VSTO solutions in VS.

Host Items and Host Controls

Host items and host controls are interfaces that have been extended to make it easier for document-level customizations to interact with Office documents. These interfaces simplify your code as they expose .NET-style events and are fully managed. The “host” part of the name of host items and host controls references the fact that these interfaces wrap and extend the native Office objects.

Often when you use host items and host controls, you will find that it is necessary to use the underlying interop types as well. For example, if you create a new Word document, then you receive a reference to the interop Word document type rather than the Word document host item. You need to be aware of this and write your code accordingly.

There are host items and host controls for both Word and Excel document-level customizations.

Word

There is a single host item for Word, `Microsoft.Office.Tools.Word.Document`. This represents a Word document. As you might expect, this interface has an enormous number of methods and properties that you can use to interact with Word documents.

There are 12 host controls for Word, as shown in the following table, all of which are found in the `Microsoft.Office.Tools.Word` namespace.

CONTROL	DESCRIPTION
`Bookmark`	This control represents a location within the Word document. This might be a single location or a range of characters.
`XMLNode, XmlNodes`	These controls are used when the document has an attached XML schema. They allow you to reference document content by the XML node location of that content. You can also manipulate the XML structure of a document with these controls.
`ContentControl`	This interface shares a base interface (`ContentControlBase`) with the remaining eight controls in this table, and enables you to deal with Word content controls. A content control is a control that presents content as a control or that enables functionality above and beyond that offered by plain text in a document.
`BuildingBlockGalleryContentControl`	This control enables you to add and manipulate document building blocks, such as formatted tables, cover pages, and so on.
`ComboBoxContentControl`	This control represents content formatted as a combo box.
`DatePickerContentControl`	This control represents content formatted in a date picker.
`DropDownListContentControl`	This control represents content formatted as a drop-down list.
`GroupContentControl`	This control represents content that is a grouped collection of other content items, including text and other content controls.
`PictureContentControl`	This control represents an image.
`RichTextContentControl`	This control represents a block of rich text content.
`PlainTextContentControl`	This control represents a block of plain text content.

Excel

There are three host items and four host controls for Excel, all of which are contained in the `Microsoft.Office.Tools.Excel` namespace.

The Excel host items are shown in the following table.

HOST ITEM	DESCRIPTION
`Workbook`	This host item represents an entire Excel workbook, which may contain multiple worksheets and chartsheets.
`Worksheet`	This host item is used for individual worksheets within a workbook.
`Chartsheet`	This host item is used for individual chartsheets within a workbook.

The Excel host controls are shown in the following table.

CONTROL	DESCRIPTION
`Chart`	This control represents a chart that is embedded in a worksheet.
`ListObject`	This control represents a list in a worksheet.
`NamedRange`	This control represents a named range in a worksheet.
`XmlMappedRange`	This control is used when an Excel spreadsheet has an attached schema, and is used to manipulate ranges that are mapped to XML schema elements.

Basic VSTO Project Structure

When you first create a VSTO project, the files you start with vary according to the project type, but there are some common features. In this section, you will see what constitutes a VSTO project.

Document-Level Customization Project Structure

When you create a document-level customization project, you will see an entry in Solution Explorer that represents the document type. This may be:

➤ A `.docx` file for a Word document
➤ A `.dotx` file for a Word template
➤ A `.xlsx` file for an Excel workbook
➤ A `.xltx` file for an Excel template

Each of these has a designer view and a code file, which you will see if you expand the item in Solution Explorer. The Excel templates also include sub-items representing the workbook as a whole and each spreadsheet in the workbook. This structure enables you to provide custom functionality on a per-sheet or per-workbook basis.

If you view the hidden files in one of these projects, you will see several designer files that you can look at to see the template-generated code. Each Office document item has an associated class from the VSTO namespaces, and the classes in the code files derive from these classes. These classes are defined as partial class definitions so that your custom code is separated from the code generated by the visual designer, similar to the structure of Windows Forms applications.

For example, the Word document template provides a class that derives from the `Microsoft.Office.Tools.Word.DocumentBase`. This class exposes the `Document` host item through a `Base` property, and is contained in `ThisDocument.cs`, as follows:

```
using System;
using System.Collections.Generic;
using System.Data;
using System.Linq;
using System.Text;
using System.Windows.Forms;
using System.Xml.Linq;
using Microsoft.VisualStudio.Tools.Applications.Runtime;
using Office = Microsoft.Office.Core;
using Word = Microsoft.Office.Interop.Word;

namespace WordDocument1
{
    public partial class ThisDocument
    {
        private void ThisDocument_Startup(object sender, System.EventArgs e)
        {
        }
```

```
            private void ThisDocument_Shutdown(object sender, System.EventArgs e)
            {
            }
            #region VSTO Designer generated code
            /// <summary>
            /// Required method for Designer support — do not modify
            /// the contents of this method with the code editor.
            /// </summary>
            private void InternalStartup()
            {
                this.Startup += new System.EventHandler(ThisDocument_Startup);
                this.Shutdown += new System.EventHandler(ThisDocument_Shutdown);
            }
            #endregion
        }
    }
```

This template-generated code includes aliases for the two main namespaces that you will use when creating a document-level customization for Word, `Microsoft.Office.Core` for the main VSTO Office classes and `Microsoft.Office.Interop.Word` for Word-specific classes. Note that if you want to use Word host controls, then you would also add a `using` statement for the `Microsoft.Office.Tools.Word` namespace. The template-generated code also defines two event handler hooks that you can use to execute code when the document is loaded or unloaded, `ThisDocument_Startup()` and `ThisDocument_Shutdown()`.

Every one of the document-level customization project types has a similar structure in its code file (or, in the case of Excel, code files). There are namespace aliases defined for you and handlers for the various `Startup` and `Shutdown` events that the VSTO classes define. From this starting point, you add dialog boxes, action panes, ribbon controls, event handlers, and custom code to define the behavior of your customization.

With document-level customizations, you can also customize the document or documents through the document designer. Depending on the type of solution you are creating, this might involve adding boilerplate content to templates, interactive content to documents, or something else. The designers are effectively hosted versions of Office applications, and you can use them to enter content just as you can in the applications themselves. However, you can also add controls such as host controls and Windows Forms controls to documents, and code around these controls.

Application-Level Add-In Project Structure

When you create an application-level add-in, there will be no document or documents in Solution Explorer. Instead, you will see an item representing the application that you are creating an add-in for, and if you expand this item, you will see a file called `ThisAddIn.cs`. This file contains a partial class definition for a class called `ThisAddIn`, which provides the entry point for your add-in. This class derives from `Microsoft.Office.Tools.AddInBase`, which provides code add-in functionality.

For example, the code generated by the Word add-in template is as follows:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Text;
using System.Xml.Linq;
using Word = Microsoft.Office.Interop.Word;
using Office = Microsoft.Office.Core;
using Microsoft.Office.Tools.Word;
```

```
namespace WordAddIn1
{
    public partial class ThisAddIn
    {
        private void ThisAddIn_Startup(object sender, System.EventArgs e)
        {
        }
        private void ThisAddIn_Shutdown(object sender, System.EventArgs e)
        {
        }
        #region VSTO generated code
        /// <summary>
        /// Required method for Designer support — do not modify
        /// the contents of this method with the code editor.
        /// </summary>
        private void InternalStartup()
        {
            this.Startup += new System.EventHandler(ThisAddIn_Startup);
            this.Shutdown += new System.EventHandler(ThisAddIn_Shutdown);
        }
        #endregion
    }
}
```

As you can see, this structure is very similar to the structure used in document-level customizations. It includes aliases for the same `Microsoft.Office.Core` and `Microsoft.Office.Interop.Word` namespaces, and gives you event handlers for `Startup` and `Shutdown` events (`ThisAddIn_Startup()` and `ThisAddIn_Shutdown()`). These events are slightly different from the document ones, as they are raised when the add-in is loaded or unloaded rather than when individual documents are opened or closed.

You proceed to customize application-level add-ins much as you do document-level customizations: by adding ribbon controls, task panes, and additional code.

The Globals Class

All VSTO project types define a class called `Globals` that gives you global access to the following:

- For document-level customizations, all documents in the solution. These are exposed through members with names that match the document class names — for example, `Globals.ThisWorkbook` and `Globals.Sheet1`.
- For application-level add-ins, the add-in object. This is exposed through `Globals.ThisAddIn`.
- For Outlook add-in projects, all Outlook form regions.
- All ribbons in the solution, through the `Globals.Ribbons` property.
- An interface that derives from `Microsoft.Office.Tools.Factory` that exposes project-type-specific utility methods, exposed through the `Factory` property.

Behind the scenes, the `Globals` class is created through a series of partial definitions in the various designer-maintained code files in your solution. For example, the default `Sheet1` worksheet in an Excel Workbook project includes the following designer-generated code:

```
internal sealed partial class Globals
{
   private static Sheet1 _Sheet1;
   internal static Sheet1 Sheet1
   {
      get
      {
         return _Sheet1;
      }
```

```
            set
            {
               if ((_Sheet1 == null))
               {
                  _Sheet1 = value;
               }
               else
               {
                  throw new System.NotSupportedException();
               }
            }
         }
      }
```

This code adds the `Sheet1` member to the `Globals` class.

The `Globals` class also allows you to transform an interop type to a VSTO type by using the `Globals.Factory.GetVstoObject()` method. This will obtain a VSTO `Workbook` interface from a `Microsoft.Office.Interop.Excel.Workbook` interface, for example. There is also a `Globals.Factory.HasVstoObject()` method that you can use to determine if such a transformation is possible.

Event Handling

Earlier in this chapter, you saw how the host item and host control classes expose events that you can handle. Unfortunately, this is not the case for the interop classes. There are a few events that you can use, but for the most part, you will find it difficult to create event-driven solutions by using these events. Most often, to respond to events you should focus on the events exposed by host items and host controls.

The obvious problem here is that there are no host items or host controls for application-level add-in projects. Sadly, this is a problem that you must learn to live with when you use VSTO. However, the most common events that you are likely to listen for in add-ins are those associated with ribbon menu and task pane interaction. You design ribbons with the integrated ribbon designer, and you can respond to any events generated by the ribbon to make the control interactive. Task panes are usually implemented as Windows Forms user controls (although you can use WPF), and you can use Windows Forms events here. This means that you will not often encounter situations in which there is no event available for the functionality you require.

When you do need to use an Office interop-exposed event, you will find that events are exposed through interfaces on these objects. Consider a Word Add-In project. The `ThisAddIn` class in this project exposes a property called `Application` through which you can obtain a reference to the Office application. This property is of type `Microsoft.Office.Interop.Word.Application`, and exposes events through the `Microsoft.Office.Interop.Word.ApplicationEvents4_Event` interface. This interface exposes a total of 29 events (which really doesn't seem to be a lot for an application as complex as Word, does it?). You can handle, for example, the `DocumentBeforeClose` event to respond to Word document close requests.

BUILDING VSTO SOLUTIONS

The previous sections explained what VSTO projects are, how they are structured, and the features that you can use in the various project types. In this section, you look at implementing VSTO solutions.

Figure 49-4 outlines the structure of document-level customization solutions.

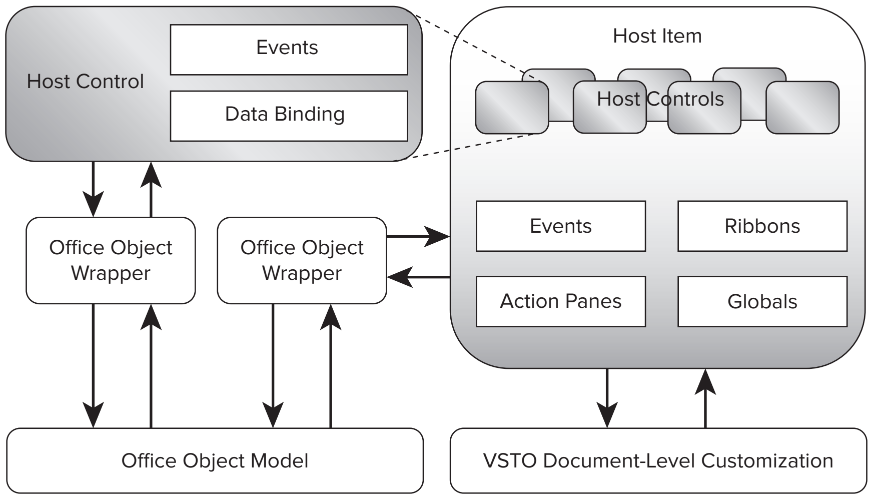

FIGURE 49-4

For document-level customizations you will interact with at least one host item, which will typically contain multiple host controls. You may use Office object wrappers directly, but for the most part, you will access the Office object model and its functionality through host items and host controls.

You will make use of host item and host control events, data binding, ribbon menus, action panes, and global objects in your code.

Figure 49-5 outlines the structure of application-level add-in solutions.

In this slightly simpler model, you are more likely to use the thinner wrappers around Office objects directly, or at least through the add-in class that encapsulates your solution. You will also use events exposed by the add-in class, ribbon menus, task panes, and global objects in your code.

In this section, you will look at both of these types of applications as appropriate, as well as the following topics:

- Managing application-level add-ins
- Interacting with applications and documents
- UI customization

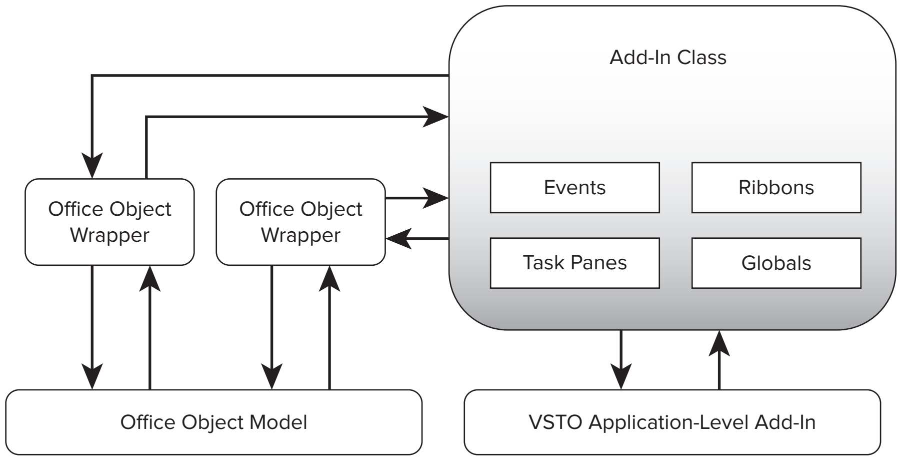

FIGURE 49-5

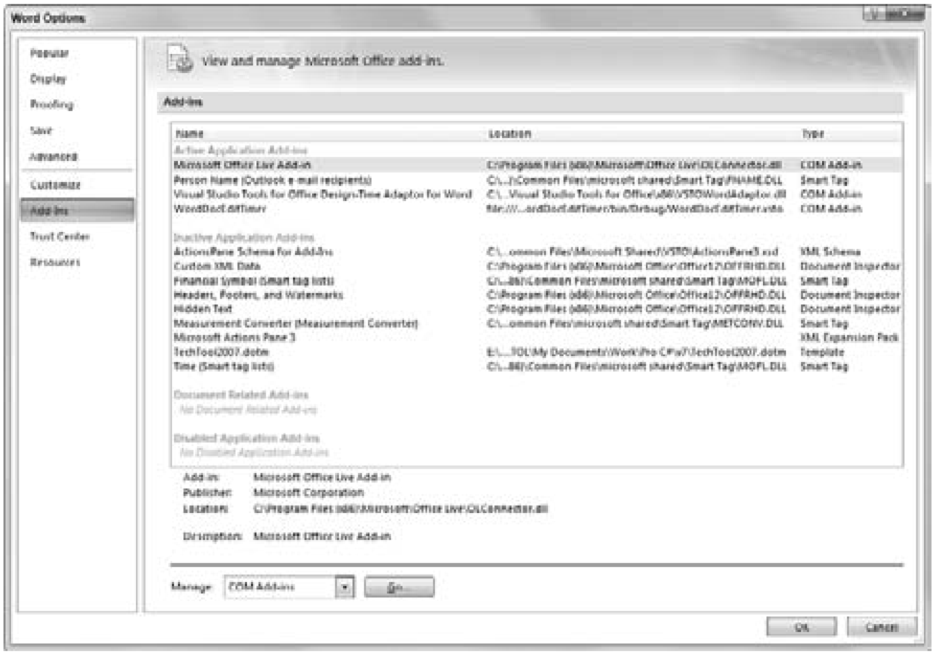
Managing Application-Level Add-Ins

One of the first things you will find when you create an application-level add-in is that VS carries out all the steps necessary to register the add-in with the Office application. This means that registry entries are added so that when the Office application starts, it will automatically locate and load your assembly. If you subsequently want to add or remove add-ins, then you must either navigate through Office application settings or manipulate the registry manually.

For example, in Word, you must open the Office Button menu, click Word Options, and select the Add-Ins tab, as shown in Figure 49-6.



Name	Location	Type
Active Application Add-ins		
Microsoft Office Live Add-in	C:\Program Files (x86)\Microsoft\Office Live\OLConnector.dll	COM Add-in
Person Name (Outlook e-mail recipients)	C:\...)\Common Files\microsoft shared\Smart Tag\FNAME.DLL	Smart Tag

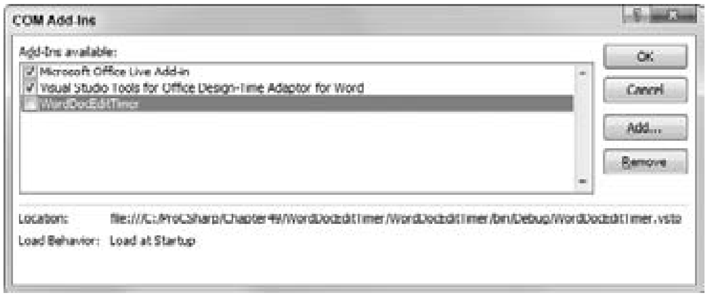
Add-in: Microsoft Office Live Add-in
Publisher: Microsoft Corporation
Location: C:\Program Files (x86)\Microsoft\Office Live\OLConnector.dll

Description: Microsoft Office Live Add-in

Manage: COM Add-ins [Go...]

FIGURE 49-6

Figure 49-6 shows an add-in that has been created with VSTO: `WordDocEditTimer`. To add or remove add-ins, you must select COM Add-Ins in the Manage drop-down (the default option) and click the Go button. The dialog box that appears is shown in Figure 49-7.



Add-Ins available:
- ✓ Microsoft Office Live Add-in
- ✓ Visual Studio Tools for Office Design-Time Adaptor for Word
- ☐ WordDocEditTimer

Location: file:///C:/ProCSharp/Chapter49/WordDocEditTimer/WordDocEditTimer/bin/Debug/WordDocEditTimer.vsto
Load Behavior: Load at Startup

FIGURE 49-7

You can unload add-ins by deselecting them in the COM Add-Ins dialog box (as shown in Figure 49-7), and you can add new add-ins or remove old ones with the Add and Remove buttons.

Interacting with Applications and Documents

Whatever type of application you are creating, you will want to interact with the host application and/or documents in the host operation. In part, this includes using UI customizations, which you learn about in the next section. However, you may also need to monitor documents within an application, which means that you must handle some Office object model events. For example, to monitor documents in Word, you require event handlers for the following events of the `Microsoft.Office.Interop.Word.ApplicationEvents4_Event` interface:

- `DocumentOpen` — Raised when a document is opened.
- `NewDocument` — Raised when a new document is created.
- `DocumentBeforeClose` — Raised when a document is saved.

Also, when Word first starts, it will have a document loaded, which will either be a blank new document or a document that was loaded.

The downloadable code for this chapter includes an example called `WordDocEditTimer`*, which maintains a list of edit times for Word documents. Part of the functionality of this application is to monitor the documents that are loaded, for reasons that are explained later. Because this example also uses a custom task pane and ribbon menu, you will look at it after covering those topics.*

You can access the currently active document in Word through `ThisAddIn.Application.ActiveDocument` property, and the collection of open documents through `ThisAddIn.Application.Documents`. Similar properties exist for the other Office applications with a Multiple Document Interface (MDI). You can manipulate various properties of documents through the properties exposed by, for example, the `Microsoft.Office.Interop.Word.Document` class.

One point to note here is that the number of classes and class members you must deal with when developing VSTO solutions is, frankly, enormous. Until you get used to it, it can be difficult to locate the features you are after. For example, it is not obvious why in Word the current active selection is available not through the active document, but through the application (through the `ThisAddIn.Application.Selection` property).

The selection is useful for inserting, reading, or replacing text through the `Range` property. For example:

```
ThisAddIn.Application.Selection.Range.Text = "Inserted text";
```

Unfortunately, there is not enough space in this chapter to cover the object libraries in great depth. Instead, you will learn about the object libraries as they are relevant to the ongoing discussion.

UI Customization

Perhaps the most important aspect of the latest release of VSTO is the flexibility that is available for customizing the UI of your customizations and add-ins. You can add content to any of the existing ribbon menus, add completely new ribbon menus, customize task panes by adding action panes, add completely new task panes, and integrate Windows Forms and WPF forms and controls.

In this section, we look at each of these subjects.

Ribbon Menus

You can add ribbon menus to any of the VSTO projects that you are looking at in this chapter. When you add a ribbon, you will see the designer window shown in Figure 49-8.

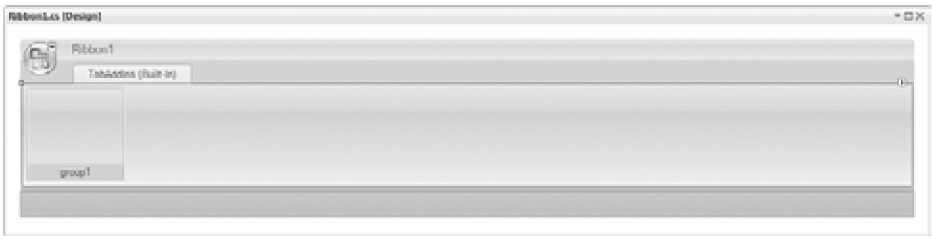


FIGURE 49-8

The designer allows you to customize this ribbon by adding controls to the Office button menu (shown in the top left of Figure 49-8) and to groups on the ribbon. You can also add additional groups.

The classes used in ribbons are found in the `Microsoft.Office.Tools.Ribbon` namespace. This includes the ribbon class that you derive from to create a ribbon, `RibbonBase`. This class can contain `RibbonTab` objects, each of which includes content for a single tab. Tabs contain `RibbonGroup` objects, like the `group1` group in Figure 49-8. These tabs can contain a variety of controls.

It is possible for the groups on a tab to be positioned on a completely new tab, or on one of the existing tabs in the Office application that you are targeting. Where the groups appear is determined by the `RibbonTab.ControlId` property. This property has a `ControlIdType` property, which you can set to `RibbonControlIdType.Custom` or `RibbonControlIdType.Office`. If you use `Custom`, then you must also set `RibbonTab.ControlId.CustomId` to a `string` value, which is the tab identifier. You can use any identifier you like here. However, if you use `Office` for `ControlIdType`, then you must set `RibbonTab.ControlId.OfficeId` to a `string` value that matches one of the identifiers used in the Office product you are using. For example, in Excel you could set this property to `TabHome` to add groups to the Home tab, `TabInsert` for the Insert tab, and so on. The default for add-ins is `TabAddIns`, which will be shared by all add-ins.

Many tabs are available, especially in Outlook; you can download a series of spreadsheets containing the full list from: `www.microsoft.com/downloads/details.aspx?FamilyID=4329D9E9-4D11-46A5-898D-23E4F331E9AE&displaylang=en`.

Once you have decided where to put your ribbon groups, you can add any of the controls shown in the following table.

CONTROL	DESCRIPTION
`RibbonBox`	This is a container control that you can use to lay out other controls in a group. You can lay out controls in a `RibbonBox` horizontally or vertically by changing the `BoxStyle` property to `RibbonBoxStyle.Horizontal` or `RibbonBoxStyle.Vertical`.
`RibbonButton`	You can use this control to add a small or large button with or without a text label to a group. Set the `ControlSize` property to `RibbonControlSize.RibbonControlSizeLarge` or `RibbonControlSize.RibbonControlSizeRegular` to control the size. The button has a `Click` event handler that you can use to respond to interaction. You can also set the image to a custom image or to one of the images stored in the Office system (described following this table).
`RibbonButtonGroup`	This is a container control that represents a group of buttons. It can contain `RibbonButton`, `RibbonGallery`, `RibbonMenu`, `RibbonSplitButton`, and `RibbonToggleButton` controls.
`RibbonCheckBox`	A check box control with a `Click` event and a `Checked` property.

continues

(continued)

CONTROL	DESCRIPTION
`RibbonComboBox`	A combo box (combined text entry with drop-down list of items). Use the `Items` property for items, the `Text` property for the entered text, and the `TextChanged` event to respond to changed.
`RibbonDropDown`	A container that can contain `RibbonDropDownItem` and `RibbonButton` items, in `Items` and `Buttons` properties respectively. The buttons and items are formatted into a drop-down list. You use the `SelectionChanged` event to respond to interaction.
`RibbonEditBox`	A text box that users can use to enter or edit text in the `Text` property. This control has a `TextChanged` event.
`RibbonGallery`	As with `RibbonDropDown`, this control can contain `RibbonDropDownItem` and `RibbonButton` items, in `Items` and `Buttons` properties respectively. This control uses `Click` and `ButtonClick` events rather than the `SelectionChanged` event that `RibbonDropDown` has.
`RibbonLabel`	Simple text display, set with the `Label` property.
`RibbonMenu`	A pop-up menu that you can populate with other controls, such as `RibbonButton` and nested `RibbonMenu` controls, when it is open in design view. Handle events for the items on the menu.
`RibbonSeparator`	A simple separator used to customize control layout in groups.
`RibbonSplitButton`	Control that combines a `RibbonButton` or `RibbonToggleButton` with a `RibbonMenu`. Set the button style with `ButtonType`, which can be `RibbonButtonType.Button` or `RibbonButtonType.ToggleButton`. Use the `Click` event for the main button or individual button `Click` events in the menu to respond to interaction.
`RibbonToggleButton`	A button that can be in a selected or unselected state, as indicated by the `Checked` property. This control also has a `Click` event.

You can also set the `DialogBoxLauncher` property of a group so that an icon appears in the bottom right of the group. You can use this to display a dialog box as its name suggests, or to open a task pane, or to perform any other action you want. You add or remove this icon through the GroupView Tasks menu, as shown in Figure 49-9, which also shows some of the other controls in the previous table as they appear on a ribbon in design view.

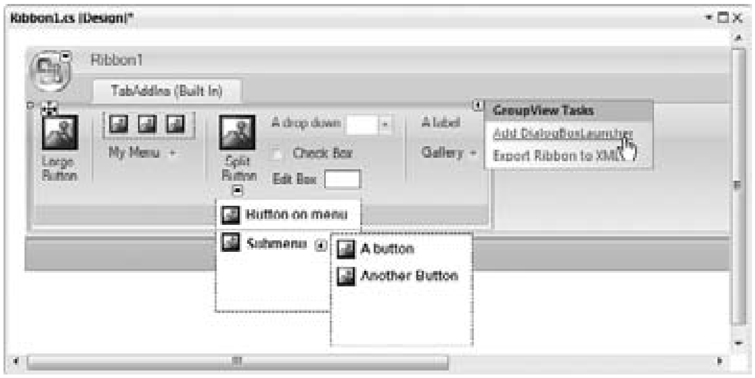

FIGURE 49-9

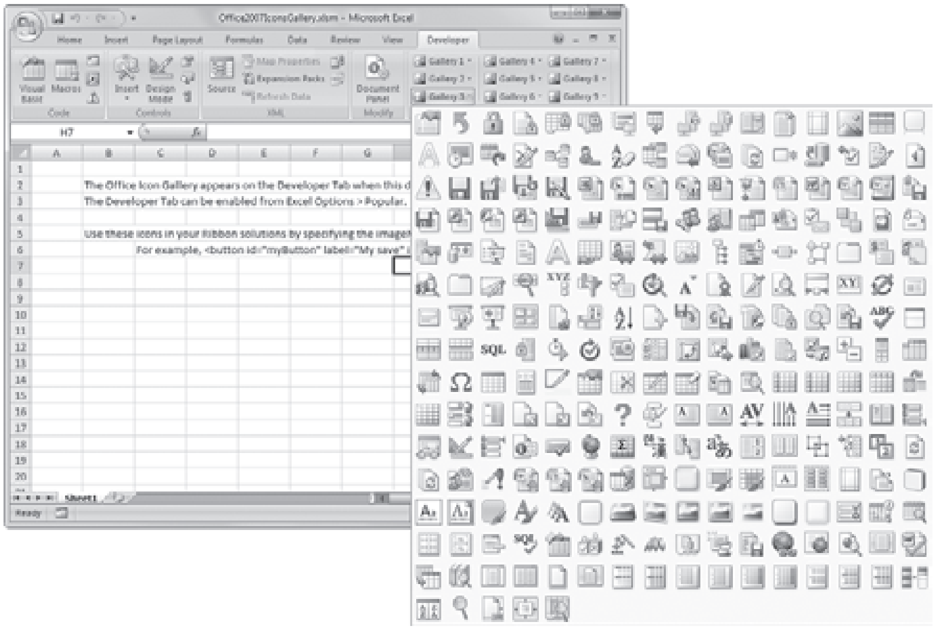
To set the image for a control, for example a `RibbonButton` control, you can either set the `Image` property to a custom image and `ImageName` to a name for the image (so that you can optimize image loading in an `OfficeRibbon.LoadImage` event hander), or you can use one of the built-in Office images. To do this, you set the `OfficeImageId` property to the ID of the image.

There are many images that you can use; you can download a spreadsheet that lists them from `www.microsoft.com/downloads/details.aspx?familyid=12b99325-93e8-4ed4-8385-74d0f7661318&displaylang=en`. Figure 49-10 shows a sample.



The Office Icon Gallery appears on the Developer Tab when this d

The Developer Tab can be enabled from Excel Options > Popular.

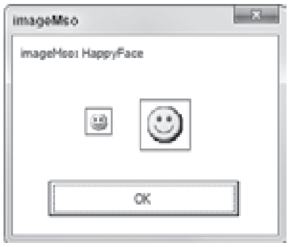
Use these icons in your Ribbon solutions by specifying the image

For example, <button id="myButton" label="My save"

FIGURE 49-10

Figure 49-10 shows the Developer ribbon tab, which you can enable through the Office button, in the Excel Options dialog box, on the Popular tab.

When you click on an image, a dialog box appears to tell you what the image ID is, as shown in Figure 49-11.



imageMso: HappyFace

FIGURE 49-11

The ribbon designer is extremely flexible, and you can provide pretty much any functionality that you would expect to find on an Office ribbon. However, if you want to customize your UI further, then you will want to use action and task panes, as you can create any UI and functionality you like there.

Action Panes and Custom Task Panes

You can use action and task panes to display content that is docked in the task pane area of the Office application interface. Task panes are used in application-level add-ins, and action panes are used in document-level customizations. Both task and action panes must inherit from `UserControl` objects, which means that you create a UI by using Windows Forms. You can also use a WPF UI if you host a WPF form in an `ElementHost` control on the `UserControl`.

To add an action pane to a document in a document-level customization, you add an instance of the action pane class to the `Controls` collection of the `ActionsPane` property of the document. For example:

```
public partial class ThisWorkbook
{
   private UserControl1 actionsPane;
```

```
      private void ThisWorkbook_Startup(object sender, System.EventArgs e)
      {
         Workbook wb = Globals.Factory.GetVstoObject(this.Application.ActiveWorkbook);
         wb.AcceptAllChanges();
         actionsPane = new UserControl1();
         this.ActionsPane.Controls.Add(actionsPane);
      }
      ...
   }
```

This code adds the actions pane when the document (in this case an Excel workbook) is loaded. You can also do this in, for example, a ribbon button event handler.

Custom task panes are added through the `ThisAddIn.CustomTaskPanes.Add()` method property in application-level add-in projects. This method also allows you to name the task window. For example:

```
   public partial class ThisAddIn
   {
      Microsoft.Office.Tools.CustomTaskPane taskPane;
      private void ThisAddIn_Startup(object sender, System.EventArgs e)
      {
         taskPane = this.CustomTaskPanes.Add(new UserControl1(), "My Task Pane");
         taskPane.Visible = true;
      }
      ...
   }
```

Note that the `Add()` method returns an object of type `Microsoft.Office.Tools.CustomTaskPane`. You can access the user control itself through the `Control` property of this object. You can also use other properties exposed by this type — for example, the `Visible` property as shown in the previous code — to control the task pane.

At this point, it is worth mentioning a slightly unusual feature of Office applications, and in particular, a difference between Word and Excel. For historical reasons, although both Word and Excel are MDI applications, the way in which these applications host documents is different. In Word, every document has a unique parent window. In Excel, every document shares the same parent window.

When you call the `CustomTaskPanes.Add()` method, the default behavior is to add the task pane to the currently active window. In Excel, this means that every document will display the task pane, as the same parent window is used for all of them. In Word, the situation is different. If you want the task pane to appear for every document, then you must add it to every window that contains a document.

To add the task pane to a specific document, you pass an instance of the `Microsoft.Office.Interop.Word.Window` class to the `Add()` method as a third parameter. You can obtain the window associated with a document through the `Microsoft.Office.Interop.Word.Document.ActiveWindow` property.

In the next section, you will see how to do this in practice.

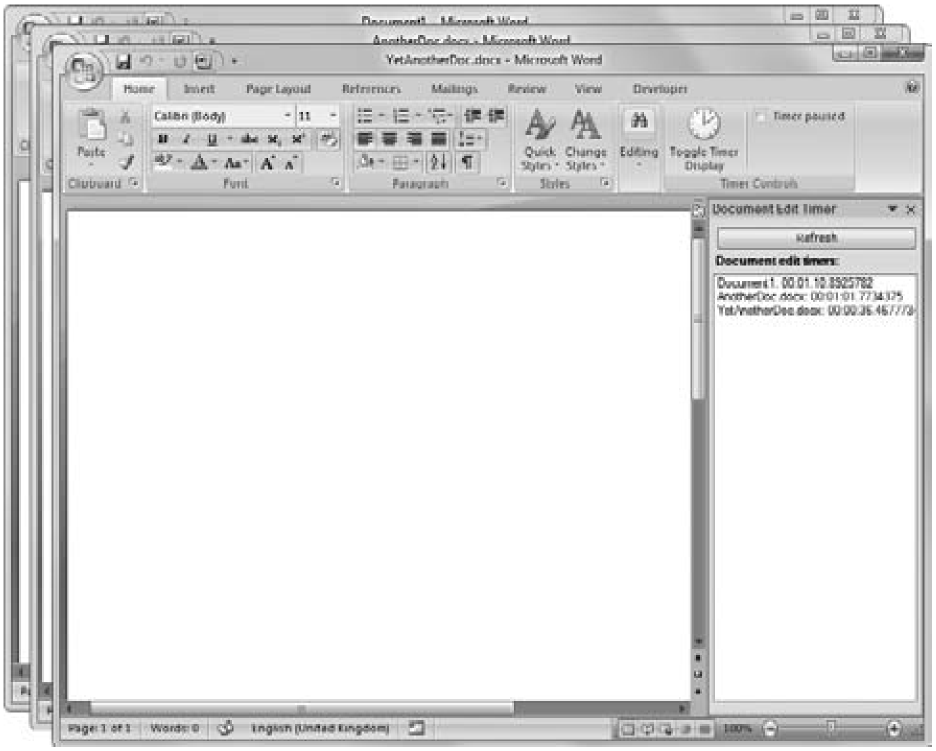
EXAMPLE APPLICATION

As mentioned in previous sections, the example code for this chapter includes an application called `WordDocEditTimer`, which maintains a list of edit times for Word documents. In this section, we examine the code for this application in detail, as it illustrates everything you've read about so far and includes some useful tips.

The general operation of this application is that whenever a document is created or loaded, a timer is started, which is linked to the document name. If you close a document, then the timer for that document pauses. If you open a document that has previously been timed, then the timer resumes. Also, if you use Save As to save a document with a different filename, then the timer is updated to use the new filename.

This application is a Word application-level add-in, and uses a custom task pane and a ribbon menu. The ribbon menu contains a button that you can use to turn the task pane on and off and a check box that enables you to pause the timer for the currently active document. The group containing these controls is appended to the Home ribbon tab. The task pane displays a list of active timers.

This user interface is shown in Figure 49-12.



```
Document1: 00:01:10.8925782
AnotherDoc.docx: 00:01:01.7734375
YetAnotherDoc.docx: 00:00:36.467773
```

FIGURE 49-12

Timers are maintained through the `DocumentTimer` class:

```
public class DocumentTimer
{
   public Word.Document Document { get; set; }
   public DateTime LastActive { get; set; }
   public bool IsActive { get; set; }
   public TimeSpan EditTime { get; set; }
}
```

code snippet DocumentTimer.cs

This keeps a reference to a `Microsoft.Office.Interop.Word.Document` interface as well as the total edit time, whether the timer is active, and the time it last became active. The `ThisAddIn` class maintains a collection of these objects, associated with document names:

```
public partial class ThisAddIn
{
   private Dictionary<string, DocumentTimer> documentEditTimes;
```

code snippet ThisAddIn.cs

Each timer can therefore be located by document reference or document name. This is necessary because document references allow you to keep track of document name changes (there is no event that you can use to monitor this), and document names allow you to keep track of closed and reopened documents.

The ThisAddIn class also maintains a list of CustomTaskPane objects (as noted earlier, one is required for each window in Word):

```
private List<Tools.CustomTaskPane> timerDisplayPanes;
```

When the add-in starts, the ThisAddIn_Startup() method performs several tasks. First, it initializes the two collections:

```
private void ThisAddIn_Startup(object sender, System.EventArgs e)
{
   // Initialize timers and display panels
   documentEditTimes = new Dictionary<string, DocumentTimer>();
   timerDisplayPanes = new List<Microsoft.Office.Tools.CustomTaskPane>();
```

Next, it adds several event handlers through the ApplicationEvents4_Event interface:

```
   // Add event handlers
   Word.ApplicationEvents4_Event eventInterface = this.Application;
   eventInterface.DocumentOpen += new Microsoft.Office.Interop.Word
      .ApplicationEvents4_DocumentOpenEventHandler(
         eventInterface_DocumentOpen);
   eventInterface.NewDocument += new Microsoft.Office.Interop.Word
      .ApplicationEvents4_NewDocumentEventHandler(
         eventInterface_NewDocument);
   eventInterface.DocumentBeforeClose += new Microsoft.Office.Interop.Word
      .ApplicationEvents4_DocumentBeforeCloseEventHandler(
         eventInterface_DocumentBeforeClose);
   eventInterface.WindowActivate += new Microsoft.Office.Interop.Word
      .ApplicationEvents4_WindowActivateEventHandler(
         eventInterface_WindowActivate);
```

These event handlers are used to monitor documents as they are opened, created, and closed, and also to ensure that the Pause check box is kept up-to-date on the ribbon. This latter functionality is achieved by keeping track of window activations with the WindowActivate event.

The last task performed in this event handler is to start monitoring the current document and add the custom task panel to the window containing the document:

```
   // Start monitoring active document
   MonitorDocument(this.Application.ActiveDocument);
   AddTaskPaneToWindow(this.Application.ActiveDocument.ActiveWindow);
}
```

The MonitorDocument() utility method adds a timer for a document:

```
internal void MonitorDocument(Word.Document Doc)
{
   // Monitor doc
   documentEditTimes.Add(Doc.Name, new DocumentTimer
   {
      Document = Doc,
      EditTime = new TimeSpan(0),
      IsActive = true,
      LastActive = DateTime.Now
   });
}
```

This method simply creates a new DocumentTimer for the document. The DocumentTimer references the document, has zero edit time, is active, and was made active at the current time. It then adds this timer to the documentEditTimes collection and associates it with the document name.

The AddTaskPaneToWindow() method adds the custom task pane to a window. This method starts by checking the existing task panes to ensure that there isn't one in the window already. Also, one other strange feature of Word is that if you immediately open an old document after loading the application, the default Document1 document vanishes, without raising a close event. This can lead to an exception being raised when the window for the task pane that was in the document is accessed, so the method also checks for the ArgumentNullException that indicates this:

```
private void AddTaskPaneToWindow(Word.Window Wn)
{
   // Check for task pane in window
   Tools.CustomTaskPane docPane = null;
   Tools.CustomTaskPane paneToRemove = null;
   foreach (Tools.CustomTaskPane pane in timerDisplayPanes)
   {
      try
      {
         if (pane.Window == Wn)
         {
            docPane = pane;
            break;
         }
      }
      catch (ArgumentNullException)
      {
         // pane.Window is null, so document1 has been unloaded.
         paneToRemove = pane;
      }
   }
```

If an exception is thrown, then the offending task pane is removed from the collection:

```
   // Remove pane if necessary
   timerDisplayPanes.Remove(paneToRemove);
```

If no task pane was found for the window, then the method finishes by adding one:

```
   // Add task pane to doc
   if (docPane == null)
   {
      Tools.CustomTaskPane pane = this.CustomTaskPanes.Add(
         new TimerDisplayPane(documentEditTimes),
         "Document Edit Timer",
         Wn);
      timerDisplayPanes.Add(pane);
      pane.VisibleChanged +=
         new EventHandler(timerDisplayPane_VisibleChanged);
   }
}
```

The added task pane is an instance of the TimerDisplayPane class. You will look at this class shortly. It is added with the name "Document Edit Timer." Also, an event handler is added for the VisibleChanged event of the CustomTaskPane that you obtain after calling the CustomTaskPanes.Add() method. This enables you to refresh the display when it first appears:

```
private void timerDisplayPane_VisibleChanged(object sender, EventArgs e)
{
   // Get task pane and toggle visibility
   Tools.CustomTaskPane taskPane = (Tools.CustomTaskPane)sender;
   if (taskPane.Visible)
   {
      TimerDisplayPane timerControl = (TimerDisplayPane)taskPane.Control;
      timerControl.RefreshDisplay();
   }
}
```

The TimerDisplayPane class exposes a RefreshDisplay() method that is called in the preceding code. This method, as its name suggests, refreshes the display of the timerControl object.

Next, there is the code that ensures that all documents are monitored. First, when a new document is created, the eventInterface_NewDocument() event handler is called, and the document is monitored by calling the `MonitorDocument()` and `AddTaskPaneToWindow()` methods, which you've already seen.

```
private void eventInterface_NewDocument(Word.Document Doc)
{
   // Monitor new doc
   MonitorDocument(Doc);
   AddTaskPaneToWindow(Doc.ActiveWindow);
```

This method also clears the Pause check box in the ribbon menu as new documents start with the time running. This is achieved through a utility method, `SetPauseStatus()`, which is defined on the ribbon:

```
   // Set checkbox
   Globals.Ribbons.TimerRibbon.SetPauseStatus(false);
}
```

Just before a document is closed, the `eventInterface_DocumentBeforeClose()` event handler is called. This method freezes the timer for the document, updates the total edit time, clears the `Document` reference, and removes the task pane from the document window (with `RemoveTaskPaneFromWindow()`, detailed shortly) before the document is closed.

```
private void eventInterface_DocumentBeforeClose(Word.Document Doc,
   ref bool Cancel)
{
   // Freeze timer
   documentEditTimes[Doc.Name].EditTime += DateTime.Now
      - documentEditTimes[Doc.Name].LastActive;
   documentEditTimes[Doc.Name].IsActive = false;
   documentEditTimes[Doc.Name].Document = null;
   // Remove task pane
   RemoveTaskPaneFromWindow(Doc.ActiveWindow);
}
```

When a document is opened, the `eventInterface_DocumentOpen()` method is called. There is a little more work to be done here, as before monitoring the document, the method must determine whether a timer already exists for the document by looking at its name:

```
private void eventInterface_DocumentOpen(Word.Document Doc)
{
   if (documentEditTimes.ContainsKey(Doc.Name))
   {
      // Monitor old doc
      documentEditTimes[Doc.Name].LastActive = DateTime.Now;
      documentEditTimes[Doc.Name].IsActive = true;
      documentEditTimes[Doc.Name].Document = Doc;
      AddTaskPaneToWindow(Doc.ActiveWindow);
   }
```

If the document isn't already being monitored, then a new monitor is configured as for a new document:

```
   else
   {
      // Monitor new doc
      MonitorDocument(Doc);
      AddTaskPaneToWindow(Doc.ActiveWindow);
   }
}
```

The `RemoveTaskPaneFromWindow()` method is used to remove the task pane from a window. The code for this method first checks that a task pane exists for the specified window:

```
private void RemoveTaskPaneFromWindow(Word.Window Wn)
{
   // Check for task pane in window
   Tools.CustomTaskPane docPane = null;
```

```
        foreach (Tools.CustomTaskPane pane in timerDisplayPanes)
        {
           if (pane.Window == Wn)
           {
              docPane = pane;
              break;
           }
        }
```

If a task window is found, then it is removed by calling the `CustomTaskPanes.Remove()` method. It is also removed from the local collection of task pane references.

```
        // Remove document task pane
        if (docPane != null)
        {
           this.CustomTaskPanes.Remove(docPane);
           timerDisplayPanes.Remove(docPane);
        }
     }
```

The last event handler in this class is `eventInterface_WindowActivate()`, called when a window is activated. This method gets the timer for the active document (testing first to see if there is one, as new documents may not have had one added at the time this method is called) and sets the check box on the ribbon menu so that the check box is kept updated for the document:

```
     private void eventInterface_WindowActivate(Word.Document Doc,
        Word.Window Wn)
     {
        if (documentEditTimes.ContainsKey(this.Application.ActiveDocument.Name))
        {
           // Ensure pause checkbox in ribbon is accurate, start by getting timer
           DocumentTimer documentTimer =
              documentEditTimes[this.Application.ActiveDocument.Name];
           // Set checkbox
           Globals.Ribbons.TimerRibbon.SetPauseStatus(!documentTimer.IsActive);
        }
     }
```

The code for `ThisAddIn` also includes two utility methods. The first of these, `ToggleTaskPaneDisplay()`, is used to show or hide the display of the task pane for the currently active document by setting the `CustomTaskPane.Visible` property.

```
     internal void ToggleTaskPaneDisplay()
     {
        // Ensure window has task window
        AddTaskPaneToWindow(this.Application.ActiveDocument.ActiveWindow);
        // toggle document task pane
        Tools.CustomTaskPane docPane = null;
        foreach (Tools.CustomTaskPane pane in timerDisplayPanes)
        {
           if (pane.Window == this.Application.ActiveDocument.ActiveWindow)
           {
              docPane = pane;
              break;
           }
        }
        docPane.Visible = !docPane.Visible;
     }
```

The `ToggleTaskPaneDisplay()` method shown in the preceding code is called by event handlers on the ribbon control, as you will see shortly.

Finally, the class has another method that is called from the ribbon menu, which enables ribbon controls to pause or resume the timer for a document:

```
        internal void PauseOrResumeTimer(bool pause)
        {
           // Get timer
           DocumentTimer documentTimer =
              documentEditTimes[this.Application.ActiveDocument.Name];
           if (pause && documentTimer.IsActive)
           {
              // Freeze timer
              documentTimer.EditTime += DateTime.Now - documentTimer.LastActive;
              documentTimer.IsActive = false;
           }
           else if (!pause && !documentTimer.IsActive)
           {
              // Resume timer
              documentTimer.IsActive = true;
              documentTimer.LastActive = DateTime.Now;
           }
        }
     }
```

The only other code in this class definition is an empty event handler for `Shutdown`, and the VSTO-generated code to hook up the `Startup` and `Shutdown` event handlers.

Next, the ribbon in the project, `TimerRibbon`, is laid out, as shown in Figure 49-13.

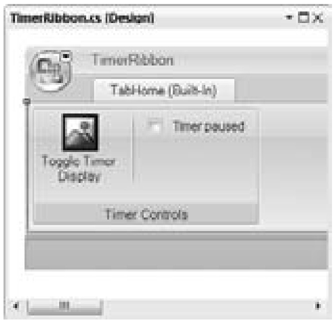


FIGURE 49-13

This ribbon contains a `RibbonButton`, a `RibbonSeparator`, a `RibbonCheckBox`, and a `DialogBoxLauncher`. The button uses the large display style, and has an `OfficeImageId` of `StartAfter Previous`, which displays the clock face shown in Figure 49-13. (These images are not visible at design time.) The ribbon uses the TabHome tab type, which causes its contents to be appended to the Home tab.

The ribbon has three event handlers, each of which calls on one of the utility methods in `ThisAddIn` described earlier:

```
     private void group1_DialogLauncherClick(object sender,
        RibbonControlEventArgs e)
     {
        // Show or hide task pane
        Globals.ThisAddIn.ToggleTaskPaneDisplay();
     }
     private void pauseCheckBox_Click(object sender, RibbonControlEventArgs e)
     {
        // Pause timer
        Globals.ThisAddIn.PauseOrResumeTimer(pauseCheckBox.Checked);
     }
     private void toggleDisplayButton_Click(object sender,
        RibbonControlEventArgs e)
     {
        // Show or hide task pane
        Globals.ThisAddIn.ToggleTaskPaneDisplay();
     }
```

code snippet TimerRibbon.cs

The ribbon also includes its own utility method, `SetPauseStatus()`, which as you saw earlier is called by code in `ThisAddIn` to select or clear the check box:

```
     internal void SetPauseStatus(bool isPaused)
     {
        // Ensure checkbox is accurate
        pauseCheckBox.Checked = isPaused;
     }
```

The other component in this solution is the `TimerDisplayPane` user control that is used in the task pane. The layout of this control is shown in Figure 49-14.

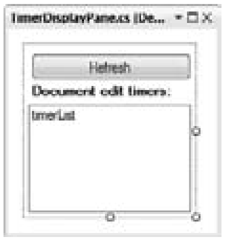

FIGURE 49-14

This control includes a button, a label, and a list box — not the most exciting of displays, although it would be simple enough to replace it with, for example, a prettier WPF control.

The code for the control keeps a local reference to the document timers, which is set in the constructor:

```
public partial class TimerDisplayPane : UserControl
{
   private Dictionary<string, DocumentTimer> documentEditTimes;
   public TimerDisplayPane()
   {
      InitializeComponent();
   }
   public TimerDisplayPane(Dictionary<string, DocumentTimer>
      documentEditTimes): this()
   {
      // Store reference to edit times
      this.documentEditTimes = documentEditTimes;
   }
```

code snippet TimerDisplayPane.cs

The button event handler calls the `RefreshDisplay()` method to refresh the timer display:

```
   private void refreshButton_Click(object sender, EventArgs e)
   {
      RefreshDisplay();
   }
```

The `RefreshDisplay()` method is also called from `ThisAddIn`, as you saw earlier. It is a surprisingly complicated method considering what it does. It also checks the list of monitored documents against the list of loaded documents and corrects any problems. This sort of code is often necessary in VSTO applications, as the interface with the COM Office object model occasionally doesn't work quite as it should. The rule of thumb here is to code defensively.

The method starts by clearing the current list of timers in the `timerList` list box:

```
   internal void RefreshDisplay()
   {
      // Clear existing list
      this.timerList.Items.Clear();
```

Next, the monitors are checked. The method iterates through each document in the `Globals.ThisAddIn.Application.Documents` collection and determines if the document is monitored, unmonitored, or monitored but has had a name change since the last refresh.

Finding monitored documents simply involves checking the document name against the document names in the `documentEditTimes` collection of keys:

```
      // Ensure all docs are monitored
      foreach (Word.Document doc in Globals.ThisAddIn.Application.Documents)
      {
         bool isMonitored = false;
         bool requiresNameChange = false;
         DocumentTimer oldNameTimer = null;
         string oldName = null;
```

```
            foreach (string documentName in documentEditTimes.Keys)
            {
               if (doc.Name == documentName)
               {
                  isMonitored = true;
                  break;
               }
```

If the names don't match, then the document references are compared, which enables you to detect name changes to documents, as shown in the following code:

```
               else
               {
                  if (documentEditTimes[documentName].Document == doc)
                  {
                     // Monitored, but name changed!
                     oldName = documentName;
                     oldNameTimer = documentEditTimes[documentName];
                     isMonitored = true;
                     requiresNameChange = true;
                     break;
                  }
               }
            }
```

For unmonitored documents, a new monitor is created:

```
            // Add monitor if not monitored
            if (!isMonitored)
            {
               Globals.ThisAddIn.MonitorDocument(doc);
            }
```

Whereas documents with name changes are re-associated with the monitor used for the old named document:

```
            // Rename if necessary
            if (requiresNameChange)
            {
               documentEditTimes.Remove(oldName);
               documentEditTimes.Add(doc.Name, oldNameTimer);
            }
         }
```

After reconciling the document edit timers, a list is generated. This code also detects whether referenced documents are still loaded, and pauses the timer for documents that aren't by setting the `IsActive` property to `false`. Again, this is defensive programming.

```
         // Create new list
         foreach (string documentName in documentEditTimes.Keys)
         {
            // Check to see if doc is still loaded
            bool isLoaded = false;
            foreach (Word.Document doc in
               Globals.ThisAddIn.Application.Documents)
            {
               if (doc.Name == documentName)
               {
                  isLoaded = true;
                  break;
               }
            }
            if (!isLoaded)
            {
               documentEditTimes[documentName].IsActive = false;
               documentEditTimes[documentName].Document = null;
            }
```

For each monitor, a list item is added to the list box that includes the document name and its total edit time:

```
            // Add item
            this.timerList.Items.Add(string.Format("{0}: {1}", documentName,
               documentEditTimes[documentName].EditTime +
               (documentEditTimes[documentName].IsActive ?
               (DateTime.Now — documentEditTimes[documentName].LastActive):
               new TimeSpan(0))));
         }
      }
   }
```

This completes the code in this example. This example has shown you how to use ribbon and task pane controls and how to maintain task panes in multiple Word documents. It has also illustrated many of the techniques covered earlier in the chapter.

SUMMARY

In this chapter you have learned how to use VSTO to create managed solutions for Office products.

In the first part of this chapter, you learned about the general structure of VSTO projects and the project types that you can create. You also saw the features that you can use to make VSTO programming easier.

In the next section, you looked, in great depth, at some of the features available in VSTO solutions and you saw how communication with the Office object model is achieved. You also looked at the namespaces and types available in VSTO and learned how to use those types to implement a variety of functionality. Then, you explored some of the code features of VSTO projects and how to use these features to get the effect you want.

After this, you moved on to the more practical side of things. You learned how add-ins are managed in Office applications and how to interact with the Office object model. You also saw how to customize the UI of your applications with ribbon menus, task panes, and action panes.

Finally, you explored an example application that illustrated the UI and interaction techniques that you learned earlier. The example contained a lot of code, but it included useful techniques, including how to manage task panes in multiple Word document windows.

50 Managed Add-In Framework

WHAT'S IN THIS CHAPTER?

- ➤ Architecture of the Managed Add-In Framework
- ➤ Defining a Contract
- ➤ Implementing a Pipeline
- ➤ Creating Add-Ins
- ➤ Hosting Add-Ins

This chapter describes in detail the Managed Add-In Framework (MAF) architecture and how to create add-ins and host add-ins using MAF. You can read about the architecture of MAF and what issues it solves by hosting add-ins, such as versioning, discovery, activation, and isolation. Then we discuss all the steps that are necessary to create the MAF pipeline that is used to connect the add-in with the host; how to create add-ins; and how to create a hosting application that uses add-ins.

MAF ARCHITECTURE

.NET 4 includes two technologies for creating and using add-ins. Probably you've already read Chapter 28, "Managed Extensibility Framework," where you saw how to create add-ins with the Managed Extensibility Framework (MEF). Applications using MEF can find add-ins during runtime from a directory or from within assemblies, and connect them using attributes. The difference from MAF is that MEF does not offer a separation of the add-in from the hosting application by using appdomains or different processes. This is where the MAF comes into play. However, to reach this, MAF adds higher complexity. If you would like to get the advantages of both MEF and MAF, you can combine these two technologies. Of course this also adds complexity.

When you create an application that allows you to add add-ins during runtime, you will need to deal with certain issues — for example, how to find the add-ins, and how to solve versioning issues so that the hosting application and the add-in can progress independently. In this section, you read about the issues of add-ins and how the architecture of MAF resolves them.

When you create a hosted application that dynamically loads assemblies that are added at a later time, there are several issues that must be dealt with, as shown in the table that follows.

ADD-INS ISSUES	DESCRIPTION
Discovery	How can new add-ins be found for the hosting application? There are several options. One way is to add information about add-ins to a configuration file. This has the disadvantage that the installation of new add-ins necessitates the changing of an existing configuration file. Another option is to just copy the assembly containing the add-in to a predefined directory and read information about the assembly with reflection. You can read more about reflection in Chapter 14, "Reflection."
Activation	With assemblies that are dynamically loaded, it is not possible to just use the `new` operator to create an instance. You can create such assemblies with the `Activator` class. Also, different activation options might apply if the add-in is loaded within a different application domain or a new process. Assemblies and application domains are described in Chapter 18, "Assemblies."
Isolation	An add-in can break the hosting application, as you've probably already seen with Internet Explorer crashes caused by various add-ins. Depending on the type of hosting application and how the add-ins are integrated, the add-in can be loaded within a different application domain or within a different process.
Lifetime	Cleaning up objects is the job of the garbage collector. However, the garbage collector cannot help here because add-ins might be active in a different application domain or a different process. Other ways to keep the object in memory are with reference count or leasing and sponsoring mechanisms.
Versioning	Versioning is a big issue with add-ins. Usually it should be possible for a new version of the host to still load old add-ins, and an old host should have the option to load new add-ins.

Now let's look at the architecture of MAF and how this framework resolves these issues. The design of MAF was influenced by these goals:

- ➤ It should be easy to develop add-ins.
- ➤ Finding add-ins during runtime should be performant.
- ➤ Developing hosts should be an easy process as well, but may not be as easy as developing add-ins.
- ➤ The add-in and the host application should progress independently.

MAF solves the issues using a pipeline that uses contracts in its center. We will discuss how MAF deals with discovery to find add-ins; how add-ins are activated; how they can be kept alive; and how you can do versioning.

Pipeline

The MAF architecture is based on a pipeline of seven assemblies. This pipeline resolves the versioning issues with add-ins. Because the assemblies from the pipeline have a very light dependency, it is possible that the contract, the hosting, and the add-in applications progress with new versions completely independent of one another.

Figure 50-1 shows the pipeline of the MAF architecture. In the center is the contract assembly. This assembly contains a contract interface that lists methods and properties that must be implemented by the add-in and can be called by the host. The left side of the contract is the host side, and the right is the add-in side. In the figure, you can see the dependencies between the assemblies. The host assembly, shown leftmost, does not have a real dependency to the contract assembly; the same is true of the add-in assembly. Both do not really implement the interface that is defined by the contract. Instead, they just have a reference to a view assembly. The host application references the host view; the add-in references the add-in view. The views contain abstract view classes that define methods and properties as defined by the contract.

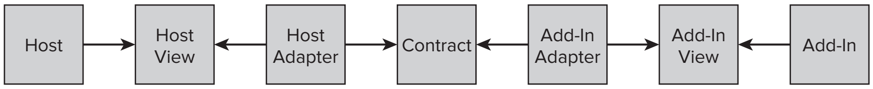

FIGURE 50-1

Figure 50-2 shows the relationship of the classes from the pipeline. The host class has an association with the abstract host view class and invokes its methods. The abstract host view class is implemented by the host adapter. Adapters make the connection between the views and the contract. The add-in adapter implements the methods and properties of the contract. This adapter contains a reference to the add-in view and forwards calls from the host side to the add-in view. The host adapter class defines a concrete class that derives from the abstract base class of the host view to implement the methods and properties. This adapter includes a reference to the contract to forward calls from the view to the contract.

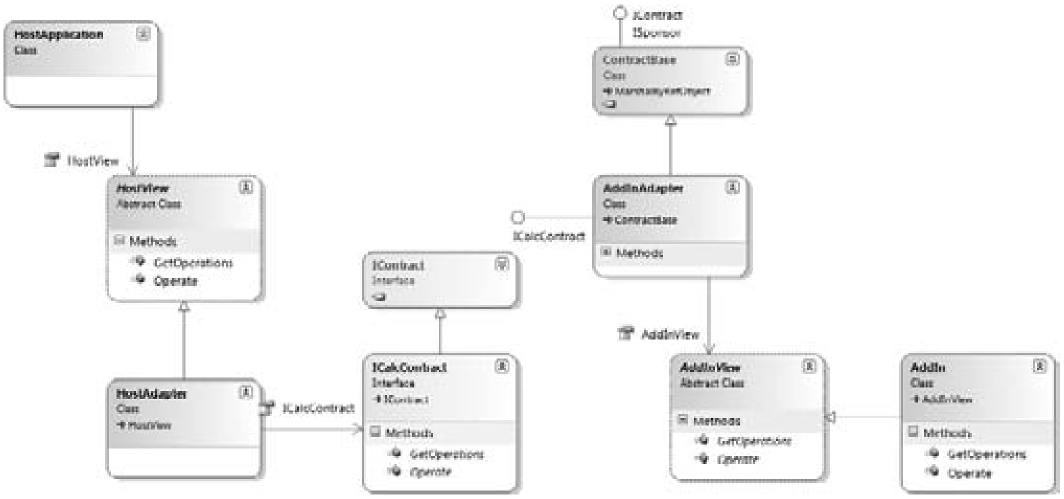

FIGURE 50-2

With this model it is possible that the add-in side and the host side emerge completely independent of each other. Just the mapping layer needs to adapt. For example, if a new version of the host is done that uses completely new methods and properties, the contract can still stay the same and only the adapter needs to change. It is also possible that a new contract is defined. Adapters can change, or several contracts can be used in parallel.

Discovery

How can new add-ins be found for the hosting application? The MAF architecture uses a predefined directory structure to find add-ins and the other assemblies of the pipeline. The components of the pipeline must be stored in these subdirectories:

- ➤ `HostSideAdapters`
- ➤ `Contracts`
- ➤ `AddInSideAdapters`
- ➤ `AddInViews`
- ➤ `AddIns`

All these directories with the exception of the `AddIns` directory directly contain the assembly of the specific part of the pipeline. The `AddIns` directory contains subdirectories for every add-in assembly. You can also store add-ins in directories that are completely independent of the other pipeline components.

The assemblies of the pipeline are not just loaded dynamically to get all the information about the add-in using reflection. With many add-ins, this would increase the startup time of the hosting application. Instead, MAF uses a cache with information about the pipeline components. The cache is created by the program installing the add-in or by the hosting application if the hosting application has write access to the directory of the pipeline.

The cache information about the pipeline components is created by invoking methods of the `AddInStore` class. The method `Update()` finds new add-ins that are not already listed with the store files. The `Rebuild()` method rebuilds the complete binary store file with information about the add-ins.

The following table lists the members of the `AddInStore` class.

ADDINSTORE MEMBERS	DESCRIPTION
`Rebuild()` `RebuildAddIns()`	The `Rebuild()` method rebuilds the cache for all components of the pipeline. If the add-ins are stored in a different directory, the method `RebuildAddIns()` can be used to rebuild the cache of the add-ins.
`Update()` `UpdateAddIns()`	While the `Rebuild()` method rebuilds the complete cache of the pipeline, the `Update` method just updates the cache with information about new pipeline components. The `UpdateAddIns()` method updates the cache of the add-ins only.
`FindAddIn()` `FindAddIns()`	These methods are used to find add-ins by using the cache. The method `FindAddIns()` returns a collection of all add-ins that match the host view. The `FindAddIn()` method returns a specific add-in.

Activation and Isolation

The `FindAddIns()` method of the `AddInStore` class returns a collection of `AddInToken` objects that represent an add-in. With the `AddInToken` class, you can access information about the add-in, such as its name, description, publisher, and version. You can activate the add-in by using the `Activate()` method. The following table lists properties and methods of the `AddInToken` class.

ADDINTOKEN MEMBERS	DESCRIPTION
`Name` `Publisher` `Version` `Description`	The `Name`, `Publisher`, `Version`, and `Description` properties of the `AddInToken` class return information about an add-in that was assigned to the add-in with the attribute `AddInAttribute`.
`AssemblyName`	`AssemblyName` returns the name of the assembly that contains the add-in.
`EnableDirectConnect`	With the property `EnableDirectConnect`, you can set a value to indicate that the host should directly connect to the add-in instead of using the components of the pipeline. This is only possible if the add-in and the host are running in the same application domain, and the types of the add-in view and the host view are the same. With this, it is still required that all components of the pipeline exist.
`QualificationData`	The add-in can mark appdomain and security requirements with the attribute `QualificationDataAttribute`. The add-in can list requirements for security and isolation requirements. For example, `[QualificationData ("Isolation", "NewAppDomain")]` means that the add-in must be hosted in a new process. You can read this information from the `AddInToken` to activate the add-in with the specified requirements. In addition to appdomain and security requirements, you can use this attribute to pass custom information through the pipeline.
`Activate()`	The add-in is activated with the `Activate()` method. With parameters of this method, you can define if the add-in should be loaded inside a new application domain or a new process. You can also define what permissions the add-in gets.

One add-in can break the complete application. You may have seen Internet Explorer crash because of a failing add-in. Depending on the application type and the add-in type, you can avoid this by letting the add-in run within a different application domain or within a different process. MAF gives you several options here. You can activate the add-in in a new application domain or a new process. The new application domain might also have restricted permissions.

The `Activate()` method of the `AddInToken` class has several overloads where you can pass the environment into which the add-in should be loaded. The different options are listed in the following table.

PARAMETERS OF ADDINTOKEN.ACTIVATE()	DESCRIPTION
`AppDomain`	You can pass a new application domain into which the add-in should be loaded. This way, you can make it independent of the host application, and it can also be unloaded with the application domain.
`AddInSecurityLevel`	If the add-in should run with different security levels, you can pass a value of the `AddInSecurityLevel` enumeration. Possible values are `Internet`, `Intranet`, `FullTrust`, and `Host`.
`PermissionSet`	If the predefined security levels are not specific enough, you can assign a `PermissionSet` to the appdomain of the add-in.
`AddInProcess`	Add-ins can also run within a different process from that of the hosting application. You can pass a new `AddInProcess` to the `Activate()` method. The new process can shut down if all add-ins are unloaded, or it can keep running. This is an option that can be set with the property `KeepAlive`.
`AddInEnvironment`	Passing an `AddInEnvironment` object is another option for defining the application domain where the add-in should be loaded. With the constructor of `AddInEnvironment`, you can pass an `AppDomain` object. You can also get an existing `AddInEnvironment` of an add-in with the `AddInEnvironment` property of the `AddInController` class.

Application domains are explained in Chapter 18, "Assemblies."

The type of application may restrict the choices you have. WPF add-ins currently do not support crossing processes. With Windows Forms, it is not possible to have Windows controls connected across different application domains.

Let's get into the steps of the pipeline when the `Activate()` method of an `AddInToken` is invoked:

1. The application domain is created with the permissions specified.
2. The assembly of the add-in is loaded into the new application domain with the `Assembly.LoadFrom()` method.
3. The default constructor of the add-in is invoked by using reflection. Because the add-in derives from the base class that is defined with the add-in view, the assembly of the view is loaded as well.
4. An instance of the add-in side adapter is constructed. The instance of the add-in is passed to the constructor of the adapter, so the adapter can connect the contract to the add-in. The add-in adapter derives from the base class `MarshalByRefObject`, so it can be invoked across application domains.
5. The activation code returns a proxy to the add-in side adapter to the application domain of the hosting application. Because the add-in adapter implements the contract interface, the proxy contains methods and properties of the contract interface.

6. An instance of the host side adapter is constructed in the application domain of the hosting application. The proxy of the add-in side adapter is passed to the constructor. The activation finds the type of host-side adapter from the add-in token.

The host-side adapter is returned to the hosting application.

Contracts

Contracts define the boundary between the host side and the add-in side of the MAF architecture. Contracts are defined with an interface that must be derived from the base interface `IContract`. The contract should be well thought out in that it supports flexible add-in scenarios as needed.

Contracts are not versionable and may not be changed so that previous add-in implementations can still run in newer hosts. New versions are created by defining a new contract.

There's some restriction on the types that you can use with the contract. The restriction exists because of versioning issues and also because application domains are crossed from the hosting application to the add-in. The types need to be safe and versionable, and able to pass it across the boundaries (application domain or cross-process) to pass it between hosts and add-ins.

Possible types that can be passed with a contract are:

- Primitive types
- Other contracts
- Serializable system types
- Simple serializable custom types. These custom types can consist of primitive types or contracts and may not have an implementation.

The members of the `IContract` interface are explained in the following table.

ICONTRACT MEMBERS	DESCRIPTION
`QueryContract()`	With `QueryContract()` it is possible to query a contract to verify if another contract is implemented as well. An add-in can support several contracts.
`RemoteToString()`	The parameter of `QueryContract()` requires a string representation of the contract. `RemoteToString()` returns a string representation of the current contract.
`AcquireLifetimeToken()` `RevokeLifetimeToken()`	The client invokes `AcquireLifetimeToken()` to keep a reference to the contract. `AcquireLifetimeToken()` increments a reference count. `RevokeLifetimeToken()` decrements a reference count.
`RemoteEquals()`	`RemoteEquals()` can be used to compare two contract references.

Contract interfaces are defined in the namespaces `System.AddIn.Contract`, `System.AddIn.Contract.Collections`, and `System.AddIn.Contract.Automation`. The following table lists contract interfaces that you can use with a contract.

CONTRACT	DESCRIPTION
`IListContract<T>`	The `IListContract<T>` can be used to return a list of contracts.
`IEnumeratorContract<T>`	`IEnumeratorContract<T>` is used to enumerate the elements of a `IListContract<T>`.
`IServiceProviderContract`	An add-in can offer services for other add-ins. Add-ins that offer services are known as service providers and implement the interface `IServiceProviderContract`. With the method `QueryService()` an add-in implementing this interface can be queried for services offered.

CONTRACT	DESCRIPTION
`IProfferServiceContract`	`IProfferServiceContract` is the interface offered by a service provider in conjunction with `IServiceProviderContract`. `IProfferServiceContract` defines the methods `ProfferService()` and `RevokeService()`. `ProfferService()` adds an `IServiceProviderContract` to the services offered, `RevokeService()` removes it.
`INativeHandleContract`	This interface provides access to native window handles with the `GetHandle()` method. This contract is used with WPF hosts to use WPF add-ins.

Lifetime

How long does an add-in need to be loaded? How long is it used? When is it possible to unload the application domain? There are several options to resolve this. One option is to use reference counts. Every use of the add-in increments the reference count. If the reference count decrements to zero, the add-in can be unloaded. Another option is to use the garbage collector. If the garbage collector runs, and there's no more reference to an object, the object is the target of garbage collection. .NET Remoting is using a leasing mechanism and a sponsor to keep objects alive. As soon as the leasing time ends, sponsors are asked if the object should stay alive.

With add-ins, there's a specific issue for unloading add-ins because they can run in different application domains and also in different processes. The garbage collector cannot work across different processes. MAF is using a mixed model for lifetime management. Within a single application domain, garbage collection is used. Within the pipeline, an implicit sponsorship is used, but reference counting is available from the outside to control the sponsor.

Let's consider a scenario where the add-in is loaded into a different application domain. Within the host application, the garbage collector cleans up the host view and the host side adapter when the reference is not needed anymore. For the add-in side, the contract defines the methods `AcquireLifetimeToken()` and `RevokeLifetimeToken()` to increment and decrement the reference count of the sponsor. These methods do not just increment and decrement a value, which could lead to the release of an object too early if one party called the revoke method too often. Instead, `AcquireLifetimeToken()` returns an identifier for the lifetime token, and this identifier must be used to invoke the `RevokeLifetimeToken()` method. So these methods are always called in pairs.

Usually you do not have to deal with invoking the `AcquireLifetimeToken()` and `RevokeLifetimeToken()` methods. Instead, you can use the `ContractHandle` class, which invokes `AcquireLifetimeToken()` in the constructor and `RevokeLifetimeToken()` in the finalizer.

In scenarios where the add-in is loaded in a new application domain, it is possible to get rid of the loaded code when the add-in is not needed anymore. MAF uses a simple model to designate one add-in as the owner of the application domain to unload the application domain if the add-in is not needed anymore. An add-in is the owner of the application domain if the application domain is created when the add-in is activated. The application domain is not unloaded automatically if it was created previously.

The class `ContractHandle` is used in the host-side adapter to add a reference count to the add-in. The members of this class are explained in the following table.

CONTRACTHANDLE MEMBERS	DESCRIPTION
`Contract`	In the construction of the `ContractHandle` class, an object implementing `IContract` can be assigned to keep a reference to it. The `Contract` property returns this object.
`Dispose()`	The `Dispose()` method can be called instead of waiting for the garbage collector to do the finalization to revoke the lifetime token.
`AppDomainOwner()`	`AppDomainOwner()` is a static method of the `ContractHandle` class that returns the add-in adapter if it owns the application domain that is passed with the method.
`ContractOwnsAppDomain()`	With the static method `ContractOwnsAppDomain()`, you can verify if the specified contract is an owner of the application domain. Thus, the application domain gets unloaded when the contract is disposed of.

Versioning

Versioning is a very big issue with add-ins. The host application is developed further, as are the add-ins. One requirement for an add-in is that it should be possible that a new version of the host application can still load old versions of add-ins. This should work in the other direction as well: older hosts should run newer versions of add-ins. But what if the contract changes?

`System.AddIn` is completely independent from the implementation of the host application and add-ins. This is done with a pipeline concept that consists of seven parts.

ADD-IN SAMPLE

Let's start a simple sample of a hosting application that can load calculator add-ins. The add-ins can support different calculation operations that are offered by other add-ins.

You need to create a solution with six library projects and one console application. The projects of the sample application are listed in the following table. The table lists the assemblies that need to be referenced. With the references to the other projects within the solution, you need to set the property Copy Local to False, so that the assembly does not get copied. One exception is the `HostApp` console project, which needs a reference to the `HostView` project. This assembly needs to be copied so that it can be found from the host application. Also, you need to change the output path of the generated assemblies so that the assemblies are copied to the correct directories of the pipeline.

PROJECT	REFERENCES	OUTPUT PATH	DESCRIPTION
`CalcContract`	`System.AddIn.Contract`	`.\Pipeline\Contracts\`	This assembly contains the contract for communication with the add-in. The contract is defined with an interface.
`CalcView`	`System.AddIn`	`.\Pipeline\AddInViews\`	The `CalcView` assembly contains an abstract class that is referenced by the add-in. This is the add-in side of the contract.
`CalcAddIn`	`System.AddIn` `CalcView`	`.\Pipeline\AddIns\CalcAddIn\`	`CalcAddIn` is the add-in project that references the add-in view assembly. This assembly contains the implementation of the add-in.

PROJECT	REFERENCES	OUTPUT PATH	DESCRIPTION
`CalcAddInAdapter`	`System.AddIn` `System.AddIn.Contract` `CalcView` `CalcContract`	`.\Pipeline\AddInSideAdapters\`	`CalcAddInAdapter` connects the add-in view and the contract assembly and maps the contract to the add-in view.
`HostView`			The assembly containing the abstract class of the host view does not need to reference any add-in assembly and also does not have a reference to another project in the solution.
`HostAdapter`	`System.AddIn` `System.AddIn.Contract` `HostView` `CalcContract`	`.\Pipeline\HostSideAdapters\`	The host adapter maps the host view to the contract. Thus, it needs to reference both of these projects.
`HostApp`	`System.AddIn` `HostView`		The hosting application activates the add-in.

Add-In Contract

Let's start by implementing the contract assembly. Contract assemblies contain a contract interface that defines the protocol for communication between the host and the add-in.

With the following code, you can see the contract defined for the calculator sample application. The application defines a contract with the methods `GetOperations()` and `Operate()`. `GetOperations()` returns a list of mathematical operations supported by the calculator add-in. An operation is defined by the interface `IOperationContract` that is a contract by itself. `IOperationContract` defines the read-only properties `Name` and `NumberOperands`.

The `Operate()` method invokes the operation within the add-in and requires an operation defined by the `IOperation` interface and the operands with a `double` array. With this contract it is possible that the add-in supports any operations that require any number of `double` operands and returns one `double`. The attribute `AddInContract` is used by the `AddInStore` to build the cache. The `AddInContract` attribute marks the class as an add-in contract interface.

The contract used here functions similarly to the contract for the add-ins in Chapter 28, "Managed Extensibility Framework." However, MEF contracts don't have the same requirements that MAF contracts have. MAF contracts are very restrictive because of the appdomain and process boundaries between the host and the add-in. However, the MEF architecture does not use different appdomains.

```
using System.AddIn.Contract;
using System.AddIn.Pipeline;
namespace Wrox.ProCSharp.MAF
{
   [AddInContract]
   public interface ICalculatorContract: IContract
   {
       IListContract<IOperationContract> GetOperations();
       double Operate(IOperationContract operation, double[] operands);
   }
```

```
        public interface IOperationContract: IContract
        {
            string Name { get; }
            int NumberOperands { get; }
        }
    }
```

code snippet CalcContract/ICalculatorContract.cs

Calculator Add-In View

The add-in view redefines the contract as it is seen by the add-in. The contract defined the interfaces `ICalculatorContract` and `IOperationContract`. For this, the add-in view defines the abstract class `Calculator` and the concrete class `Operation`.

With `Operation`, a specific implementation is not required by every add-in. Instead, the class is already implemented with the add-in view assembly. This class describes an operation for mathematical calculations with the `Name` and `NumberOperands` properties.

The abstract class `Calculator` defines the methods that need to be implemented by the add-ins. While the contract defines parameters and return types that need to be passed across appdomain and process boundaries, that's not the case with the add-in view. Here, you can use types, which make it easy to write add-ins for the add-in developer. The `GetOperations()` method returns `IList<Operation>` instead of `IListOperation<IOperationContract>`, as you've seen with the contract assembly.

The `AddInBase` attribute identifies the class as an add-in view for the store.

```
    using System.AddIn.Pipeline;
    using System.Collections.Generic;
    namespace Wrox.ProCSharp.MAF
    {
       [AddInBase]
       public abstract class Calculator
       {
          public abstract IList<Operation> GetOperations();
          public abstract double Operate(Operation operation, double[] operand);
       }
       public class Operation
       {
           public string Name { get; set; }
           public int NumberOperands { get; set; }
       }
    }
```

code snippet CalcView/CalculatorView.cs

Calculator Add-In Adapter

The add-in adapter maps the contract to the add-in view. This assembly has references to both the contract and the add-in view assemblies. The implementation of the adapter needs to map the method `IListContract<IOperationContract> GetOperations()` from the contract to the view method `IList<Operation> GetOperations()`.

The assembly includes the classes `OperationViewToContractAddInAdapter` and `CalculatorViewToContractAddInAdapter`. These classes implement the interfaces `IOperationContract` and `ICalculatorContract`. The methods of the base interface `IContract` can be implemented by deriving it from the base class `ContractBase`. This class offers a default implementation. `OperationViewToContractAddInAdapter` implements the other members of the `IOperationContract` interface and just forwards the calls to the `Operation view` that is assigned in the constructor.

The class `OperationViewToContractAddInAdapter` also contains static helper methods `ViewToContractAdapter()` and `ContractToViewAdapter()` that map `Operation` to `IOperationContract` and the other way around.

```
using System.AddIn.Pipeline;
namespace Wrox.ProCSharp.MAF
{
   internal class OperationViewToContractAddInAdapter: ContractBase,
         IOperationContract
   {
      private Operation view;
      public OperationViewToContractAddInAdapter(Operation view)
      {
         this.view = view;
      }
      public string Name
      {
         get { return view.Name; }
      }
      public int NumberOperands
      {
         get { return view.NumberOperands; }
      }
      public static IOperationContract ViewToContractAdapter(Operation view)
      {
         return new OperationViewToContractAddInAdapter(view);
      }
      public static Operation ContractToViewAdapter(
            IOperationContract contract)
      {
         return (contract as OperationViewToContractAddInAdapter).view;
      }
   }
}
```

code snippet CalcAddInAdapter/OperationViewToContractAddInAdapter.cs

The class `CalculatorViewToContractAddInAdapter` is very similar to `OperationViewToContractAddInAdapter`: It derives from `ContractBase` to inherit a default implementation of the `IContract` interface, and it implements a contract interface. This time the `ICalculatorContract` interface is implemented with the `GetOperations()` and `Operate()` methods.

The `Operate()` method of the adapter invokes the `Operate()` method of the view class `Calculator`, where `IOperationContract` must be converted to `Operation`. This is done with the static helper method `ContractToViewAdapter()`, which is defined with the `OperationViewToContractAddInAdapter` class.

The implementation of the `GetOperations` method needs to convert the collection `IListContract<IOperationContract>` to `IList<Operation>`. For such collection conversions, the class `CollectionAdapters` defines the conversion methods `ToIList()` and `ToIListContract()`. Here, the method `ToIListContract()` is used for the conversion.

The attribute `AddInAdapter` identifies the class as an add-in-side adapter for the add-in store.

```
using System.AddIn.Contract;
using System.AddIn.Pipeline;
namespace Wrox.ProCSharp.MAF
{
   [AddInAdapter]
   internal class CalculatorViewToContractAddInAdapter: ContractBase,
         ICalculatorContract
   {
      private Calculator view;
```

```
         public CalculatorViewToContractAddInAdapter(Calculator view)
         {
            this.view = view;
         }
         public IListContract<IOperationContract> GetOperations()
         {
            return CollectionAdapters.ToIListContract<Operation,
                  IOperationContract>(view.GetOperations(),
                  OperationViewToContractAddInAdapter.ViewToContractAdapter,
                  OperationViewToContractAddInAdapter.ContractToViewAdapter);
         }
         public double Operate(IOperationContract operation, double[] operands)
         {
            return view.Operate(
                  OperationViewToContractAddInAdapter.ContractToViewAdapter(
                        operation), operands);
         }
      }
   }
```

code snippet CalcAddInAdapter/CalculatorViewToContractAddInAdapter.cs

Because the adapter classes are invoked by .NET reflection, it is possible that the internal access modifier is used with these classes. As these classes are an implementation detail, it's a good idea to use the `internal` *access modifier.*

Calculator Add-In

The add-in now contains the implementation of the functionality. The add-in is implemented by the class `CalculatorV1`. The add-in assembly has a dependency on the add-in view assembly, as it needs to implement the abstract `Calculator` class.

The attribute `AddIn` marks the class as an add-in for the add-in store, and adds publisher, version, and description information. On the host side, this information can be accessed from the `AddInToken`.

`CalculatorV1` returns a list of supported operations in the method `GetOperations()`. `Operate()` calculates the operands based on the operation.

```
using System;
using System.AddIn;
using System.Collections.Generic;
namespace Wrox.ProCSharp.MAF
{
   [AddIn("CalculatorAddIn", Publisher="Wrox Press", Version="1.0.0.0",
         Description="Sample AddIn")]
   public class CalculatorV1: Calculator
   {
      private List<Operation> operations;
      public CalculatorV1()
      {
         operations = new List<Operation>();
         operations.Add(new Operation() { Name = "+", NumberOperands = 2 });
         operations.Add(new Operation() { Name = "-", NumberOperands = 2 });
         operations.Add(new Operation() { Name = "/", NumberOperands = 2 });
         operations.Add(new Operation() { Name = "*", NumberOperands = 2 });
      }
      public override IList<Operation> GetOperations()
      {
         return operations;
```

```
            }
            public override double Operate(Operation operation, double[] operand)
            {
               switch (operation.Name)
               {
                  case "+":
                     return operand[0] + operand[1];
                  case "-":
                     return operand[0]—operand[1];
                  case "/":
                     return operand[0] / operand[1];
                  case "*":
                     return operand[0] * operand[1];
                  default:
                     throw new InvalidOperationException(
                           String.Format("invalid operation {0}", operation.Name));
               }
            }
         }
      }
```

code snippet CalcAddIn/Calculator.cs

Calculator Host View

Let's continue with the host view of the host side. Like the add-in view, the host view defines an abstract class with methods similar to the contract. However, the methods defined here are invoked by the host application.

Both the classes `Calculator` and `Operation` are abstract, as the members are implemented by the host adapter. The classes here just need to define the interface to be used by the host application.

```
using System.Collections.Generic;
namespace Wrox.ProCSharp.MAF
{
   public abstract class Calculator
   {
       public abstract IList<Operation> GetOperations();
       public abstract double Operate(Operation operation,
             params double[] operand);
   }
   public abstract class Operation
   {
       public abstract string Name { get; }
       public abstract int NumberOperands { get; }
   }
}
```

code snippet HostView/CalculatorHostView.cs

Calculator Host Adapter

The host adapter assembly references the host view and the contract to map the view to the contract. The class `OperationContractToViewHostAdapter` implements the members of the abstract `Operation` class. The class `CalculatorContractToViewHostAdapter` implements the members of the abstract `Calculator` class.

With `OperationContractToViewHostAdapter`, the reference to the contract is assigned in the constructor. The adapter class also contains a `ContractHandle` instance that adds a lifetime reference to the `contract`, so that the add-in stays loaded as long it is needed by the hosting application.

```
using System.AddIn.Pipeline;
namespace Wrox.ProCSharp.MAF
{
   internal class OperationContractToViewHostAdapter: Operation
   {
      private ContractHandle handle;
      public IOperationContract Contract { get; private set; }
      public OperationContractToViewHostAdapter(IOperationContract contract)
      {
         this.Contract = contract;
         handle = new ContractHandle(contract);
      }
      public override string Name
      {
         get
         {
            return Contract.Name;
         }
      }
      public override int NumberOperands
      {
         get
         {
            return Contract.NumberOperands;
         }
      }
   }
   internal static class OperationHostAdapters
   {
      internal static IOperationContract ViewToContractAdapter(Operation view)
      {
         return ((OperationContractToViewHostAdapter)view).Contract;
      }
      internal static Operation ContractToViewAdapter(
            IOperationContract contract)
      {
         return new OperationContractToViewHostAdapter(contract);
      }
   }
```

code snippet HostAdapter/OperationContractToViewHostAdapter.cs .

The class `CalculatorContractToViewHostAdapter` implements the methods of the abstract host view `Calculator` class and forwards the call to the contract. Again, you can see the `ContractHandle` holding the reference to the contract, which is similar to the adapter from the add-in-side type conversions. This time the type conversions are just in the other direction from the add-in adapters.

The attribute `HostAdapter` marks the class as an adapter that needs to be installed in the `HostSideAdapters` directory.

```
using System.Collections.Generic;
using System.AddIn.Pipeline;
namespace Wrox.ProCSharp.MAF
{
   [HostAdapter]
   internal class CalculatorContractToViewHostAdapter: Calculator
   {
      private ICalculatorContract contract;
      private ContractHandle handle;
      public CalculatorContractToViewHostAdapter(ICalculatorContract contract)
      {
          this.contract = contract;
```

```
            handle = new ContractHandle(contract);
        }
        public override IList<Operation> GetOperations()
        {
            return CollectionAdapters.ToIList<IOperationContract, Operation>(
                contract.GetOperations(),
                OperationHostAdapters.ContractToViewAdapter,
                OperationHostAdapters.ViewToContractAdapter);
        }
        public override double Operate(Operation operation, double[] operands)
        {
            return contract.Operate(OperationHostAdapters.ViewToContractAdapter(
                operation), operands);
        }
    }
}
```

code snippet HostAdapter/CalculatorContractToViewHostAdapter.cs

Calculator Host

The sample host application uses the WPF technology. You can see the user interface of this application in Figure 50-3. On top is the list of available add-ins. On the left, the operations of the active add-in are shown. As you select the operation that should be invoked, operands are shown. After entering the values for the operands, the operation of the add-in can be invoked.

The buttons on the bottom row are used to rebuild and update the add-in store, and to exit the application.

The XAML code that follows shows the tree of the user interface. With the `ListBox` elements, different styles with item templates are used to give a specific representation of the list of add-ins, the list of operations, and the list of operands.

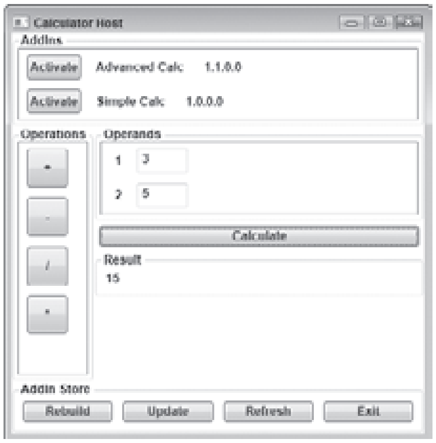

FIGURE 50-3

```
<DockPanel>
   <GroupBox Header="AddIn Store" DockPanel.Dock="Bottom">
      <UniformGrid Columns="4">
         <Button x:Name="rebuildStore" Click="RebuildStore"
               Margin="5">Rebuild</Button>
         <Button x:Name="updateStore" Click="UpdateStore"
               Margin="5">Update</Button>
         <Button x:Name="refresh" Click="RefreshAddIns"
               Margin="5">Refresh</Button>
         <Button x:Name="exit" Click="App_Exit" Margin="5">Exit</Button>
      </UniformGrid>
   </GroupBox>
   <GroupBox Header="AddIns" DockPanel.Dock="Top">
      <ListBox x:Name="listAddIns" ItemsSource="{Binding}"
            Style="{StaticResource listAddInsStyle}" />
   </GroupBox>
   <GroupBox DockPanel.Dock="Left" Header="Operations">
      <ListBox x:Name="listOperations" ItemsSource="{Binding}"
             Style="{StaticResource listOperationsStyle}" />
   </GroupBox>
```

```
      <StackPanel DockPanel.Dock="Right" Orientation="Vertical">
         <GroupBox Header="Operands">
            <ListBox x:Name="listOperands" ItemsSource="{Binding}"
                  Style="{StaticResource listOperandsStyle}">
            </ListBox>
         </GroupBox>
         <Button x:Name="buttonCalculate" Click="Calculate" IsEnabled="False"
               Margin="5">Calculate</Button>
         <GroupBox DockPanel.Dock="Bottom" Header="Result">
            <Label x:Name="labelResult" />
         </GroupBox>
      </StackPanel>
   </DockPanel>
```

code snippet HostAppWPF/CalculatorHostWindow.xaml

In the code-behind, the `FindAddIns()` method is invoked in the constructor of the Window. `FindAddIns()` uses the `AddInStore` class to get a collection of `AddInToken` objects and pass them to the `DataContext` property of the `ListBox listAddIns` for display. The first parameter of the `AddInStore.FindAddIns()` method passes the abstract `Calculator` class, which is defined by the host view to find all add-ins from the store that apply to the contract. The second parameter passes the directory of the pipeline that is read from the application configuration file. When you run the sample application from the Wrox download site (http://www.wrox.com), you have to change the directory in the application configuration file to match your directory structure.

```
using System;
using System.AddIn.Hosting;
using System.Diagnostics;
using System.IO;
using System.Linq;
using System.Windows;
using Wrox.ProCSharp.MAF.Properties;
namespace Wrox.ProCSharp.MAF
{
   public partial class CalculatorHostWindow: Window
   {
      private Calculator activeAddIn = null;
      private Operation currentOperation = null;
      public CalculatorHostWindow()
      {
         InitializeComponent();
         FindAddIns();
      }
      void FindAddIns()
      {
         try
         {
            this.listAddIns.DataContext =
                  AddInStore.FindAddIns(typeof(Calculator),
                  Settings.Default.PipelinePath);
         }
         catch (DirectoryNotFoundException ex)
         {
            MessageBox.Show("Verify the pipeline directory in the " +
                  "config file");
            Application.Current.Shutdown();
         }
      }
      //...
```

code snippet HostAppWPF/CalculatorHostWindow.xaml.cs

To update the cache of the add-in store, the UpdateStore() and RebuildStore() methods are mapped to the Click events of the Update and Rebuild buttons. Within the implementation of these methods, the Rebuild() or Update() methods of the AddInStore class are used. These methods return a string array of warnings if assemblies are stored in the wrong directories. Because of the complexity of the pipeline structure, there's a good chance that the first time you may not get the project configuration completely right for copying the assemblies to the correct directories. Reading the returned information from these methods, you will get a clear explanation about what's wrong. For example, the message "No usable AddInAdapter parts could be found in assembly Pipeline\AddInSideAdapters\CalcView.dll" gives you a hint that the assembly CalcView is stored in the wrong directory.

```
private void UpdateStore(object sender, RoutedEventArgs e)
{
   string[] messages = AddInStore.Update(Settings.Default.PipelinePath);
   if (messages.Length != 0)
   {
      MessageBox.Show(string.Join("\n", messages),
            "AddInStore Warnings", MessageBoxButton.OK,
            MessageBoxImage.Warning);
   }
}
private void RebuildStore(object sender, RoutedEventArgs e)
{
   string[] messages =
         AddInStore.Rebuild(Settings.Default.PipelinePath);
   if (messages.Length != 0)
   {
      MessageBox.Show(string.Join("\n", messages),
            "AddInStore Warnings", MessageBoxButton.OK,
            MessageBoxImage.Warning);
   }
}
```

In Figure 50-3, you can see an Activate button beside the available add-in. Clicking this button invokes the handler method ActivateAddIn(). With this implementation, the add-in is activated by using the Activate() method of the AddInToken class. Here, the add-in is loaded inside a new process that is created with the AddInProcess class. This class starts the process AddInProcess32.exe. Setting the KeepAlive property of the process to false, the process is stopped as soon as the last add-in reference is garbage collected. The parameter AddInSecurityLevel.Internet leads to an add-in running with restricted permissions. The last statement of ActivateAddIn() invokes the ListOperations() method, which in turn invokes the GetOperations() method of the add-in. GetOperations() assigns the returned list to the data context of the ListBox listOperations for displaying all operations.

```
private void ActivateAddIn(object sender, RoutedEventArgs e)
{
   FrameworkElement el = sender as FrameworkElement;
   Trace.Assert(el != null, "ActivateAddIn invoked from the wrong " +
         "control type");

   AddInToken addIn = el.Tag as AddInToken;
   Trace.Assert(el.Tag != null, String.Format(
         "An AddInToken must be assigned to the Tag property " +
         "of the control {0}", el.Name);
   AddInProcess process = new AddInProcess();
   process.KeepAlive = false;

   activeAddIn = addIn.Activate<Calculator>(process,
         AddInSecurityLevel.Internet);
   ListOperations();
}
```

```
    void ListOperations()
    {
       this.listOperations.DataContext = activeAddIn.GetOperations();
    }
```

After the add-in is activated and the list of operations is displayed in the UI, the user can select an operation. The `Click` event of the `Button` shown in the Operations category is assigned to the handler method `OperationSelected()`. In the implementation, the `Operation` object that is assigned to the `Tag` property of the `Button` is retrieved to get the number of operands needed with the operation. To allow the user to add values to the operands, an array of `OperandUI` objects is bound to the `ListBox listOperands`.

```
    private void OperationSelected(object sender, RoutedEventArgs e)
    {
       FrameworkElement el = sender as FrameworkElement;
       Trace.Assert(el != null, "OperationSelected invoked from " +
             "the wrong control type");

       Operation op = el.Tag as Operation;
       Trace.Assert(el.Tag != null, String.Format(
             "An AddInToken must be assigned to the Tag property " +
             "of the control {0}", el.Name);
       currentOperation = op;
       ListOperands(new double[op.NumberOperands]);
    }
    private class OperandUI
    {
       public int Index { get; set; }
       public double Value { get; set; }
    }
    void ListOperands(double[] operands)
    {
       this.listOperands.DataContext =
          operands.Select((operand, index) =>
                new OperandUI()
                { Index = index + 1, Value = operand }).ToArray();
    }
```

The `Calculate()` method is invoked with the `Click` event of the Calculate button. Here, the operands are retrieved from the UI, the operation and operands are passed to the `Operate()` method of the add-in, and the result is shown with the content of a label.

```
    private void Calculate(object sender, RoutedEventArgs e)
    {
       OperandUI[] operandsUI = (OperandUI[])this.listOperands.DataContext;
       double[] operands = operandsUI.Select(opui => opui.Value).ToArray();
       labelResult.Content = activeAddIn.Operate(currentOperation,
             operands);
    }
```

Additional Add-Ins

The hard work is now done. The pipeline components and the host application are created. The pipeline is now working, yet it's an easy task to add other add-ins to the host application, such as the Advanced Calculator add-in shown in the following code segment.

```
[AddIn("Advanced Calc", Publisher = "Wrox Press", Version = "1.1.0.0",
      Description = "Another AddIn Sample")]
public class AdvancedCalculatorV1: Calculator
```

code snippet AdvancedCalcAddIn/AdvancedCalculator.cs

SUMMARY

In this chapter, you've learned the concepts of a new .NET 3.5 technology: the Managed Add-In Framework.

MAF uses a pipeline concept to create complete independence between the hosting and add-in assemblies. A clearly defined contract separates the host view from the add-in view. Adapters make it possible for both sides to change independently of each other.

The next chapter provides information on how to use .NET components with .NET Enterprise Services.

51 Enterprise Services

WHAT'S IN THIS CHAPTER?

- Features of Enterprise Services
- Using Enterprise Services
- Creating a serviced component
- Deploying COM+ applications
- Using transactions with COM+
- Creating a WCF façade to Enterprise Services
- Using Enterprise Services from a WCF client

Enterprise Services is the name of the Microsoft application server technology that offers services for distributed solutions. Enterprise Services is based on the COM+ technology that has already been in use for many years. However, instead of wrapping .NET objects as COM objects to use these services, .NET offers extensions for .NET components to take direct advantage of these services. With .NET you get easy access to COM+ services for .NET components.

Enterprise Services also has a great integration story with Windows Communication Foundation (WCF). You can use a tool to automatically create a WCF service front-end to a serviced component, and you can invoke a WCF service from a COM+ client.

USING ENTERPRISE SERVICES

The complexity of Enterprise Services and the different configuration options (many of them are not needed if all the components of the solution are developed with .NET) can be more easily understood if you know the history of Enterprise Services. This section starts with that history.

You then get an overview of the different services offered by the technology, so you know what features could be useful for your application.

This section describes the history of Enterprise Services, contexts that are the foundation of the functionality, and the key features such as automatic transactions, object pooling, role-based security, queued components, and loosely coupled events

History

Enterprise Services can be traced back to Microsoft Transaction Server (MTS), which was released as an option pack for Windows NT 4.0. MTS extended COM by offering services such as transactions for COM objects. The services could be used by configuring metadata: the configuration of the component defined whether or not a transaction was required. With MTS it was no longer necessary to deal with transactions programmatically. However, MTS had a big disadvantage. COM was not designed to be extensible, so MTS made extensions by overwriting the COM component registry configuration to direct the instantiation of the component to MTS, and some special MTS API calls have been required to instantiate COM objects within MTS. This problem was solved with Windows 2000.

One of the most important features of Windows 2000 was the integration of MTS and COM in a new technology with the name COM+. In Windows 2000, COM+ base services are aware of the context that is needed by COM+ services (previously MTS services), so the special MTS API calls are no longer needed. With COM+ services some new service functionality is offered in addition to distributed transactions.

Windows 2000 includes COM+ 1.0. COM+ 1.5 has been available since Windows XP and Windows Server 2003. COM+ 1.5 adds more features to increase scalability and availability, including application pooling and recycling, and configurable isolation levels.

.NET Enterprise Services allows you to use COM+ services from within .NET components. Support is offered for Windows 2000 and later. When .NET components are run within COM+ applications, no COM callable wrapper is used (see Chapter 26, "Interop"); the application runs as a .NET component instead. When you install the .NET runtime on an operating system, some runtime extensions are added to COM+ services. If two .NET components are installed with Enterprise Services, and component A is using component B, COM marshaling is not used; instead, the .NET components can invoke each other directly.

Where to Use Enterprise Services

Business applications can be logically separated into presentation, business, and data service layers. The *presentation service layer* is responsible for user interaction. Here, the user can interact with the application to enter and view data. Technologies used with this layer are Windows Forms, WPF, and ASP.NET. The *business service layer* consists of business rules and data rules. The *data service layer* interacts with persistent storage. Here, you can use components that make use of ADO.NET. Enterprise Services fits both to the business service layer and to the data service layer.

Figure 51-1 shows two typical application scenarios. Enterprise Services can be used directly from a rich client using Windows Forms or WPF or from a web application that is running ASP.NET.

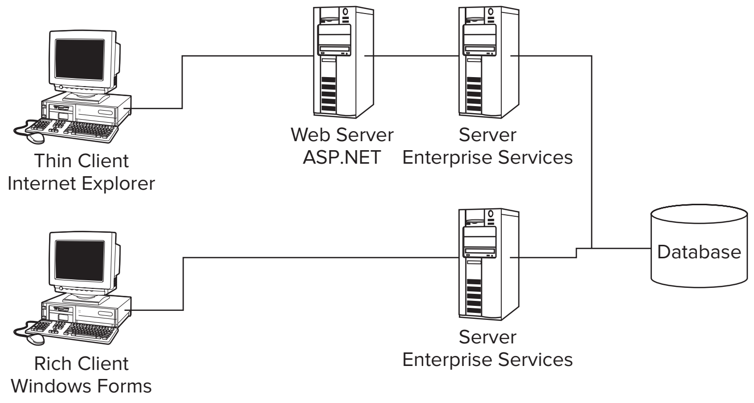

FIGURE 51-1

Enterprise Services is also a scalable technology. Using *component load balancing* makes it possible to distribute the load of the clients across different systems.

You can also use Enterprise Services on the client system, because this technology is included in Windows 7 and Windows Vista.

Key Features

Now let's get into the advantages of using Enterprise Services by looking at its key features, such as automatic transactions, role-based security, queued components, and loosely coupled events.

Contexts

The base functionality behind the services offered by Enterprise Services is the context that is the foundation of all the features of Enterprise Services. The context makes it possible to intercept a method call, and some service functionality can be carried out before the expected method call is invoked. For example, a transactional or a synchronization scope can be created before the method implemented by the component is invoked. Figure 51-2 shows object A and object B running in two different contexts, X and Y. Between the contexts the call is intercepted by a proxy. The proxy can uses services offered by Enterprise Services that are explained with the following features.

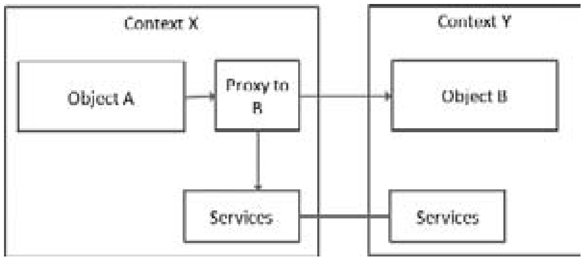

FIGURE 51-2

With the contexts here, a COM component and a .NET component can participate in the same transaction. All this is done with the help of the base class `ServicedComponent` that itself derives from `MarshalByRefObject` to integrate .NET and COM+ contexts.

Automatic Transactions

The most commonly used feature of Enterprise Services is *automatic transactions*. With automatic transactions, it is not necessary to start and commit a transaction in the code; an attribute can be applied to a class instead. By using the `[Transaction]` attribute with the options `Required`, `Supported`, `RequiresNew`, and `NotSupported`, you can mark a class with the requirements it has for transactions. If you mark the class with the option `Required`, a transaction is created automatically when a method starts and is committed to or aborted when the root component of the transaction is finished.

Such a declarative way to program is of particular advantage when a complex object model is developed. Here, automatic transactions have a big advantage over programming transactions manually. Assume that you have a `Person` object with multiple `Address` and `Document` objects that are associated with the `Person`, and you want to store the `Person` object together with all associated objects in a single transaction. Doing transactions programmatically would mean passing a transaction object to all the related objects so that they can participate in the same transaction. Using transactions declaratively means there is no need to pass the transaction object, because this happens behind the scenes by using the context.

Distributed Transactions

Enterprise Services not only offers automatic transactions, but the transactions can also be distributed across multiple databases. Enterprise Services transactions are enlisted with the *Distributed Transaction Coordinator* (*DTC*). The DTC supports databases that make use of the XA protocol, which is a two-phase commit protocol, and is supported by SQL Server and Oracle. A single transaction can span writing data to both a SQL Server and an Oracle database.

Distributed transactions are not only useful with databases, but a single transaction can also span writing data to a database and writing data to a message queue. If one of these two actions fails, a rollback is done with the other action. You can read more about message queuing in Chapter 46, "Message Queuing."

Later in this chapter, you see how to create a component that requires transactions.

Object Pooling

Pooling is another feature offered by Enterprise Services. These services use a pool of threads to answer requests from clients. Object pooling can be used for objects with a long initialization time. With object pooling, objects are created in advance so that clients don't have to wait until the object is initialized.

Role-Based Security

Using *role-based security* allows you to define roles declaratively and define what methods or components can be used from what roles. The system administrator assigns users or user groups to these roles. In the program there is no need to deal with access control lists; instead, roles that are simple strings can be used.

Queued Components

Queued components is an abstraction layer to message queuing. Instead of sending messages to a message queue, the client can invoke methods with a recorder that offers the same methods as a .NET class configured in Enterprise Services. The recorder in turn creates messages that are transferred via a message queue to the server application.

Queued components and message queuing are useful if the client application is running in a disconnected environment (for example, on a laptop that does not always have a connection to the server), or if the request that is sent to the server should be cached before it is forwarded to a different server (for example, to a server of a partner company).

Loosely Coupled Events

Chapter 8, "Delegates, Lambdas, and Events," explains the event model of .NET. Chapter 26 describes how to use events in a COM environment. With both of these event mechanisms, the client and the server have a tight connection. This is different with *loosely coupled events* (*LCE*). With LCE the COM+ facility is inserted between client and server (see Figure 51-3). The publisher registers the events it will offer with COM+ by defining an event class. Instead of sending the events directly to the client, the publisher sends events to the event class that is registered with the LCE service. The LCE service forwards the events to the subscriber, which is the client application that registered a subscription for the event.

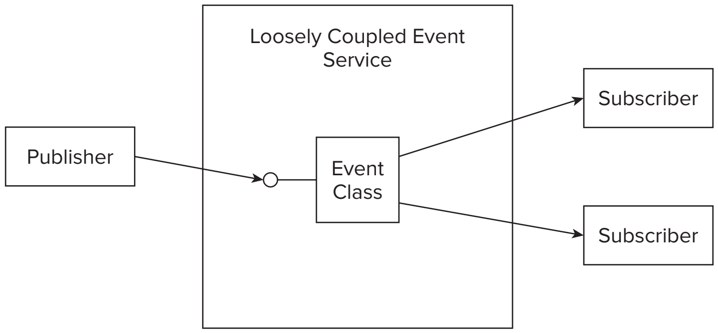

FIGURE 51-3

CREATING A SIMPLE COM+ APPLICATION

To create a .NET class that can be configured with Enterprise Services, you have to reference the assembly `System.EnterpriseServices` and add the namespace `System.EnterpriseServices` to the using declarations. The most important class to use is `ServicedComponent`.

The first example shows the basic requirements to create a serviced component. You start by creating a C# library application. All COM+ applications must be written as library applications regardless of whether they will run in their own process or in the process of the client. Name the library `SimpleServer`. Reference the assembly `System.EnterpriseServices` and add the declaration `using System .EnterpriseServices;` to the `Assmblyinfo.cs` and `Class1.cs` files.

With the project you also need to apply a strong name to the library. For some Enterprise Services features it is also necessary to install the assembly in the GAC (global assembly cache). Strong names and the global assembly cache are discussed in Chapter 18, "Assemblies."

The ServicedComponent Class

Every serviced component class must derive from the base class `ServicedComponent`. `ServicedComponent` itself derives from the class `ContextBoundObject`, so an instance is bound to a .NET Remoting context.

The class `ServicedComponent` has some protected methods that can be overridden, as shown in the following table.

PROTECTED METHOD	DESCRIPTION
`Activate()` `Deactivate()`	The `Activate()` and `Deactivate()` methods are called if the object is configured to use object pooling. When the object is taken from the pool, the `Activate()` method is called. Before the object is returned to the pool, `Deactivate()` is called.
`CanBePooled()`	This is another method for object pooling. If the object is in an inconsistent state, you can return `false` in your overridden implementation of `CanBePooled()`. This way the object is not put back into the pool, but destroyed instead. A new object is created for the pool.
`Construct()`	This method is called at instantiation time, where a construction string can be passed to the object. The construction string can be modified by the system administrator. Later in this chapter, you use the construction string to define the database connection string.

Assembly Attributes

Some Enterprise Services attributes are also needed. The attribute `ApplicationName` defines the name of the application as it will be seen in the Component Services Explorer. The value of the `Description` attribute shows up as a description within the application configuration tool.

`ApplicationActivation` allows you to define whether the application should be configured as a library application or a server application, using the options `ActivationOption.Library` or `ActivationOption .Server`. With a library application, the application is loaded inside the process of the client. In that case the client might be the ASP.NET runtime. With a server application, a process for the application is started. The name of the process is `dllhost.exe`. With the attribute `ApplicationAccessControl`, you can turn off security so that every user is allowed to use the component.

Rename the file `Class1.cs` to `SimpleComponent.cs` and add these attributes outside the namespace declaration:

```
[assembly: ApplicationName("Wrox EnterpriseDemo")]
[assembly: Description("Wrox Sample Application for Professional C#")]
[assembly: ApplicationActivation(ActivationOption.Server)]
[assembly: ApplicationAccessControl(false)]
```

The following table lists the most important assembly attributes that can be defined with Enterprise Services applications.

ATTRIBUTE	DESCRIPTION
`ApplicationName`	The attribute `ApplicationName` defines the name for the COM+ application that shows up in the Component Services Explorer after the component is configured.
`ApplicationActivation`	The attribute `ApplicationActivation` defines if the application should run as a library within the client application or if a separate process should be started. The options to configure are defined with the enumeration `ActivationOption`. `ActivationOption.Library` defines to run the application inside the process of the client; `ActivationOption.Server` starts its own process, `dllhost.exe`.
`ApplicationAccessControl`	The attribute `ApplicationAccessControl` defines the security configuration of the application. Using a Boolean value you can enable or disable access control. With the `Authentication` property you can set privacy levels — whether the client should be authenticated with every method call or just with the connection, and whether the data sent should be encrypted.

Creating the Component

In the `SimpleComponent.cs` file, you can create your serviced component class. With serviced components, it is best to define interfaces that are used as the contract between the client and the component. This is not a strict requirement, but some of the Enterprise Services features (such as setting role-based security on a method or interface level) require interfaces. Create the interface `IGreeting` with the method `Welcome()`. The attribute `ComVisible` is required for serviced component classes and interfaces that can be accessed from Enterprise Services features:

```
using System.Runtime.InteropServices;

namespace Wrox.ProCSharp.EnterpriseServices
{
   [ComVisible(true)]
   public interface IGreeting
   {
      string Welcome(string name);
   }
```

code snippet SimpleServer/IGreeting.cs

The class `SimpleComponent` derives from the base class `ServicedComponent` and implements the interface `IGreeting`. The class `ServicedComponent` acts as a base class of all serviced component classes, and offers some methods for the activation and construction phases. Applying the attribute `EventTrackingEnabled` to this class makes it possible to monitor the objects with the Component Services Explorer. By default, monitoring is disabled because using this feature reduces performance. The `Description` attribute only specifies text that shows up in the Explorer:

```
using System.EnterpriseServices;
using System.Runtime.InteropServices;

namespace Wrox.ProCSharp.EnterpriseServices
{
   [EventTrackingEnabled(true)]
   [ComVisible(true)]
   [Description("Simple Serviced Component Sample")]
   public class SimpleComponent: ServicedComponent, IGreeting
```

```
      {
         public SimpleComponent()
         {
         }
```

code snippet SimpleServer/SimpleComponent.cs

The method `Welcome()` returns only `"Hello, "` with the name that is passed to the argument. So that you can see some visible result in the Component Services Explorer while the component is running, `Thread.Sleep()` simulates some processing time:

```
         public string Welcome(string name)
         {
            // simulate some processing time
            System.Threading.Thread.Sleep(1000);
            return "Hello, " + name;
         }
      }
   }
```

Other than applying some attributes and deriving the class from `ServicedComponent`, there's nothing special to do with classes that should use Enterprises Services features. All that is left to do is build and deploy a client application.

In the first sample component, the attribute `[EventTrackingEnabled]` was set. Some more commonly used attributes that influence the configuration of serviced components are described in the following table.

ATTRIBUTE CLASS	DESCRIPTION
`EventTrackingEnabled`	Setting the attribute `EventTrackingEnabled` allows monitoring the component with the Component Services Explorer. Setting this attribute to `true` has some additional overhead associated; that's why, by default, event tracking is turned off.
`JustInTimeActivation`	With this attribute, the component can be configured to not activate when the caller instantiates the class, but instead when the first method is invoked. Also, with this attribute the component can deactivate itself.
`ObjectPooling`	If the initialization time of a component is long compared to the time of a method call, an object pool can be configured with the attribute `ObjectPooling`. With this attribute, minimum and maximum values can be defined that influence the number of objects in the pool.
`Transaction`	The attribute `Transaction` defines transactional characteristics of the component. Here, the component defines whether a transaction is required, supported, or not supported.

DEPLOYMENT

Assemblies with serviced components must be configured with COM+. This configuration can be done automatically or by registering the assembly manually.

Automatic Deployment

If a .NET client application that uses the serviced component is started, the COM+ application is configured automatically. This is true for all classes that are derived from the class `ServicedComponent`. Application and class attributes such as `EventTrackingEnabled` define the characteristics of the configuration.

Automatic deployment has an important drawback. For automatic deployment to work, the client application needs administrative rights. If the client application that invokes the serviced component is ASP.NET, the ASP.NET runtime usually doesn't have administrative rights. With this drawback, automatic deployment is useful only during development time. However, during development, automatic deployment is an extremely advantageous feature because it is not necessary to do manual deployment after every build.

Manual Deployment

You can deploy the assembly manually with the command-line utility .NET Services installation tool `regsvcs.exe`. Starting the command

```
regsvcs SimpleServer.dll
```

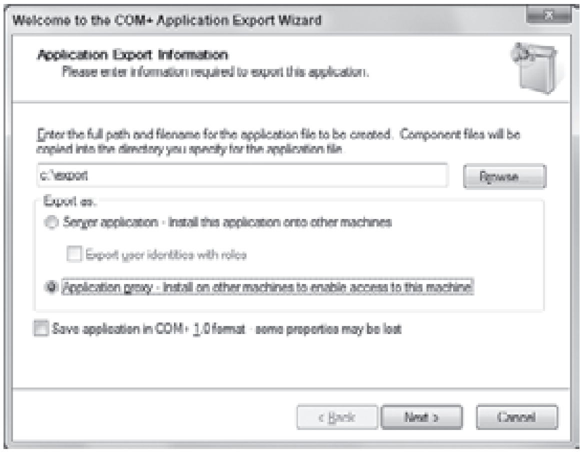
registers the assembly `SimpleServer` as a COM+ application and configures the included components according to their attributes; it also creates a type library that can be used by COM clients accessing the .NET component.

After you've configured the assembly, you can start the Component Services Explorer by selecting Administrative Tools ➪ Component Services. In the left tree view of this application, you can select Component Services ➪ Computers ➪ My ➪ Computer ➪ COM+ Applications to verify that the application was configured.

Creating an Installer Package

With the Component Services Explorer, you can create Windows installer packages for server or client systems. An installer package for the server includes the assemblies and configuration settings to install the application on a different server. If the serviced component is invoked from applications running on different systems, a proxy must be installed on the client system. The installer package for the client includes assemblies and configuration for proxies.

To create an installer package, you can start the Component Services Explorer, select the COM+ application, select the menu options Action ➪ Export, and click the Next button in the first dialog. The dialog shown in Figure 51-4 opens. Within this box you can export either a Server application or an Application proxy. With the option Server application you can also configure to Export user identities with roles. This option should be selected only if the target system is in the same domain as the system where the package is created, because the configured user identities are put into the installer package. With Application proxy, an installer package for the client system is created.



Welcome to the COM+ Application Export Wizard

Application Export Information
Please enter information required to export this application.

Enter the full path and filename for the application file to be created. Component files will be copied into the directory you specify for the application file.

c:\export

Export as:
Server application - Install this application onto other machines
Export user identities with roles
[✓ Application proxy - Install on other machines to enable access to this machine]

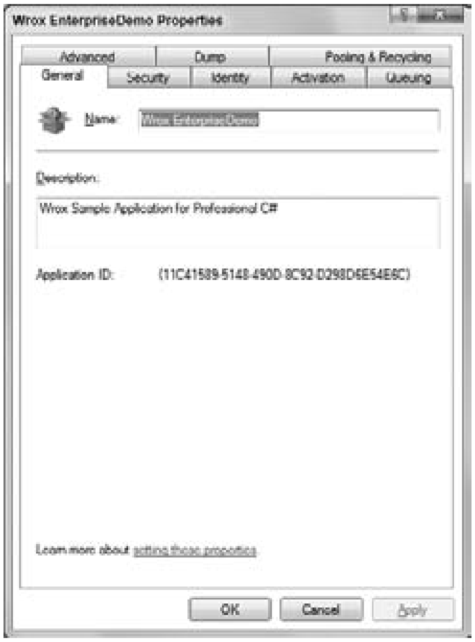
Save application in COM+ 1.0 format - some properties may be lost

FIGURE 51-4

To install the proxy, you have to start `setup.exe` from the installer package. Be aware that an application proxy cannot be installed on the same system where the application is installed. After installation of the application proxy, you can see an entry in Component Services Explorer that represents the application proxy. With the application proxy the only option that can be configured is the name of the server in the Activation tab, as discussed in the next section.

COMPONENT SERVICES EXPLORER

After a successful configuration, you can see `Wrox EnterpriseDemo` as an application name in the tree view of the Component Services Explorer. This name was set by the attribute `[ApplicationName]`. Selecting **Action ➪ Properties** opens the dialog shown in Figure 51-5. Both the name and the description have been configured by using attributes. When you select the **Activation** tab, you can see that the application is configured as a server application because it has been defined with the `[ApplicationActivation]` attribute, and selecting the Security tab shows that the Enforce access checks for this application option is not selected because the attribute `[ApplicationAccessControl]` was set to `false`.



Name: Wrox EnterpriseDemo

Description: Wrox Sample Application for Professional C#

Application ID: {11C41589-5148-490D-8C92-D298D6E54E6C}

FIGURE 51-5

The following is a list of more options that can be set with this application:

- **Security** — With security configuration, you can enable or disable access checks. If security is enabled, you can set access checks to the application level, the component, the interface, and to the method level. It is also possible to encrypt messages that are sent across the network using packet privacy as an authentication level for calls. Of course, this also increases the overhead.
- **Identity** — With server applications, you can use the Identity tab to configure the user account that will be used for the process that hosts the application. By default, this is the interactive user. This setting is very useful while debugging the application but cannot be used on a production system if the application is running on a server, because there might not be anybody logged on. Before installing the application on the production system you should test the application by using a specific user for the application.
- **Activation** — The Activation tab allows you to configure the application either as a library or as a server application. Two new options with COM+ 1.5 are the option to run the application as a Windows Service and to use SOAP to access the application. Windows Services are discussed in Chapter 25, "Windows Services." Selecting the SOAP option uses .NET Remoting configured within Internet Information Server to access the component. Instead of using .NET Remoting, later in this chapter the component will be accessed using WCF. WCF is discussed in Chapter 43, "Windows Communication Foundation."

  With an application proxy, the option "Remote server name" is the only option that can be configured. This option sets the name of the server. By default, the DCOM protocol is used as the network protocol. However, if SOAP is selected in the server configuration, the communication happens through .NET Remoting.
- **Queuing** — The Queuing configuration is required for service components that make use of message queuing.
- **Advanced** — On the Advanced tab, you can specify whether the application should be shut down after a certain period of client inactivity. You can also specify whether to lock a certain configuration so that no one can change it accidentally.
- **Dump** — If the application crashes, you can specify the directory where the dumps should be stored. This is useful for components developed with C++.
- **Pooling and Recycling** — Pooling and recycling is a new option with COM+ 1.5. With this option, you can configure whether the application should be restarted (recycled) depending on application lifetime, memory needs, number of calls, and so on.

With the Component Services Explorer, you can also view and configure the component itself. When opening child elements of the application, you can view the component `Wrox.ProCSharp.EnterpriseServices.SimpleComponent`. Selecting Action Properties opens the dialog shown in Figure 51-6.

Using this dialog, you can configure these options:

- **Transactions** — On the Transactions tab, you can specify whether the component requires transactions. You use this feature in the next example.
- **Security** — If security is enabled for the application, you can define what roles are allowed to use the component with this configuration.
- **Activation** — The Activation configuration enables you to set object pooling and to assign a construction string.
- **Concurrency** — If the component is not thread-safe, concurrency can be set to Required or Requires New. This way the COM+ runtime allows only one thread at a time to access the component.

Name: Wrox.ProCSharp.EnterpriseServices.SimpleComponent

Description:

Simple Serviced Component Sample

DLL: mscoree.dll

CLSID: {346794A1-0090-3D15-944A-6238EEBDAE9F}

Application: {11C41589-5148-490D-8C92-D298D6E54E6C}

FIGURE 51-6

CLIENT APPLICATION

After building the serviced component library, you can create a client application. This can be as simple as a C# console application. After you've created the project for the client, you have to reference both the assembly from the serviced component, `SimpleServer`, and the assembly `System.EnterpriseServices`. Then you can write the code to instantiate a new `SimpleComponent` instance and invoke the method `Welcome()`. In the following code, the `Welcome()` method is called 10 times. The `using` statement helps release the resources allocated with the instance before the garbage collector takes action. With the `using` statement, the `Dispose()` method of the serviced component is called when the scope of the `using` statement ends:

```
using System;

namespace Wrox.ProCSharp.EnterpriseServices
{
   class Program
   {
      static void Main()
      {
         using (SimpleComponent obj = new SimpleComponent())
         {
            for (int i = 0; i < 10; i++)
            {
               Console.WriteLine(obj.Welcome("Stephanie"));
            }
         }
      }
   }
}
```

code snippet ClientApplication/Program.cs

If you start the client application before configuring the server, the server will be configured automatically. The automatic configuration of the server is done with the values that you've specified using attributes. For a test you can unregister the serviced component and start the client again. If the serviced component is configured during the start of the client application, the startup needs more time. Remember that this feature is useful only during development time. Administrative rights are also needed for automatic deployment. If you are starting the application from within Visual Studio, you should start Visual Studio with administrative rights.

While the application is running, you can monitor the serviced component with the Component Services Explorer. By selecting Components in the tree view and choosing View ➪ Detail, you can view the number of instantiated objects if the attribute `[EventTrackingEnabled]` is set.

As you've seen, creating serviced components is just a matter of deriving the class from the base class `ServicedComponent` and setting some attributes to configure the application. Next, you see how transactions can be used with serviced components.

TRANSACTIONS

Automatic transactions are the most frequently used feature of Enterprise Services. Using Enterprise Services, you can mark the components as requiring a transaction, and the transaction is then created from the COM+ runtime. All transaction-aware objects inside the component, such as ADO.NET connections, run inside the transaction.

Transaction Attributes

Serviced components can be marked with the `[Transaction]` attribute to define if and how transactions are required for the component.

Figure 51-7 shows multiple components with different transactional configurations. The client invokes component A. Because component A is configured with `Transaction Required` and no transaction existed previously, the new transaction, `1`, is created. Component A invokes component B, which in turn invokes component C. Because component B is configured with `Transaction Supported`, and the configuration of component C is set to `Transaction Required`, all three components (A, B, and C) use the same transaction context. If component B were configured with the transaction setting `NotSupported`, component C would get a new transaction. Component D is configured with the setting `New Transaction Required`, so a new transaction is created when it is called by component A.

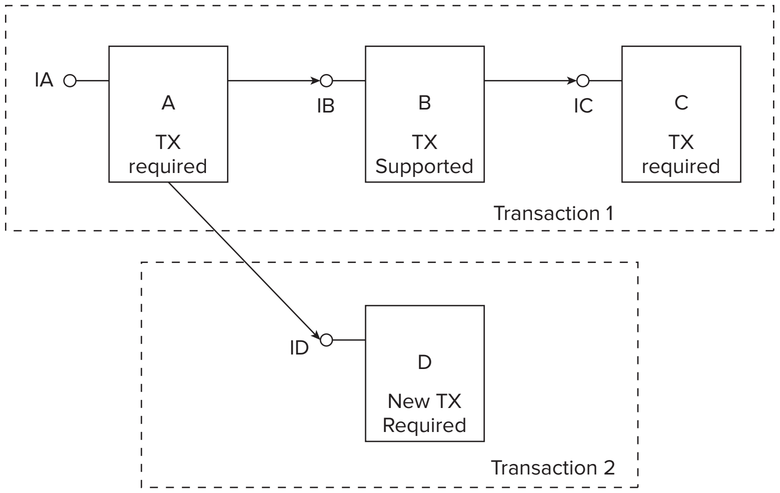

FIGURE 51-7

The following table lists the different values that you can set with the `TransactionOption` enumeration:

TRANSACTIONOPTION VALUE	DESCRIPTION
`Required`	Setting the `[Transaction]` attribute to `TransactionOption.Required` means that the component runs inside a transaction. If a transaction has been created already, the component will run in the same transaction. If no transaction exists, a transaction is created.
`RequiresNew`	`TransactionOption.RequiresNew` always results in a newly created transaction. The component never participates in the same transaction as the caller.
`Supported`	With `TransactionOption.Supported`, the component doesn't need transactions itself. However, the transaction spans the caller and the called component, if these components require transactions.
`NotSupported`	The option `TransactionOption.NotSupported` means that the component never runs in a transaction, regardless of whether the caller has a transaction.
`Disabled`	`TransactionOption.Disabled` means that a possible transaction of the current context is ignored.

Transaction Results

A transaction can be influenced by setting the *consistent* and the *done* bit of the context. If the consistent bit is set to `true`, the component is happy with the outcome of the transaction. The transaction can be committed if all components participating with the transaction are similarly successful. If the consistent bit is set to `false`, the component is not happy with the outcome of the transaction, and the transaction is aborted when the root object that started the transaction is finished. If the done bit is set, the object can be deactivated after the method call ends. A new instance is created with the next method call.

The consistent and done bits can be set using four methods of the `ContextUtil` class with the results that you can see in the following table.

CONTEXTUTIL METHOD	CONSISTENT BIT	DONE BIT
`SetComplete`	`True`	`true`
`SetAbort`	`False`	`true`
`EnableCommit`	`True`	`false`
`DisableCommit`	`False`	`false`

With .NET it is also possible to set the consistent and done bit by applying the attribute `[AutoComplete]` to the method instead of calling the `ContextUtil` methods. With this attribute the method `ContextUtil.SetComplete()` is called automatically if the method is successful. If the method fails and an exception is thrown, with `[AutoComplete]` the method `ContextUtil.SetAbort()` is called.

SAMPLE APPLICATION

This sample application simulates a simplified scenario that writes new orders to the Northwind sample database. As shown in Figure 51-8, multiple components are used with the COM+ application. The class `OrderControl` is called from the client application to create new orders. `OrderControl` uses the `OrderData` component. `OrderData` has the responsibility of creating a new entry in the `Order` table of the Northwind database. The `OrderData` component uses the `OrderLineData` component to write Order Detail entries to the database. Both `OrderData` and `OrderLineData` must participate in the same transaction.

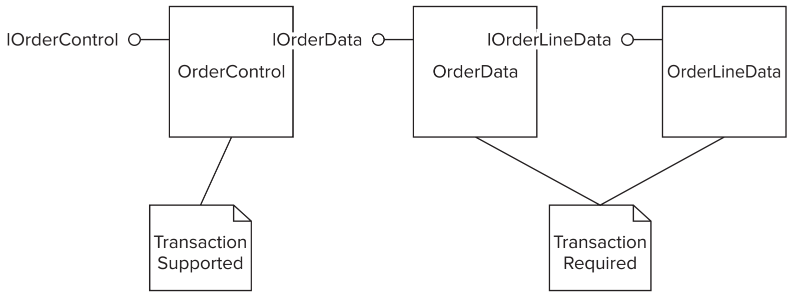

FIGURE 51-8

Start by creating a C# Component library with the name `NorthwindComponents`. Sign the assembly with a keyfile, and define the Enterprise Services application attributes as shown in the following code:

```
 [assembly: ApplicationName("Wrox.NorthwindDemo")]
[assembly: ApplicationActivation(ActivationOption.Server)]
[assembly: ApplicationAccessControl(false)]
```

code snippet NorthwindComponents/AssemblyInfo.cs

Entity Classes

Next add the entity classes `Order` and `OrderLine` that represent the columns in the Northwind database tables `Order` and `Order Details`. Entity classes are data holders representing the data that is important for the application domain — in that case for doing orders. The class `Order` has a static method `Create()` that creates and returns a new instance of the class `Order`, and initializes this instance with the arguments passed to this method. Also, the class `Order` has some read-only properties `OrderId`, `CustomerId`, `OrderData`, `ShipAddress`, `ShipCity`, and `ShipCountry`. The value of the `OrderId` property is not known at creation time of the class `Order`, but because the `Order` table in the Northwind database has an auto-increment attribute, the value is known after the order is written to the database. The method `SetOrderId()` is used to set the corresponding ID after the order has been written to the database. Because this method is called by a class inside the same assembly, the access level of this method is set to `internal`. The method `AddOrderLine()` adds order details to the order:

```
using System;
using System.Collections.Generic;

namespace Wrox.ProCSharp.EnterpriseServices
{
   [Serializable]
   public class Order
   {
      public static Order Create(string customerId, DateTime orderDate,
                      string shipAddress, string shipCity, string shipCountry)
      {
         return new Order
         {
            CustomerId = customerId,
            OrderDate = orderDate,
            ShipAddress = shipAddress,
            ShipCity = shipCity,
            ShipCountry = shipCountry
         };
      }

      public Order()
      {
      }
```

```
        internal void SetOrderId(int orderId)
        {
           this.OrderId = orderId;
        }

        public void AddOrderLine(OrderLine orderLine)
        {
           orderLines.Add(orderLine);
        }

        private readonly List<OrderLine> orderLines = new List<OrderLine>();

        public int OrderId { get; private set; }
        public string CustomerId { get; private set; }
        public DateTime OrderDate { get; private set; }
        public string ShipAddress { get; private set; }
        public string ShipCity { get; private set; }
        public string ShipCountry { get; private set; }

        public OrderLine[] OrderLines
        {
           get
           {
              OrderLine[] ol = new OrderLine[orderLines.Count];
              orderLines.CopyTo(ol);
              return ol;
           }
        }
     }
  }
```

code snippet NorthwindComponents/Order.cs

The second entity class is `OrderLine`. `OrderLine` has a static `Create()` method similar to the one of the `Order` class. Other than that, the class only has some properties `ProductId`, `UnitPrice`, and `Quantity`:

```
  using System;

  namespace Wrox.ProCSharp.EnterpriseServices
  {
     [Serializable]
     public class OrderLine
     {
        public static OrderLine Create(int productId, float unitPrice, int quantity)
        {
           return new OrderLine
           {
              ProductId = productId,
              UnitPrice = unitPrice,
              Quantity = quantity
           };
        }
        public OrderLine()
        {
        }

        public int ProductId { get; set; }
        public float UnitPrice { get; set; }
        public int Quantity { get; set; }
     }
  }
```

code snippet NorthwindComponents/OrderLine.cs

The OrderControl Component

The class `OrderControl` represents a simple business services component. In this example, just one method, `NewOrder()`, is defined in the interface `IOrderControl`. The implementation of `NewOrder()` does nothing more than instantiate a new instance of the data services component `OrderData` and call the method `Insert()` to write an `Order` object to the database. In a more complex scenario, this method could be extended to write a log entry to a database or to invoke a queued component to send the `Order` object to a message queue:

```
using System;
using System.EnterpriseServices;
using System.Runtime.InteropServices;

namespace Wrox.ProCSharp.EnterpriseServices
{
   [ComVisible(true)]
   public interface IOrderControl
   {
      void NewOrder(Order order);
   }

   [Transaction(TransactionOption.Supported)]
   [EventTrackingEnabled(true)]
   [ComVisible(true)]
   public class OrderControl: ServicedComponent, IOrderControl
   {
      [AutoComplete()]
      public void NewOrder(Order order)
      {
         using (OrderData data = new OrderData())
         {
            data.Insert(order);
         }
      }
   }
}
```

code snippet NorthwindComponents/OrderControl.cs

The OrderData Component

The `OrderData` class is responsible for writing the values of `Order` objects to the database. The interface `IOrderUpdate` defines the `Insert()` method. You can extend this interface to also support an `Update()` method where an existing entry in the database is updated:

```
using System;
using System.Data.SqlClient;
using System.EnterpriseServices;
using System.Runtime.InteropServices;

namespace Wrox.ProCSharp.EnterpriseServices
{
   [ComVisible(true)]
   public interface IOrderUpdate
   {
      void Insert(Order order);
   }
```

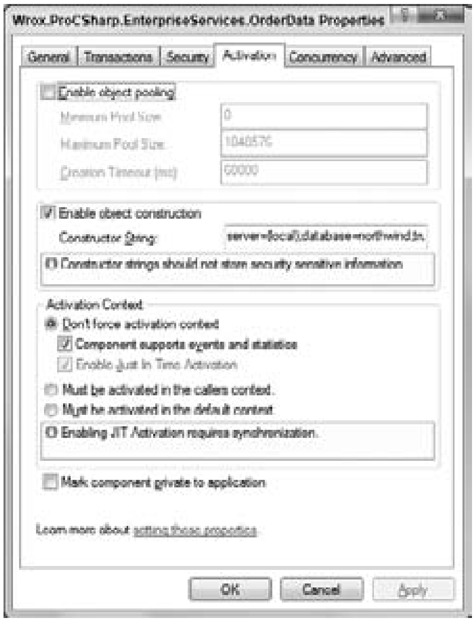
code snippet NorthwindComponents/OrderData.cs

The class `OrderData` has the attribute `[Transaction]` with the value `TransactionOption.Required` applied. This means that the component will run in a transaction in any case. Either a transaction is created by the caller and `OrderData` uses the same transaction, or a new transaction is created. Here a new transaction is created because the calling component `OrderControl` doesn't have a transaction.

With serviced components, you can use only default constructors. However, you can use the Component Services Explorer to configure a construction string that is sent to a component (see Figure 51-9). Selecting the Activation tab of the component configuration enables you to change the constructor string. The option "Enable object construction" is turned on when the attribute `ConstructionEnabled` is set, as it is with the class `OrderData`. The `Default` property of the `ConstructionEnabled` attribute defines the default connection string shown in the Activation settings after registration of the assembly. Setting this attribute also requires you to overload the method `Construct()` from the base class `ServicedComponent`. This method is called by the COM+ runtime at object instantiation, and the construction string is passed as an argument. The construction string is set to the variable `connectionString`, which is used later to connect to the database:

```
[Transaction(TransactionOption.Required)]
[EventTrackingEnabled(true)]
[ConstructionEnabled
   (true, Default="server=(local);database=northwind;trusted_connection=true")]
[ComVisible(true)]
public class OrderData: ServicedComponent, IOrderUpdate
{
   private string connectionString;

   protected override void Construct(string s)
   {
      connectionString = s;
   }
```



Enable object pooling [ ]
Minimum Pool Size: 0
Maximum Pool Size: 1048576
Creation Timeout (ms): 60000

Enable object construction [✓]
Constructor String: server=(local);database=northwind;tr
Constructor strings should not store security sensitive information.

Activation Context
[● Don't force activation context]
Component supports events and statistics [✓]
Enable Just In Time Activation [✓]
Must be activated in the callers context.
Must be activated in the default context.
Enabling JIT Activation requires synchronization.

Mark component private to application [ ]

FIGURE 51-9

The method `Insert()` is at the heart of the component. Here, you use ADO.NET to write the `Order` object to the database. (ADO.NET is discussed in more detail in Chapter 30, "Core ADO.NET.") In this example, you create a `SqlConnection` object where the connection string that was set with the `Construct()` method is used to initialize the object.

The attribute `AutoComplete` is applied to the method to use automatic transaction handling as discussed earlier:

```
   [AutoComplete()]
   public void Insert(Order order)
   {
      var connection = new SqlConnection(
                             connectionString);
```

The method `connection.CreateCommand()` creates a `SqlCommand` object where the `CommandText` property is set to a SQL `INSERT` statement to add a new record to the `Orders` table. The method `ExecuteNonQuery()` executes the SQL statement:

```
      try
      {
         var command = connection.CreateCommand();
         command.CommandText = "INSERT INTO Orders (CustomerId," +
            "OrderDate, ShipAddress, ShipCity, ShipCountry)" +
            "VALUES(@CustomerId, @OrderDate, @ShipAddress, @ShipCity, " +
            "@ShipCountry)";
         command.Parameters.AddWithValue("@CustomerId", order.CustomerId);
         command.Parameters.AddWithValue("@OrderDate", order.OrderDate);
```

```
                command.Parameters.AddWithValue("@ShipAddress", order.ShipAddress);
                command.Parameters.AddWithValue("@ShipCity", order.ShipCity);
                command.Parameters.AddWithValue("@ShipCountry", order.ShipCountry);

                connection.Open();

                command.ExecuteNonQuery();
```

Because `OrderId` is defined as an auto-increment value in the database, and this ID is needed for writing the Order Details to the database, `OrderId` is read by using `@@IDENTITY`. Then it is set to the `Order` object by calling the method `SetOrderId()`:

```
                command.CommandText = "SELECT @@IDENTITY AS 'Identity'";
                object identity = command.ExecuteScalar();
                order.SetOrderId(Convert.ToInt32(identity));
```

After the order is written to the database, all order lines of the order are written using the `OrderLineData` component:

```
                using (OrderLineData updateOrderLine = new OrderLineData())
                {
                   foreach (OrderLine orderLine in order.OrderLines)
                   {
                      updateOrderLine.Insert(order.OrderId, orderLine);
                   }
                }
             }
```

Finally, regardless of whether the code in the `try` block was successful or an exception occurred, the connection is closed:

```
             finally
             {
                connection.Close();
             }
          }
       }
    }
```

The OrderLineData Component

The `OrderLineData` component is implemented similarly to the `OrderData` component. You use the attribute `ConstructionEnabled` to define the database connection string:

```
using System;
using System.EnterpriseServices;
using System.Runtime.InteropServices;
using System.Data;
using System.Data.SqlClient;

namespace Wrox.ProCSharp.EnterpriseServices
{
   [ComVisible(true)]
   public interface IOrderLineUpdate
   {
      void Insert(int orderId, OrderLine orderDetail);
   }

   [Transaction(TransactionOption.Required)]
   [EventTrackingEnabled(true)]
   [ConstructionEnabled
       (true, Default="server=(local);database=northwind;trusted_connection=true")]
   [ComVisible(true)]
   public class OrderLineData: ServicedComponent, IOrderLineUpdate
```

```
      {
         private string connectionString;

         protected override void Construct(string s)
         {
            connectionString = s;
         }
```

code snippet NorthwindComponents/OrderLineData.cs

With the `Insert()` method of the `OrderLineData` class in this example, the `AutoComplete` attribute isn't used to demonstrate a different way to define the transaction outcome. It shows how to set the consistent and done bits with the `ContextUtil` class instead. The method `SetComplete()` is called at the end of the method, depending on whether inserting the data in the database was successful. If there is an error where an exception is thrown, the method `SetAbort()` sets the consistent bit to `false` instead, so that the transaction is undone along with all components participating in the transaction:

```
         public void Insert(int orderId, OrderLine orderDetail)
         {
            var connection = new SqlConnection(connectionString);
            try
            {
               var command = connection.CreateCommand();
               command.CommandText = "INSERT INTO [Order Details] (OrderId, " +
                  "ProductId, UnitPrice, Quantity)" +
                  "VALUES(@OrderId, @ProductId, @UnitPrice, @Quantity)";
               command.Parameters.AddWithValue("@OrderId", orderId);
               command.Parameters.AddWithValue("@ProductId", orderDetail.ProductId);
               command.Parameters.AddWithValue("@UnitPrice", orderDetail.UnitPrice);
               command.Parameters.AddWithValue("@Quantity", orderDetail.Quantity);

               connection.Open();

               command.ExecuteNonQuery();
            }
            catch (Exception)
            {
               ContextUtil.SetAbort();
               throw;
            }
            finally
            {
               connection.Close();
            }
            ContextUtil.SetComplete();
         }
      }
   }
```

Client Application

Having built the component, you can create a client application. For testing purposes, a console application serves the purpose. After referencing the assembly `NorthwindComponent` and the assembly `System.EnterpriseServices`, you can create a new `order` with the static method `Order.Create()`. The `order.AddOrderLine()` method adds an order line to the order. `OrderLine.Create()` accepts product IDs, the price, and quantity to create an order line. In a real application, it would be useful to add a `Product` class instead of using product IDs, but the purpose of this example is to demonstrate transactions in general.

Finally, the serviced component class `OrderControl` is created to invoke the method `NewOrder()`:

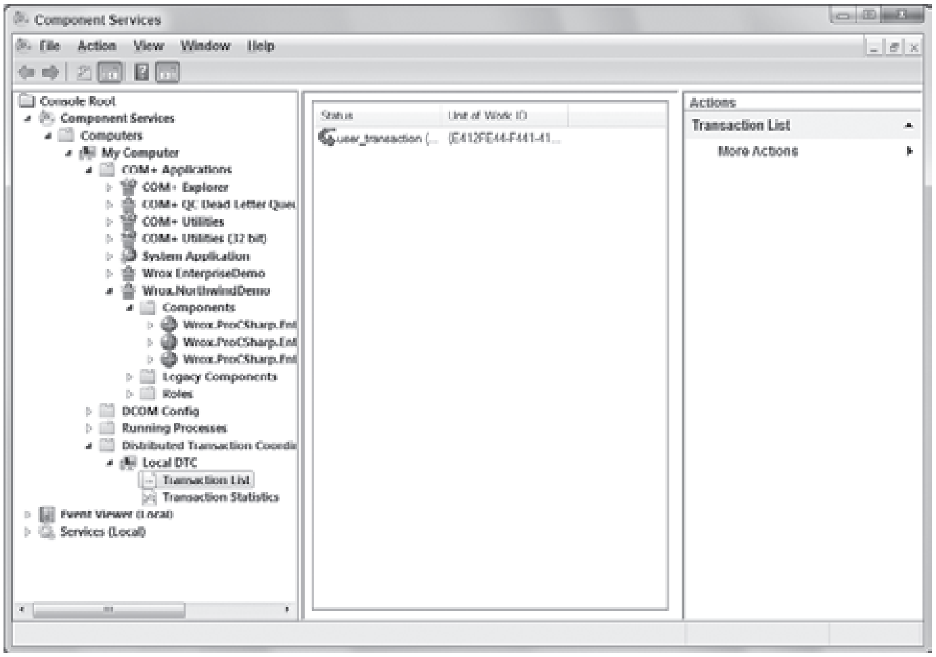
```
var order = Order.Create("PICCO", DateTime.Today, "Georg Pipps",
                         "Salzburg", "Austria");
order.AddOrderLine(OrderLine.Create(16, 17.45F, 2));
order.AddOrderLine(OrderLine.Create(67, 14, 1));

using (var orderControl = new OrderControl())
{
   orderControl.NewOrder(order);
}
```

code snippet ClientApplication/Program.cs

You can try to write products that don't exist to the `OrderLine` (using a product ID that is not listed in the table Products). In this case, the transaction is aborted, and no data is written to the database.

While a transaction is active, you can see the transaction in the Component Services Explorer by selecting Distributed Transaction Coordinator in the tree view (see Figure 51-10).



Status	Unit of Work ID
user_transaction (...	{E412FE44-F441-41...

FIGURE 51-10

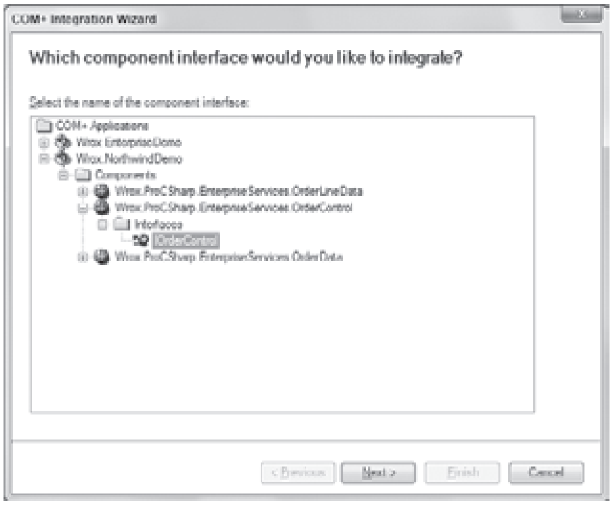
INTEGRATING WCF AND ENTERPRISE SERVICES

Windows Communication Foundation (WCF) is the preferred communication technology for .NET Framework 4. WCF is covered in detail in Chapter 43. .NET Enterprise Services offers a great integration model with WCF.

WCF Service Façade

Adding a WCF façade to an Enterprise Services application allows WCF clients to access the serviced components. Instead of using the DCOM protocol, with WCF you can have different protocols such as HTTP with SOAP or TCP with a binary formatting.

You can create a WCF façade from Visual Studio 2010 by selecting **Tools ➪ WCF Service Configuration Editor**. Then select **File ➪ Integrate ➪ COM+** Applications. Finally, select the COM+ Application Wrox.NorthwindDemo, the component `Wrox.ProCSharp.EnterpriseServices.OrderControl`, and the interface `IOrderControl`, as shown in Figure 51-11.



COM+ Integration Wizard

Which component interface would you like to integrate?

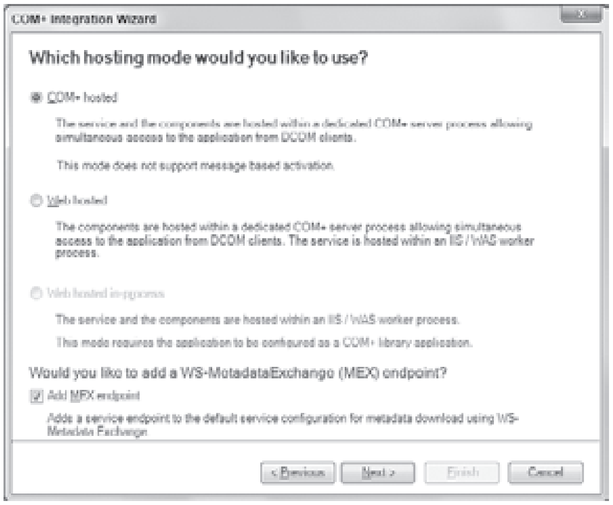
Select the name of the component interface:

```
COM+ Applications
  Wrox.EnterpriseDemo
  Wrox.NorthwindDemo
    Components
      Wrox.ProCSharp.EnterpriseServices.OrderLineData
      Wrox.ProCSharp.EnterpriseServices.OrderControl
        Interfaces
          OrderControl
      Wrox.ProCSharp.EnterpriseServices.OrderData
```

FIGURE 51-11

With the next dialog you can select all the methods from the interface `IOrderControl` that should be available to WCF clients. With the interface `IOrderControl` just one method, `NewOrder()`, is shown.

The next dialog, shown in Figure 51-12, allows configuration of the hosting options. With the hosting option, you can specify in which process the WCF service should run. When you select the COM+ hosted option, the WCF façade runs within the `dllhost.exe` process of COM+. This option can only be configured if the application is configured as a server application.



COM+ Integration Wizard

Which hosting mode would you like to use?

[✓ COM+ hosted]

The service and the components are hosted within a dedicated COM+ server process allowing simultaneous access to the application from DCOM clients.

This mode does not support message based activation.

Web hosted

The components are hosted within a dedicated COM+ server process allowing simultaneous access to the application from DCOM clients. The service is hosted within an IIS / WAS worker process.

Web hosted in-process

The service and the components are hosted within an IIS / WAS worker process.

This mode requires the application to be configured as a COM+ library application.

Would you like to add a WS-MetadataExchange (MEX) endpoint?

[✓ Add MEX endpoint]

Adds a service endpoint to the default service configuration for metadata download using WS-Metadata Exchange

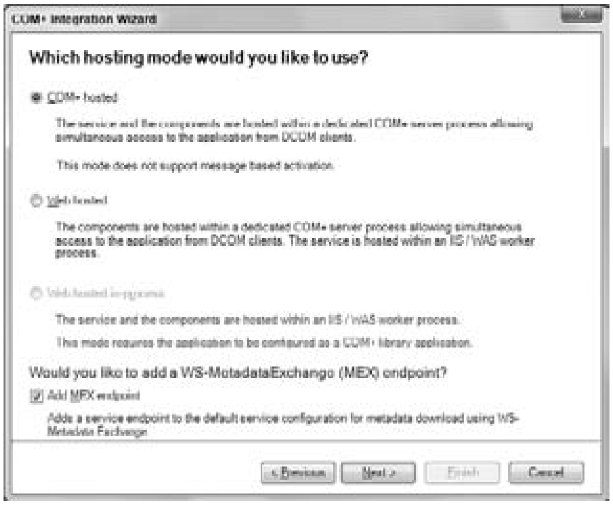
FIGURE 51-12

`ApplicationActivation(ActivationOption.Server)`. The Web hosted option specifies that the WCF channel listens inside a process of the IIS or WAS (Windows Activation Services) worker process. WAS is new since Windows Vista and Windows Server 2008. Selecting "Web hosted in-process" means that the library of the Enterprise Services component runs within the IIS or WAS worker process. This configuration is possible only if the application is configured as a library application: `ApplicationActivation(ActivationOption.Library)`.

Selecting the "Add MEX endpoint" option adds a Metadata Exchange (MEX) endpoint to the WCF configuration file, so that the client programmer can access the metadata of the service using WS-Metadata Exchange.

MEX is explained in Chapter 43.

With the next dialog shown in Figure 51-13 you can specify the communication mode to access the WCF façade. Depending on your requirements, if the client is accessing the service across a firewall or platform-independent communication is required, HTTP is the best choice. TCP offers faster communication across machines for .NET clients, and Named Pipes is the fastest option if the client application is running on the same system as the service.



COM+ Integration Wizard

Which hosting mode would you like to use?

[● COM+ hosted]

The service and the components are hosted within a dedicated COM+ server process allowing simultaneous access to the application from DCOM clients.

This mode does not support message based activation.

○ Web hosted

The components are hosted within a dedicated COM+ server process allowing simultaneous access to the application from DCOM clients. The service is hosted within an IIS / WAS worker process.

○ Web hosted in-process

The service and the components are hosted within an IIS / WAS worker process.

This mode requires the application to be configured as a COM+ library application.

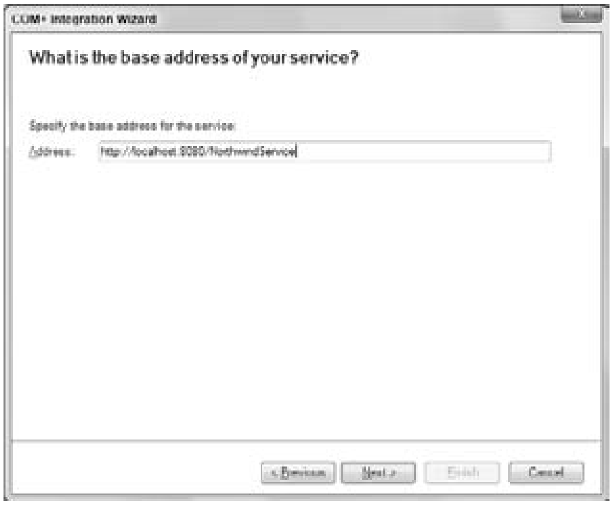
Would you like to add a WS-MetadataExchange (MEX) endpoint?

[✓ Add MEX endpoint]

Adds a service endpoint to the default service configuration for metadata download using WS-Metadata Exchange

FIGURE 51-13

The next dialog requests information about the base address of the service that depends on the communication protocol selection, as shown in Figure 51-14.



COM+ Integration Wizard

What is the base address of your service?

Specify the base address for the service:

Address: http://localhost:8080/NorthwindService

FIGURE 51-14

The last dialog shows the location of the endpoint configuration. The base directory for the configurations is `<Program Files>\ComPlus Applications` followed by the unique ID of the application. In this directory you can find the file `application.config`. This configuration file lists the behaviors and endpoints for WCF.

The `<service>` element specifies the exposed WCF service with the endpoint configuration. The binding is set to `wsHttpBinding` with a `comTransactionalBinding` configuration, so transactions can flow from the caller to the serviced component. With other network and client requirements, you can specify a different binding, but this is all covered in Chapter 43:

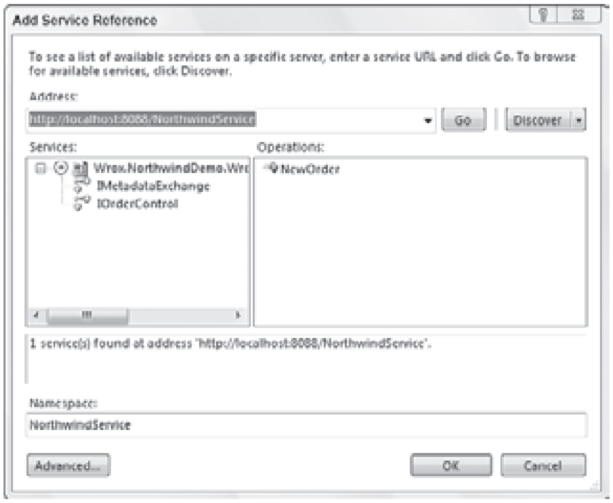
```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
   <system.serviceModel>
      <behaviors>
         <serviceBehaviors>
            <behavior name="ComServiceMexBehavior">
               <serviceMetadata httpGetEnabled="true" />
               <serviceDebug />
            </behavior>
         </serviceBehaviors>
      </behaviors>
      <bindings>
         <netNamedPipeBinding>
            <binding name="comNonTransactionalBinding" />
            <binding name="comTransactionalBinding" transactionFlow="true" />
         </netNamedPipeBinding>
         <wsHttpBinding>
            <binding name="comNonTransactionalBinding" />
            <binding name="comTransactionalBinding" transactionFlow="true" />
         </wsHttpBinding>
      </bindings>
      <comContracts>
         <comContract contract="{E1B02E09-EE48-3B6B-946F-E6A8BAEC6340}"
            name="IOrderControl"
            namespace=
                "http://tempuri.org/E1B02E09-EE48-3B6B-946F-E6A8BAEC6340"
            requiresSession="true">
            <exposedMethods>
               <add exposedMethod="NewOrder" />
            </exposedMethods>
         </comContract>
      </comContracts>
      <services>
         <service behaviorConfiguration="ComServiceMexBehavior"
            name="{196F39D0-4F47-454A-BC16-955C2C54B6F5},
                  {A16C0740-C2A0-38C9-9FD3-7C583B3B42FA}">
            <endpoint address="IOrderControl" binding="wsHttpBinding"
                bindingConfiguration="comTransactionalBinding"
                contract="{E1B02E09-EE48-3B6B-946F-E6A8BAEC6340}" />
            <endpoint address="mex" binding="mexHttpBinding"
                contract="IMetadataExchange" />
            <host>
               <baseAddresses>
                  <add baseAddress=
           "net.pipe://localhost/Wrox.NorthwindDemo/Wrox.ProCSharp.
                 EnterpriseServices.OrderControl" />
                  <add baseAddress=
                     "http://localhost:8088/NorthwindService" />
               </baseAddresses>
            </host>
         </service>
      </services>
   </system.serviceModel>
</configuration>
```

Before you can start the server application you need to change the security to allow the user that runs the application to register ports for listening. Otherwise a normal user is not allowed to register a listener port. On Windows 7 you can do this with the `netsh` command as shown. The option `http` changes the ACL for the HTTP protocol. The port number and the name of the service are defined with the URL, and the user option specifies the name of the user that starts the listener service:

```
netsh http add urlacl url=http://+:8088/NorthwindService user=username
```

Client Application

Create a new console application named `WCFClientApp`. Because the service offers a MEX endpoint, you can add a service reference from Visual Studio by selecting Project ➪ Add Service Reference . . . (see Figure 51-15).



Add Service Reference
To see a list of available services on a specific server, enter a service URL and click Go. To browse for available services, click Discover.
Address:
http://localhost:8088/NorthwindService
Go
Discover
Services:
Wrox.NorthwindDemo.Wro
IMetadataExchange
IOrderControl
Operations:
NewOrder
1 service(s) found at address 'http://localhost:8088/NorthwindService'.
Namespace:
NorthwindService
Advanced...
OK
Cancel

FIGURE 51-15

With the service reference a proxy class is created, the assemblies `System.ServiceModel` and `System.Runtime.Serialization` are referenced, and an application configuration file referencing the service is added to the client application.

Now you can use the generated entity classes and the proxy class `OrderControlClient` to send an order request to the serviced component:

```
static void Main()
{
   var order = new Order
   {
       CustomerId = "PICCO",
       OrderDate = DateTime.Today,
       ShipAddress = "Georg Pipps",
       ShipCity = "Salzburg",
       ShipCountry = "Austria"
   };
   var line1 = new OrderLine
   {
       ProductId = 16,
       UnitPrice = 17.45F,
       Quantity = 2
   };
   var line2 = new OrderLine
```

```
            {
                ProductId = 67,
                UnitPrice = 14,
                Quantity = 1
            }
            OrderLine[] orderLines = { line1, line2 };
            order.orderLines = orderLines;

            var occ = new OrderControlClient();
            occ.NewOrder(order);
         }
```

SUMMARY

This chapter discussed the rich features offered by Enterprise Services, such as automatic transactions, object pooling, queued components, and loosely coupled events.

To create serviced components, you have to reference the assembly `System.EnterpriseServices`. The base class of all serviced components is `ServicedComponent`. In this class, the context makes it possible to intercept method calls. You can use attributes to specify the interception that will be used. You also learned how to configure an application and its components using attributes, as well as how to manage transactions and specify the transactional requirements of components by using the `[Transaction]` attribute. You've also seen how well Enterprise Services integrates with the new communication technology WCF, by creating a WCF façade.

This chapter showed how to use Enterprise Services, a feature offered by the operating system. The next chapter gives information on how to use another feature from the operating system that is used for communication: message queuing.

52

Directory Services

WHAT'S IN THIS CHAPTER?

- The architecture and concepts of Active Directory
- Tools for accessing the Active Directory
- How to read and modify data in Active Directory
- Searching for objects in Active Directory
- User and group management programmatically
- Using DSML (Directory Service Markup Language) to access the Active Directory

Microsoft's Active Directory is a *directory service* that provides a central, hierarchical store for user information, network resources, services, and so on. The information in this directory service can be extended to also store custom data that is of interest for the enterprise. For example, Microsoft Exchange Server and Microsoft Dynamics use Active Directory extensively to store public folders and other items.

Before the release of Active Directory, Exchange Server used its own private store for its objects. It was necessary for a system administrator to configure two user IDs for a single person: a user account in the Windows NT domain to enable a logon and a user in Exchange Directory. This was necessary because of the additional information required by users (such as e-mail addresses, phone numbers, and so on), and the user information for the NT domain was not extensible to add the required information.

Now, the system administrator has to configure just a single user for a person in Active Directory; the information for a `user` object can be extended so that it fits the requirements of Exchange Server. You can also extend this information. For example, you can extend user information in Active Directory with a skills list. Then, it would easily be possible to track down a C# developer by searching for the required C# skill.

This chapter shows how you can use the .NET Framework to access and manipulate the data in a directory service using classes from the `System.DirectoryServices`, `System.DirectoryServices.AccountManagement`, and `System.DirectoryServices.Protocols` namespaces.

This chapter uses Windows Server 2008 R2 with Active Directory configured. You can also use Windows 2003 Server or other directory services.

After discussing the architecture and how to program Active Directory, you create a Windows application in which you can specify properties and a filter to search for `user` objects. Similar to other chapters, you can also download the code for the examples in this chapter from the Wrox web site at `www.wrox.com`.

THE ARCHITECTURE OF ACTIVE DIRECTORY

Before starting to program Active Directory, you need to know how it works, what it is used for, and what data can be stored there.

Active Directory Features

The features of Active Directory can be summarized as follows:

- **Hierarchical grouping of data.** Objects can be stored inside other container objects. Instead of having a single, large list of users, you can group users inside organizational units. An organizational unit can contain other organizational units, so you can build a tree.
- **Multimaster replication.** With Active Directory, every *domain controller* (DC) is a master. With multiple masters, updates can be applied to any DC. This model is much more scalable than a single-master model because updates can be made to different servers concurrently. The disadvantage of this model is more complex replication, which is discussed later in this chapter.
- **Flexible replication topology.** This supports replications across slow links in WANs. How often data should be replicated is configurable by the domain administrators.
- **Open standards**. Active Directory supports open standards. The *Lightweight Directory Access Protocol* (LDAP) is an Internet standard that can be used to access many different directory services, including the data in Active Directory. With LDAP, a programming interface, LDAP API, is also defined. The LDAP API can be used to access Active Directory with the C language. Another standard used within Active Directory is *Kerberos*, which is used for authentication. The Windows Server Kerberos service can also be used to authenticate UNIX clients.
- **Active Directory Service Interface (ADSI)**. ADSI defines COM interfaces to access directory services. ADSI makes it possible to access all features of Active Directory. Classes from the namespace `System.DirectoryServices` wrap ADSI COM objects to make directory services accessible from .NET applications.
- **Directory Service Markup Language (DSML)**. DSML is another standard to access directory services. It is a platform-independent approach and is supported by the OASIS group.
- **Fine-grained security.** With Active Directory, fine-grained security is available. Every object stored in Active Directory can have an associated access control list that defines who can do what with that object.

The objects in the directory are *strongly typed,* which means that the type of an object is exactly defined; no attributes that are not specified may be added to an object. In the *schema,* the object types as well as the parts of an object (attributes) are defined. Attributes can be mandatory or optional.

Active Directory Concepts

Before programming Active Directory, you need to know some basic terms and definitions.

Objects

Active Directory stores objects. An object refers to something concrete such as a user, a printer, or a network share. Objects have mandatory and optional attributes that describe them. Some examples of the attributes of a `user` object are the first name, last name, e-mail address, phone number, and so on.

Figure 52-1 shows a container object called Wrox Press that contains some other objects: two user objects, a contact object, a printer object, and a user group object.

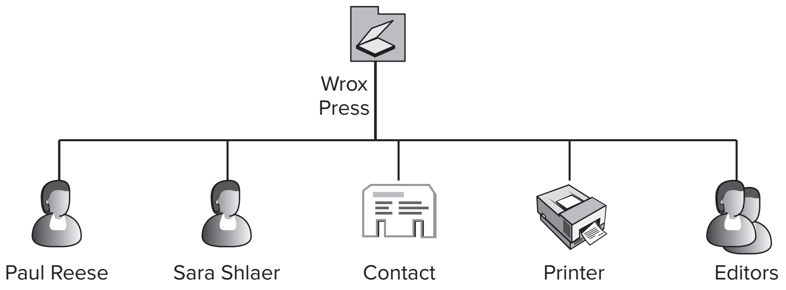


FIGURE 52-1

Schema

Every object is an instance of a class defined in the *schema*. The schema *defines the types* and is itself stored in objects in Active Directory. You must differentiate between `classSchema` and `attributeSchema`: `classSchema` defines the types of objects and details what mandatory and optional attributes an object has. `attributeSchema` defines what an attribute looks like and the allowed syntax for a specific attribute.

You can define custom types and attributes and add these to the schema. Be aware, however, that a new schema type cannot be removed from Active Directory. You can mark it as inactive so that new objects cannot be created, but there can be existing objects of that type, so it is not possible to remove classes or attributes defined in the schema.

The user group Administrator doesn't have enough rights to create new schema entries; the group Enterprise Admins is needed for that.

Configuration

In addition to objects and class definitions stored as objects, the configuration of Active Directory itself is stored in Active Directory. It stores the information about all sites, such as the replication interval, which is set up by the system administrator. Because the configuration itself is stored in Active Directory, you can access the configuration information like all other objects in Active Directory.

The Active Directory Domain

A domain is a security boundary of a Windows network. In the Active Directory domain, the objects are stored in a hierarchical order. Active Directory itself is made up of one or more domains. Figure 52-2 shows the hierarchical order of objects in a domain; the domain is represented by a triangle. Container objects such as `Users`, `Computers`, and `Books` can store other objects. Each oval in the picture represents an object, with the lines between the objects representing parent-child relationships. For example, `Books` is the parent of `.NET` and `Java`, and `Pro C#`, `Beg C#`, and `ASP.NET` are child objects of the `.NET` object.

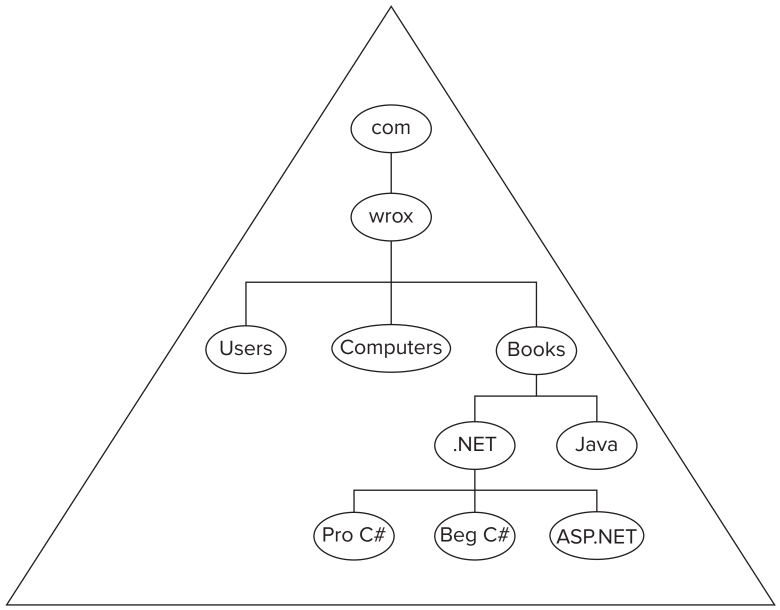

FIGURE 52-2

Domain Controller

A single domain can have multiple domain controllers, each of which stores all of the objects in the domain. There is no master server, and all DCs are treated equally; you have a multimaster model. The objects are replicated across the servers inside the domain.

Site

A *site* is a location in the network that holds at least one DC. If you have multiple locations in the enterprise, which are connected with slow network links, you can use multiple sites for a single domain. For backup or scalability reasons, each site can have one or more DCs running. Replication between servers in a site can happen at shorter intervals because of the faster network connection. Replication is configured to occur at larger time intervals between servers across sites, depending on the speed of the network. Of course, replication intervals can be configured by the domain administrator.

Domain Tree

Multiple domains can be connected by trust relationships. These domains share a *common schema,* a *common configuration,* and a *global catalog* (more on global catalogs shortly). A common schema and a common configuration imply that this data is replicated across domains. Domain trees share the same class and attribute schema. The objects themselves are not replicated across domains.

Domains connected in such a way form a domain tree. Domains in a domain tree have a contiguous, hierarchical namespace. This means that the domain name of the child domain is the name of that child domain appended to the name of the parent domain. Between domains, trusts using the Kerberos protocol are established.

For example, you have the root domain `wrox.com`, which is the *parent domain* of the child domains `india.wrox.com` and `uk.wrox.com`. A trust is set up between the parent and the child domains, so that accounts from one domain can be authenticated by another domain.

Forest

Multiple domain trees that are connected by using a common schema, a common configuration, and a global catalog without a contiguous namespace are called a *forest*. A forest is a set of domain trees; it can be used if the company has a subcompany for which a different domain name should be used. Here is one example: `wrox.com` should be relatively independent of the domain `wiley.com`, but it should be possible to have a common management, and be possible for users from `wrox.com` to access resources from the `wiley.com` domain and vice versa. With a forest, you can have trusts between multiple domain trees.

Global Catalog

A search for an object can span multiple domains. If you look for a specific `user` object with some attributes, you must search every domain. Starting with `wrox.com`, the search continues to `uk.wrox.com` and `india.wrox.com`; across slow links, such a search could take a while.

To make searches faster, all objects are copied to the *global catalog* (GC). The GC is replicated in every domain of a forest. There is at least one server in every domain holding a GC. For performance and scalability reasons, you can have more than one GC server in a domain. Using a GC, a search through all the objects can happen on a single server.

The GC is a *read-only cache* of all the objects that can be used only for searches; the domain controllers must be used to do updates.

Not all attributes of an object are stored in the GC. You can define whether an attribute should be stored with an object. The decision whether to store an attribute in the GC depends on how the attribute is used. If the attribute is frequently used in searches, putting it into the GC makes the search faster. A picture of a user isn't useful in the GC because you would never search for a picture. Conversely, a phone number would be a useful addition to the store. You can also define that an attribute should be indexed so that a query for it is faster.

Replication

As a programmer, you are unlikely ever to configure replication, but because it affects the data you store in Active Directory, you need to know how it works. Active Directory uses a *multimaster* server architecture. Updates happen to every domain controller in the domain. The *replication latency* defines how long it takes until an update starts:

- The configurable *change notification* happens, by default, every 5 minutes inside a site if some attributes change. The DC where a change occurred informs one server after the other with 30-second intervals, so the fourth DC can get the change notification after 7 minutes. The default change notification across sites is set to 180 minutes. Intra- and intersite replication can each be configured to other values.
- If no changes have occurred, the *scheduled replication* occurs every 60 minutes inside a site. This is to ensure that a change notification wasn't missed.
- For security-sensitive information, such as account lockout, *immediate notification* can occur.

With a replication, only the changes are copied to the DCs. With every change of an attribute, a version number (update sequence number or USN) and a time stamp are recorded. These are used to help resolve conflicts if updates have been made to the same attribute on different servers.

Here's an example. The mobile phone attribute of the user John Doe has the USN number 47. This value is already replicated to all DCs. One system administrator changes the phone number. The change occurs on the server DC1; the new USN of this attribute on the server DC1 is now 48, whereas the other DCs still have the USN 47. For someone still reading the attribute, the old value can be read until the replication to all domain controllers has occurred.

The rare case can happen that another administrator changes the phone number attribute, and a different DC is selected because this administrator received a faster response from the server DC2. The USN of this attribute on the server DC2 is also changed to 48.

At the notification intervals, notification happens because the USN for the attribute changed, and the last time replication occurred was with a USN value of 47. The replication mechanism now detects that the servers DC1 and DC2 both have a USN of 48 for the phone number attribute. Which server is the winner is not really important, but one server must definitely win. To resolve this conflict, the time stamp of the change is used. Because the change happened later on DC2, the value stored in the DC2 domain controller is replicated.

Characteristics of Active Directory Data

Active Directory doesn't replace a relational database or the registry, so what kind of data would you store in it?

- With Active Directory you get **hierarchical data**. You can have containers that store further containers and objects, too. Containers themselves are objects as well.
- The data should be used for **read-mostly**. Because of replication occurring at certain time intervals, you cannot be sure that you will read up-to-date data. You must be aware that, in applications, the information you read is possibly not the current up-to-date information.
- Data should be of **global interest** to the enterprise, because adding a new data type to the schema replicates it to all the servers in the enterprise. For data types of interest to only a small number of users, the domain enterprise administrator normally wouldn't install new schema types.
- The data stored should be of **reasonable size** because of replication issues. It is fine to store data with a size of 100K in the directory, if the data changes only once a week. However, if the data changes every hour, data of this size is too large. Always think about replicating the data to different servers: where the data gets transferred to and at what intervals. If you have larger data, it's possible to put a link into Active Directory and store the data itself in a different place.

To summarize, the data you store in Active Directory should be hierarchically organized, of reasonable size, and of importance to the enterprise.

Specifying Schema

Active Directory objects are strongly typed. The schema defines the types of the objects, mandatory and optional attributes, and the syntax and constraints of these attributes. As mentioned earlier, in the schema, it is necessary to differentiate between class-schema and attribute-schema objects.

A class is a collection of attributes. With the classes, single inheritance is supported. As you can see in Figure 52-3, the `user` class derives from the `organizationalPerson` class, `organizationalPerson` is a subclass of `person`, and the base class is `top`. The `classSchema` that defines a class describes the attributes with the `systemMayContain` attribute.

Figure 52-3 shows only a few of all the `systemMayContain` values. Using the ADSI Edit tool, you can easily see all the values; you look at this tool in the next section, "ADSI Edit." In the root class `top`, you can see that every object can have common name (`cn`), `displayName`, `objectGUID`, `whenChanged`, and `whenCreated` attributes. The `person` class derives from `top`. A `person` object also has a `userPassword` and a

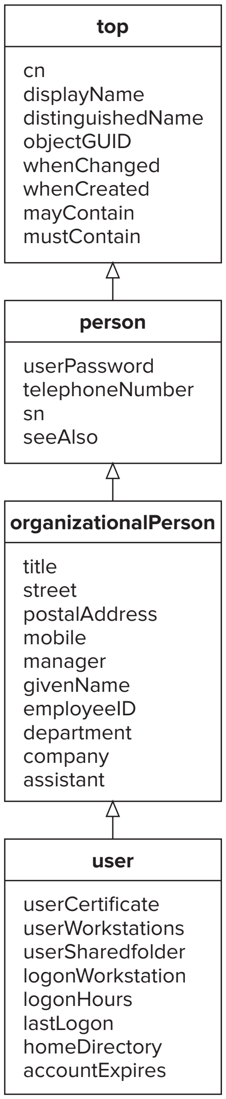

FIGURE 52-3

telephoneNumber. organizationalPerson is derived from person. In addition to the attributes of person, it has a manager, department, and company, and a user has extra attributes needed to log on to a system.

ADMINISTRATION TOOLS FOR ACTIVE DIRECTORY

Looking into some of the Active Directory administration tools can help to give you an idea of Active Directory, what data is in there, and what can be done programmatically.

The system administrator has many tools to enter new data, update data, and configure Active Directory:

- The *Active Directory Users and Computers* MMC snap-in is used to enter new users and update user data.
- The *Active Directory Sites and Services* MMC snap-in is used to configure sites in a domain and for replication between these sites.
- The *Active Directory Domains and Trusts* MMC snap-in can be used to build up a trust relationship between domains in a tree.
- *ADSI Edit* is the editor for Active Directory, where every object can be viewed and edited.

To run these tools on Windows 7, you need to install Windows 7 Remote Administration Tools. For other Windows versions, there are also separate downloads for these system management tools.

The following sections get into the functionality of the tools Active Directory Users and Computers and ADSI Edit because these tools are important in regard to creating applications using Active Directory.

Active Directory Users and Computers

The Active Directory Users and Computers snap-in is the tool that system administrators use to manage users. Select Start ➪ Administrative ➪ Tools ➪ Active Directory Users and Computers to start this program (see Figure 52-4).

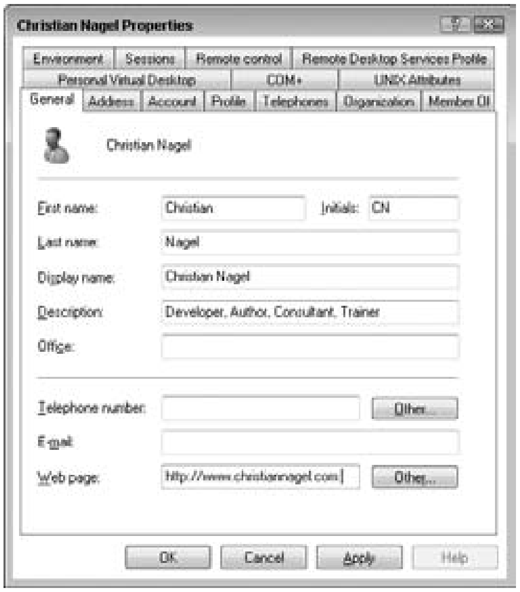
FIGURE 52-4

With this tool you can add new users, groups, contacts, organizational units, printers, shared folders, or computers, and modify existing ones. Figure 52-5 shows the attributes that can be entered for a user object: office, phone numbers, e-mail addresses, web pages, organization information, addresses, groups, and so on.

Active Directory Users and Computers can also be used in big enterprises with millions of objects. It's not necessary to look through a list with a thousand objects, because you can select a custom filter to display only some of the objects. You can also perform an LDAP query to search for the objects in the enterprise. You explore these possibilities later in this chapter.



Christian Nagel

First name:	Christian
Initials:	CN
Last name:	Nagel
Display name:	Christian Nagel

FIGURE 52-5

ADSI Edit

ADSI Edit is the editor of Active Directory. ADSI Edit offers greater control than the Active Directory Users and Computers tool (see Figure 52-6); with ADSI Edit, everything can be configured, and you can also look at the schema and the configuration. This tool is not very intuitive to use, however, and it is very easy to enter wrong data.

FIGURE 52-7

PROGRAMMING ACTIVE DIRECTORY

To develop programs for Active Directory, you can use the classes from either the `System.DirectoryServices` or the `System.DirectoryServices.Protocols` namespaces. In the namespace `System.DirectoryServices`, you can find classes that wrap Active Directory Service Interfaces (ADSI) COM objects to access Active Directory.

ADSI is a programmatic interface to directory services. It defines some COM interfaces that are implemented by ADSI providers. This means that the client can use different directory services with the same programmatic interfaces. The .NET Framework classes in the `System.DirectoryServices` namespace make use of ADSI.

Figure 52-8 shows some ADSI Providers (LDAP, IIS, and NDS) that implement COM interfaces such as `IADs` and `IUnknown`. The assembly `System.DirectoryServices` makes use of the ADSI providers.

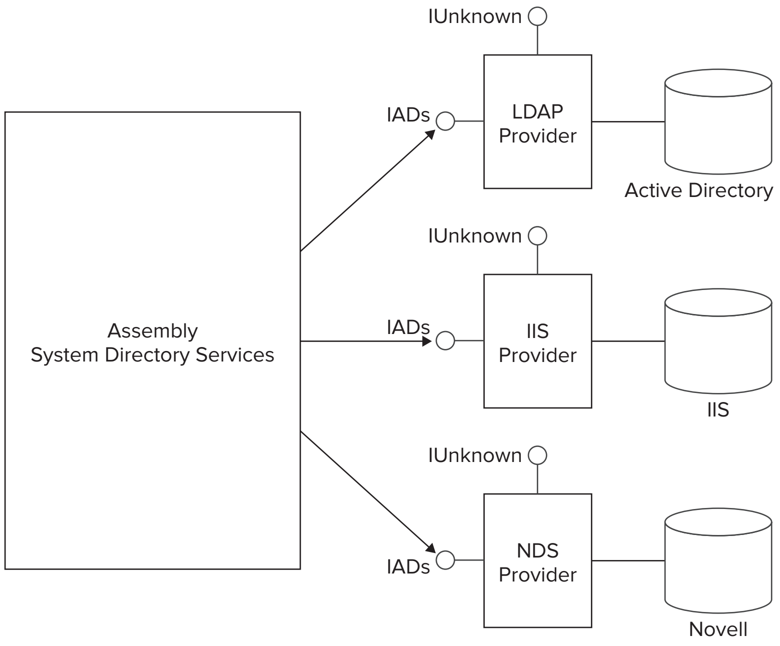

FIGURE 52-8

Classes from the namespace `System.DirectoryServices.Protocols` make use of Directory Services Markup Language (DSML) Services for Windows. With DSML, standardized Web service interfaces are defined by the OASIS group (`www.oasis-open.org/committees/dsml`).

To use the classes from the `System.DirectoryServices` namespace, you need to reference the `System.DirectoryServices` assembly. With the classes in this assembly, you can query objects, view and update properties, search for objects, and move objects to other container objects. In the code segments that follow later in this section, you use a simple C# console application that demonstrates the functionality of the classes in the `System.DirectoryServices` namespace.

This section covers the following:

- Classes in the `System.DirectoryServices` namespace
- The process of connecting to Active Directory (binding)
- Getting directory entries, creating new objects, and updating existing entries
- Searching Active Directory

Classes in System.DirectoryServices

The following table shows the major classes in the `System.DirectoryServices` namespace.

CLASS	DESCRIPTION
`DirectoryEntry`	This is the main class of the `System.DirectoryServices` namespace. An object of this class represents an object in the Active Directory store. This class is used to bind to an object and to view and update properties. The properties of the object are represented in a `PropertyCollection`. Every item in the `PropertyCollection` has a `PropertyValueCollection`.
`DirectoryEntries`	`DirectoryEntries` is a collection of `DirectoryEntry` objects. The `Children` property of a `DirectoryEntry` object returns a list of objects in a `DirectoryEntries` collection.
`DirectorySearcher`	This is the main class used for searching for objects with specific attributes. To define the search, the `SortOption` class and the enumerations `SearchScope`, `SortDirection`, and `ReferralChasingOption` can be used. The search results in a `SearchResult` or a `SearchResultCollection`. You also get `ResultPropertyCollection` and `ResultPropertyValueCollection` objects.

Binding to Directory Services

To get the values of an object in Active Directory, you need to connect to the Active Directory service. This connecting process is called *binding*. The binding path can look like this:

```
LDAP://dc01.thinktecture.com/OU=Development, DC=thinktecture, DC=Com
```

With the binding process, you can specify these items:

- The *protocol* specifies the provider to be used
- The *server name* of the domain controller
- The *port number* of the server process
- The *distinguished name* of the object; this identifies the object you want to access
- The *username and password,* if the user who is allowed to access Active Directory is different from the current logged-on user
- An *authentication* type, if encryption is needed

The following subsections discuss these options in more detail.

Protocol

The first part of a binding path, the protocol, specifies the ADSI provider. The provider is implemented as a COM server; for identification, a `progID` can be found in the registry directly under `HKEY_CLASSES_ROOT`. The providers that are available with Windows 7 are listed in the following table.

PROVIDER	DESCRIPTION
`LDAP`	LDAP Server, such as the Exchange directory and Active Directory Servers since Windows 2000.
`GC`	GC is used to access the global catalog in Active Directory. It can be used for fast queries.
`IIS`	With the ADSI provider for IIS, it's possible to create new web sites and to administer them in the IIS catalog.
`NDS`	This progID is used to communicate with Novell Directory Services.

Server Name

The server name follows the protocol in the binding path. The server name is optional if you are logged on to an Active Directory domain. Without a server name, *serverless binding* occurs; this means that Windows Server 2008 tries to get the "best" domain controller in the domain that's associated with the user doing the bind. If there is no server inside a site, the first domain controller that can be found will be used.

A serverless binding might look like this: `LDAP`:

```
//OU=Sales, DC=Thinktecture, DC=Local
```

Port Number

After the server name, you can specify the port number of the server process by using the syntax *xxx*. The default port number for the LDAP server is 389:

```
LDAP://dc01.sentinel.net:389.
```

The Exchange server uses the same port number as the LDAP server. If the Exchange server is installed on the same system — for example, as a domain controller of Active Directory — a different port can be configured.

Distinguished Name

The fourth part that you can specify in the path is the distinguished name (DN). The DN is a unique name that identifies the object you want to access. With Active Directory, you can use LDAP syntax that is based on X.500 to specify the name of the object.

Here's an example of a distinguished name:

```
CN=Christian Nagel, OU=Consultants, DC=thinktecture, DC=local
```

This DN specifies the common name (`CN`) of `Christian Nagel` in the organizational unit (`OU`) called `Consultants` in the domain component (`DC`) called `thinktecture` of the domain `thinktecture.local`. The part specified at the right (DC) is the root object of the domain. The name must follow the hierarchy in the object tree.

You can find the LDAP specification for the string representation of distinguished names in RFC 2253 at `www.ietf.org/rfc/rfc2253.txt`.

Relative Distinguished Name

A *relative distinguished name* (RDN) is used to reference objects within a container object. With an RDN, the specification of `OU` and `DC` is not needed because a common name is enough. `CN=Christian Nagel` is the relative distinguished name inside the organizational unit. A relative distinguished name can be used if you already have a reference to a container object and if you want to access child objects.

Default Naming Context

If a distinguished name is not specified in the path, the binding process will be made to the default naming context. You can read the default naming context with the help of `rootDSE`. LDAP 3.0 defines `rootDSE` as the root of a directory tree on a directory server. For example:

```
LDAP://rootDSE
```

or

```
LDAP://servername/rootDSE
```

By enumerating all properties of the `rootDSE`, you can get the information about the `defaultNamingContext` that will be used when no name is specified. `schemaNamingContext` and `configurationNamingContext` specify the required names to be used to access the schema and the configuration in the Active Directory store.

The following code is used to get all properties of `rootDSE`:

```
try
{
   using (var de = new DirectoryEntry())
   {
      de.Path = "LDAP://magellan/rootDSE";
      de.Username = @"cninnovation\christian";
      de.Password = "Pa$$w0rd";

      PropertyCollection props = de.Properties;
      foreach (string prop in props.PropertyNames)
      {
         PropertyValueCollection values = props[prop];
         foreach (string val in values)
         {
            Console.Write("{0}: ", prop);
            Console.WriteLine(val);
         }
      }
   }
}
catch (COMException ex)
{
   Console.WriteLine(ex.Message);
}
```

code snippet DirectoryServicesSamples/Program.cs

To have this code running on your machine, you must change the path to the object to access, including the server name.

This program shows the default naming context (`defaultNamingContext DC=cninnovation, DC=local`), the context that can be used to access the schema (`CN=Schema, CN=Configuration, DC=cninnovation, DC=local`), and the naming context of the configuration (`CN=Configuration, DC=cninnovation, DC=local`), as you can see here:

```
currentTime: 20090925131508.0Z
subschemaSubentry: CN=Aggregate,CN=Schema,CN=Configuration,DC=cninnovation,
DC=local
dsServiceName: CN=NTDS Settings,CN=MAGELLAN,CN=Servers,

supportedControl: 1.2.840.113556.1.4.319
supportedControl: 1.2.840.113556.1.4.801
```

Object Identifier

Every object has a *globally unique identifier* (GUID). A GUID is a unique 128-bit number as you may already know from COM development. You can bind to an object using the GUID. This way, you always get to the same object, regardless of whether the object was moved to a different container. The GUID is generated at object creation and always remains the same.

You can get to a GUID string representation with `DirectoryEntry.NativeGuid`. This string representation can then be used to bind to the object.

This example shows the pathname for a serverless binding to bind to a specific object represented by a GUID:

```
LDAP://<GUID=14abbd652aae1a47abc60782dcfc78ea>
```

Username

If a different user must be used for accessing the directory (maybe the current user doesn't have the required permissions to access Active Directory), explicit *user credentials* must be specified for the binding process. Active Directory has multiple ways to specify the username.

Downlevel Logon

With a downlevel logon, the username can be specified with the pre-Windows 2000 domain name:

```
domain\username
```

Distinguished Name

The user can also be specified by a distinguished name of a `user` object, for example:

```
CN=Administrator, CN=Users, DC=thinktecture, DC=local
```

User Principal Name

The *user principal name* (UPN) of an object is defined with the `userPrincipalName` attribute. The system administrator specifies this with the logon information in the Account tab of the User properties with the Active Directory Users and Computers tool. Note that this is not the e-mail address of the user.

This information also uniquely identifies a user and can be used for a logon:

```
Nagel@thinktecture.local
```

Authentication

For secure encrypted authentication, the *authentication* type can also be specified. The authentication can be set with the `AuthenticationType` property of the `DirectoryEntry` class. The value that can be assigned is one of the `AuthenticationTypes` enumeration values. Because the enumeration is marked with the `[Flags]` attribute, multiple values can be specified. Some of the possible values are where the data sent is encrypted; `ReadonlyServer`, where you specify that you need only read access; and `Secure` for secure authentication.

Binding with the DirectoryEntry Class

The `System.DirectoryServices.DirectoryEntry` class can be used to specify all the binding information. You can use the default constructor and define the binding information with the properties `Path`, `Username`, `Password`, and `AuthenticationType`, or pass all the information in the constructor:

```
var de = new DirectoryEntry();
de.Path = "LDAP://platinum/DC=thinktecture, DC=local";
de.Username = "Christian.Nagel@thinktecture.local";
de.Password = "password";

// use the current user credentials
var de2 = new DirectoryEntry("LDAP://DC=thinktecture, DC=local");
```

Even if the construction of the `DirectoryEntry` object is successful, this doesn't mean that the binding was a success. Binding will happen the first time a property is read to avoid unnecessary network traffic. At the first access of the object, you can see if the object exists and if the specified user credentials are correct.

Getting Directory Entries

Now that you know how to specify the binding attributes to an object in Active Directory, you can move on to read the attributes of an object. In the following example, you read the properties of user objects.

The `DirectoryEntry` class has some properties to get information about the object: the `Name`, `Guid`, and `SchemaClassName` properties. The first time a property of the `DirectoryEntry` object is accessed, the binding occurs, and the cache of the underlying ADSI object is filled. (This is discussed in more detail shortly.) Additional properties are read from the cache, and communication with the server isn't necessary for data from the same object.

In the following example, the `user` object with the common name `Christian Nagel` in the organizational unit `thinktecture` is accessed:

```
using (var de = new DirectoryEntry())
{
   de.Path = "LDAP://magellan/CN=Christian Nagel, " +
             "OU=thinktecture, DC=cninnovation, DC=local";

   Console.WriteLine("Name: {0}", de.Name);
   Console.WriteLine("GUID: {0}", de.Guid);
   Console.WriteLine("Type: {0}", de.SchemaClassName);
   Console.WriteLine();

   //...
}
```

code snippet DirectoryServicesSamples/Program.cs

An Active Directory object holds much more information, with the information available depending on the type of the object; the `Properties` property returns a `PropertyCollection`. Each property is a collection itself, because a single property can have multiple values; for example, the `user` object can have multiple phone numbers. In this case, you go through the values with an inner `foreach` loop. The collection returned from `properties[name]` is an `object` array. The attribute values can be strings, numbers, or other types. Here, just the `ToString()` method is used to display the values:

```
Console.WriteLine("Properties: ");
PropertyCollection properties = de.Properties;
foreach (string name in properties.PropertyNames)
{
   foreach (object o in properties[name])
   {
      Console.WriteLine("{0}: {1}", name, o.ToString());
   }
}
```

In the resulting output, you can see all attributes of the specified `user` object. Some properties such as `otherTelephone` have multiple values. With this property, many phone numbers can be defined. Some of the property values just display the type of the object, `System.__ComObject`; for example, `lastLogoff`, `lastLogon`, and `nTSecurityDescriptor`. To get the values of these attributes, you must use the ADSI COM interfaces directly from the classes in the `System.DirectoryServices` namespace.

```
Name: CN=Christian Nagel
GUID: 0238fd5c-7e67-48bc-985f-c2f1ccf0f86c
Type: user

Properties:
objectClass: top
objectClass: person
objectClass: organizationalPerson
objectClass: user
cn: Christian Nagel
sn: Nagel
givenName: Christian
distinguishedName: CN=Christian Nagel,OU=thinktecture,DC=cninnovation,DC=local
instanceType: 4
whenCreated: 9/25/2009 12:42:05 PM
whenChanged: 9/25/2009 12:42:05 PM
displayName: Christian Nagel
uSNCreated: System.__ComObject
uSNChanged: System.__ComObject
name: Christian Nagel
objectGUID: System.Byte[]
userAccountControl: 66048

dSCorePropagationData: 1/1/1601 12:00:00 AM
nTSecurityDescriptor: System.__ComObject
```

With `DirectoryEntry.Properties`, you can access all properties. If a property name is known, you can access the values directly by name:

```
foreach (string homePage in de.Properties["wWWHomePage"])
   Console.WriteLine("Home page: " + homePage);
```

Object Collections

Objects are stored hierarchically in Active Directory. Container objects contain children. You can enumerate these child objects with the `Children` property of the class `DirectoryEntry`. In the other direction, you can get the container of an object with the `Parent` property.

A `user` object doesn't have children, so you use an organizational unit in the following example. Non-container objects return an empty collection with the `Children` property. Get all `user` objects from the organizational unit `thinktecture` in the domain `explorer.local`. The `Children` property returns a `DirectoryEntries` collection that collects `DirectoryEntry` objects. You iterate through all `DirectoryEntry` objects to display the name of the child objects:

```
using (var de = new DirectoryEntry())
{
   de.Path = "LDAP://magellan/OU=thinktecture, DC=cninnovation, DC=local";

   Console.WriteLine("Children of {0}", de.Name);
   foreach (DirectoryEntry obj in de.Children)
   {
      Console.WriteLine(obj.Name);
   }
}
```

code snippet DirectoryServicesSamples/Program.cs

When you run the program, the common names of the objects are displayed:

```
Children of OU=thinktecture
OU=Admin
CN=Buddhike de Silva
CN=Christian Nagel
CN=Christian Weyer
CN=Consultants
CN=demos
CN=Dominick Baier
CN=Ingo Rammer
CN=Neno Loye
```

In this example, you see all the objects in the organizational unit: `users`, `contacts`, `printers`, `shares`, and others. If you want to display only some object types, you can use the `SchemaFilter` property of the `DirectoryEntries` class. The `SchemaFilter` property returns a `SchemaNameCollection`. With this `SchemaNameCollection`, you can use the `Add()` method to define the object types you want to see. Here, you are just interested in seeing the `user` objects, so `user` is added to this collection:

```
using (var de = new DirectoryEntry())
{
   de.Path = "LDAP://magellan/OU=thinktecture, DC=cninnovation, DC=local";

   Console.WriteLine("Children of {0}", de.Name);
   de.Children.SchemaFilter.Add("user");
   foreach (DirectoryEntry obj in de.Children)
   {
      Console.WriteLine(obj.Name);
   }
}
```

As a result, you see only the `user` objects in the organizational unit:

```
Children of OU=thinktecture
CN=Christian Nagel
CN=Christian Weyer
CN=Dominick Baier
CN=Ingo Rammer
CN=Jörg Neumann
CN=Richard Blewett
```

Cache

To reduce the network transfers, ADSI uses a cache for the object properties. As mentioned earlier, the server isn't accessed when a `DirectoryEntry` object is created; instead, with the first reading of a value from the directory store, all the properties are written into the cache so that a round trip to the server isn't necessary when the next property is accessed.

Writing any changes to objects changes only the cached object; setting properties doesn't generate network traffic. You must use `DirectoryEntry.CommitChanges()` to flush the cache and to transfer any changed data to the server. To get the newly written data from the directory store, you can use `DirectoryEntry.RefreshCache()` to read the properties. Of course, if you change some properties without calling `CommitChanges()` and do a `RefreshCache()`, all your changes will be lost, because you read the values from the directory service again using `RefreshCache()`.

It is possible to turn off this property cache by setting the `DirectoryEntry.UsePropertyCache` property to `false`. However, unless you are debugging your code, it's better not to turn off the cache because of the extra round trips to the server that will be generated.

Creating New Objects

When you want to create new Active Directory objects — such as users, computers, printers, contacts, and so on — you can do this programmatically with the `DirectoryEntries` class.

To add new objects to the directory, first you have to bind to a container object, such as an organizational unit, where new objects can be inserted — you cannot use objects that are not able to contain other objects. The following example uses the container object with the distinguished name `CN=Users, DC=thinktecture, DC=local`:

```
var de = new DirectoryEntry();
de.Path = "LDAP://magellan/CN=Users, DC=cninnovation, DC=local";
```

code snippet DirectoryServicesSamples/Program.cs

You can get to the `DirectoryEntries` object with the `Children` property of a `DirectoryEntry`:

```
DirectoryEntries users = de.Children;
```

The class `DirectoryEntries` offers methods to add, remove, and find objects in the collection. Here, a new `user` object is created. With the `Add()` method, the name of the object and a type name are required. You can get to the type names directly using ADSI Edit.

```
DirectoryEntry user = users.Add("CN=John Doe", "user");
```

The object now has the default property values. To assign specific property values, you can add properties with the `Add()` method of the `Properties` property. Of course, all of the properties must exist in the schema for the `user` object. If a specified property doesn't exist, you'll get a `COMException: "The specified directory service attribute or value doesn't exist"`:

```
user.Properties["company"].Add("Some Company");
user.Properties["department"].Add("Sales");
user.Properties["employeeID"].Add("4711");
user.Properties["samAccountName"].Add("JDoe");
user.Properties["userPrincipalName"].Add("JDoe@explorer.local");
user.Properties["givenName"].Add("John");
user.Properties["sn"].Add("Doe");
user.Properties["userPassword"].Add("someSecret");
```

Finally, to write the data to Active Directory, you must flush the cache:

```
user.CommitChanges();
```

Updating Directory Entries

Objects in the Active Directory service can be updated as easily as they can be read. After reading the object, you can change the values. To remove all values of a single property, you can call the method `PropertyValueCollection.Clear()`. You can add new values to a property with `Add()`. `Remove()` and `RemoveAt()` remove specific values from a property collection.

You can change a value simply by setting it to the specified value. The following example uses an indexer for `PropertyValueCollection` to set the mobile phone number to a new value. With the indexer a value can be changed only if it exists. Therefore, you should always check with `DirectoryEntry.Properties.Contains()` to see if the attribute is available:

```
using (var de = new DirectoryEntry())
{
   de.Path = "LDAP://magellan/CN=Christian Nagel, " +
             "OU=thinktecture, DC=cninnovation, DC=local";

   if (de.Properties.Contains("mobile"))
   {
      de.Properties["mobile"][0] = "+43(664)3434343434";
   }
   else
   {
      de.Properties["mobile"].Add("+43(664)3434343434");
   }

   de.CommitChanges();
}
```

The `else` part in this example uses the method `PropertyValueCollection.Add()` to add a new property for the mobile phone number, if it doesn't exist already. If you use the `Add()` method with already existing properties, the resulting effect would depend on the type of the property (single-value or multivalue property). Using the `Add()` method with a single-value property that already exists results in a `COMException: "A constraint violation occurred."` Using `Add()` with a multivalue property, however, succeeds, and an additional value is added to the property.

The `mobile` property for a `user` object is defined as a single-value property, so additional mobile phone numbers cannot be added. However, a user can have more than one mobile phone number. For multiple mobile phone numbers, the `otherMobile` property is available. `otherMobile` is a multivalue property that allows setting multiple phone numbers, so calling `Add()` multiple times is allowed. Note that multivalue properties are checked for uniqueness. If the second phone number is added to the same `user` object again, you get a `COMException: "The specified directory service attribute or value already exists."`

Remember to call `DirectoryEntry.CommitChanges()` *after creating or updating new directory objects. Otherwise, only the cache gets updated, and the changes are not sent to the directory service.*

Accessing Native ADSI Objects

Often, it is much easier to call methods of predefined ADSI interfaces instead of searching for the names of object properties. Some ADSI objects also support methods that cannot be used directly from the `DirectoryEntry` class. One example of a practical use is the `IADsServiceOperations` interface, which has methods to start and stop Windows services. (For more details on Windows services see Chapter 25, "Windows Services.")

The classes of the `System.DirectoryServices` namespace use the underlying ADSI COM objects, as mentioned earlier. The `DirectoryEntry` class supports calling methods of the underlying objects directly by using the `Invoke()` method.

The first parameter of `Invoke()` requires the method name that should be called in the ADSI object; the `params` keyword of the second parameter allows a flexible number of additional arguments that can be passed to the ADSI method:

```
public object Invoke(string methodName, params object[] args);
```

You can find the methods that can be called with the `Invoke()` method in the ADSI documentation. Every object in the domain supports the methods of the `IADs` interface. The `user` object that you created previously also supports the methods of the `IADsUser` interface.

In the following example, the method `IADsUser.SetPassword()` changes the password of the previously created `user` object:

```
using (var de = new DirectoryEntry())
{
   de.Path = "LDAP://magellan/CN=John Doe, CN=Users, DC=cninnovation, DC=local";

   de.Invoke("SetPassword", "anotherSecret");
   de.CommitChanges();
}
```

It is also possible to use the underlying ADSI object directly instead of using `Invoke()`. To use these objects, choose Project ➪ Add Reference to add a reference to the Active DS Type Library (see Figure 52-9). This creates a wrapper class where you can access these objects in the namespace `ActiveDs`.

FIGURE 52-9

The native object can be accessed with the `NativeObject` property of the `DirectoryEntry` class. In the following example, the object `de` is a `user` object, so it can be cast to `ActiveDs.IADsUser`. `SetPassword()` is a method documented in the `IADsUser` interface, so you can call it directly instead of using the `Invoke()` method. By setting the `AccountDisabled` property of `IADsUser` to `false`, you can enable the account. As in the previous examples, the changes are written to the directory service by calling `CommitChanges()` with the `DirectoryEntry` object:

```
ActiveDs.IADsUser user = (ActiveDs.IADsUser)de.NativeObject;
user.SetPassword("someSecret");
user.AccountDisabled = false;
de.CommitChanges();
```

Searching in Active Directory

Because Active Directory is a data store optimized for *read-mostly* access, you will generally search for values. To search in Active Directory, the .NET Framework provides the `DirectorySearcher` class.

In the constructor of the `DirectorySearcher` class, you can define four important parts for the search: the root where the search starts, the filter, the properties that should be loaded, and the scope of the search. You can also use a default constructor and define the search options with properties.

SearchRoot

The search root specifies where the search should start. The default of `SearchRoot` is the root of the domain you are currently using. `SearchRoot` is specified with the `Path` of a `DirectoryEntry` object.

Filter

The filter defines the values where you want to get hits. The filter is a string that must be enclosed in parentheses.

Relational operators such as `<=`, `=`, and `>=` are allowed in expressions. `(objectClass=contact)` searches all objects of type `contact`; `(lastName>=Nagel)` searches all objects alphabetically where the `lastName` property is equal to or larger than `Nagel`.

Expressions can be combined with the `&` and `|` prefix operators. For example, `(&(objectClass=user)(description=Auth*))` searches all objects of type `user` where the property description starts with the string `Auth`. Because the `&` and `|` operators are at the beginning of the expressions, it is possible to combine more than two expressions with a single prefix operator.

The default filter is `(objectClass=*)` so all objects are valid.

The filter syntax is defined in RFC 2254, "The String Representation of LDAP Search Filters." You can find this RFC at `www.ietf.org/rfc/rfc2254.txt`.

PropertiesToLoad

With `PropertiesToLoad`, you can define a `StringCollection` of all the properties in which you are interested. Objects can have a lot of properties, most of which will not be important for your search request. You define the properties that should be loaded into the cache. The default properties that are returned if nothing is specified are the path and the name of the object.

SearchScope

`SearchScope` is an enumeration that defines how deep the search should extend:

- `SearchScope.Base` searches only the attributes in the object where the search started, so at most one object is found.
- With `SearchScope.OneLevel`, the search continues in the child collection of the base object. The base object itself is not searched for a hit.
- `SearchScope.Subtree` defines that the search should go down the complete tree.

The default value of the `SearchScope` property is `SearchScope.Subtree`.

Search Limits

A search for specific objects in a directory service can span multiple domains. To limit the search to the number of objects or the time taken, you have some additional properties to define, as shown in the following table.

PROPERTY	DESCRIPTION
`ClientTimeout`	The maximum time the client waits for the server to return a result. If the server does not respond, no records are returned.
`PageSize`	With a *paged search*, the server returns a number of objects defined with the `PageSize` instead of the complete result. This reduces the time for the client to get a first answer and the memory needed. The server sends a cookie to the client, which is sent back to the server with the next search request so that the search can continue at the point where it finished.
`ServerPageTimeLimit`	For paged searches, this value defines the time a search should continue to return a number of objects that are defined with the `PageSize` value. If the time is reached before the `PageSize` value, the objects that were found up to that point are returned to the client. The default value is `-1`, which means infinite.
`SizeLimit`	Defines the maximum number of objects that should be returned by the search. If you set the limit to a value larger than defined by the server (which is 1000), the server limit is used.
`ServerTimeLimit`	Defines the maximum time the server will search for objects. When this time is reached, all objects that are found up to this point are returned to the client. The default is 120 seconds, and you cannot set the search to a higher value.
`ReferralChasing`	A search can cross multiple domains. If the root that's specified with `SearchRoot` is a parent domain or no root was specified, the search can continue to child domains. With this property, you can specify if the search should continue on different servers. `ReferralChasingOption.None` means that the search does not continue on other servers. The value `ReferralChasingOption.Subordinate` specifies that the search should go on to child domains. When the search starts at `DC=Wrox, DC=com` the server can return a result set and the referral to `DC=France, DC=Wrox, DC=COM`. The client can continue the search in the subdomain. `ReferralChasingOption.External` means that the server can refer the client to an independent server that is not in the subdomain. This is the default option. With `ReferralChasingOption.All`, both external and subordinate referrals are returned.
`Tombstone`	If the property `Tombstone` is set to `true`, all deleted objects that match the search are returned, too.
`VirtualListView`	If large results are expected with the search, the property `VirtualListView` can be used to define a subset that should be returned from the search. The subset is defined with the class `DirectoryVirtualListView`.

In the search example, all `user` objects with a property `description` value of `Author` are searched in the organizational unit `thinktecture`.

First, bind to the organizational unit `thinktecture`. This is where the search should start. Create a `DirectorySearcher` object where the `SearchRoot` is set. The filter is defined as `(&(objectClass=user)(description=Auth*))`, so that the search spans all objects of type `user` with a description of `Auth` followed by something else. The scope of the search should be a subtree so that child organizational units within `thinktecture` are searched, too:

```
using (var de = new DirectoryEntry("LDAP://OU=thinktecture, DC=cninnovation, DC=local"))
using (var searcher = new DirectorySearcher())
{
   searcher.SearchRoot = de;
   searcher.Filter = "(&(objectClass=user)(description=Auth*))";
   searcher.SearchScope = SearchScope.Subtree;
```

code snippet DirectoryServicesSamples/Program.cs

The properties that should be in the result of the search are `name`, `description`, `givenName`, and `wWWHomePage`:

```
searcher.PropertiesToLoad.Add("name");
searcher.PropertiesToLoad.Add("description");
searcher.PropertiesToLoad.Add("givenName");
searcher.PropertiesToLoad.Add("wWWHomePage");
```

You are ready to do the search. However, the result should also be sorted. `DirectorySearcher` has a `Sort` property, where you can set a `SortOption`. The first argument in the constructor of the `SortOption` class defines the property that will be used for a sort; the second argument defines the direction of the sort. The `SortDirection` enumeration has `Ascending` and `Descending` values.

To start the search, you can use the `FindOne()` method to find the first object, or `FindAll()`. `FindOne()` returns a simple `SearchResult`, whereas `FindAll()` returns a `SearchResultCollection`. Here, all authors should be returned, so `FindAll()` is used:

```
searcher.Sort = new SortOption("givenName", SortDirection.Ascending);

SearchResultCollection results = searcher.FindAll();
```

With a `foreach` loop, every `SearchResult` in the `SearchResultCollection` is accessed. A `SearchResult` represents a single object in the search cache. The `Properties` property returns a `ResultPropertyCollection`, where you access all properties and values with the property name and the indexer:

```
        SearchResultCollection results = searcher.FindAll();

        foreach (SearchResult result in results)
        {
           ResultPropertyCollection props = result.Properties;
           foreach (string propName in props.PropertyNames)
           {
              Console.Write("{0}: ", propName);
              Console.WriteLine(props[propName][0]);
           }
           Console.WriteLine();
        }
     }
```

It is also possible to get the complete object after a search: `SearchResult` has a `GetDirectoryEntry()` method that returns the corresponding `DirectoryEntry` of the found object.

The resulting output shows the beginning of the list of all `thinktecture` associates with the properties that have been chosen:

```
givenname: Christian
adspath: LDAP://magellan/CN=Christian Weyer,OU=thinktecture,DC=cninnovation,
DC=local
description: Author
name: Christian Weyer

givenname: Christian
adspath: LDAP://magellan/CN=Christian Nagel,OU=thinktecture,DC=cninnovation,
DC=local
description: Author
name: Christian Nagel

givenname: Dominick
adspath: LDAP://magellan/CN=Dominick Baier,OU=thinktecture,DC=cninnovation,
DC=local
description: Author
name: Dominick Baier
```

```
givenname: Ingo
adspath: LDAP://magellan/CN=Ingo Rammer,OU=thinktecture,DC=cninnovation,
DC=local
description: Author

givenname: Jörg
adspath: LDAP://magellan/CN=Jörg Neumann,OU=thinktecture,DC=cninnovation,
DC=local
description: Author
name: Jörg Neumann
```

SEARCHING FOR USER OBJECTS

In this section, you build a WPF application called `UserSearch`. This application is flexible insofar as a specific domain controller, username, and password to access Active Directory can be entered; otherwise, the user of the running process is used. In this application, you access the schema of the Active Directory service to get the properties of a `user` object. The user can enter a filter string to search all `user` objects of a domain. It's also possible to set the properties of the `user` objects that should be displayed.

User Interface

The user interface shows numbered steps to indicate how to use the application (see Figure 52-10):

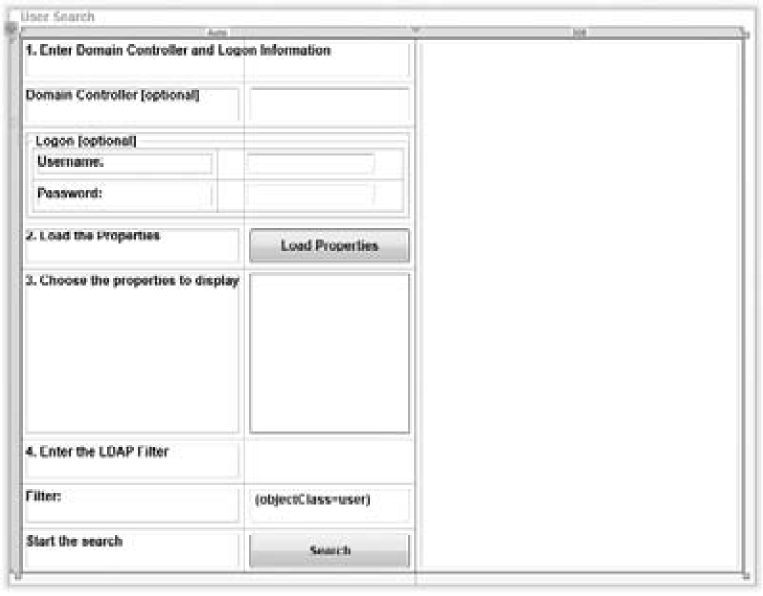

FIGURE 52-10

1. `Username`, `Password`, and the `Domain Controller` can be entered. All this information is optional. If no domain controller is entered, the connection works with serverless binding. If the username is missing, the security context of the current user is taken.
2. A button allows all the property names of the `user` object to be loaded dynamically in the `listBoxProperties` list box.

3. The properties to be displayed can be selected. The `SelectionMode` of the list box is set to `MultiSimple`.
4. The filter to limit the search can be entered. The default value set in this dialog box searches for all `user` objects: `(objectClass=user)`.
5. Now the search can start.

Get the Schema Naming Context

This application has only two handler methods: one method for the button to load the properties and one to start the search in the domain. First, you read the properties of the `user` class dynamically from the schema to display it in the user interface.

In the handler `buttonLoadProperties_Click()` method, `SetLogonInformation()` reads the username, password, and host name from the dialog box and stores them in members of the class. Next, the method `SetNamingContext()` sets the LDAP name of the schema and the LDAP name of the default context. This schema LDAP name is used in the call to set the properties in the list box: `SetUserProperties()`.

```
private void OnLoadProperties(object sender, RoutedEventArgs e)
{
    try
    {
        SetLogonInformation();

        SetNamingContext();

        SetUserProperties(schemaNamingContext);
    }
    catch (Exception ex)
    {
        MessageBox.Show(String.Format("check your input! {0}", ex.Message));
    }
}
```

code snippet UserSearch/MainWindow.xaml.cs

In the helper method `SetNamingContext()`, you are using the root of the directory tree to get the properties of the server. You are interested in the value of only two properties: `schemaNamingContext` and `defaultNamingContext`.

```
private void SetNamingContext()
{
    using (var de = new DirectoryEntry())
    {
        string path = "LDAP://" + hostname + "rootDSE";
        de.Username = username;
        de.Password = password;
        de.Path = path;
        schemaNamingContext = de.Properties["schemaNamingContext"][0].ToString();
        defaultNamingContext = de.Properties["defaultNamingContext"][0].
                                  ToString();
    }
}
```

Get the Property Names of the User Class

You have the LDAP name to access the schema. You can use this to access the directory and read the properties. You are interested in not only the properties of the `user` class but also those of the base classes of user: Organizational-Person, Person, and Top. In this program, the names of the base classes are hard-coded. You could also read the base class dynamically with the subClassOf attribute.

GetSchemaProperties() returns IEnumerable<string> with all property names of the specific object type. All the property names are added to the list box:

```
private void SetUserProperties(string schemaNamingContext)
{
    var properties = from p in GetSchemaProperties(schemaNamingContext,
                                                   "User").Concat(
                         GetSchemaProperties(schemaNamingContext,
                                             "Organizational-Person")).Concat(
                         GetSchemaProperties(schemaNamingContext, "Top"))
                     orderby p
                     select p;

    listBoxProperties.DataContext = properties;
}
```

code snippet UserSearch/MainWindow.xaml.cs

In GetSchemaProperties(), you are accessing the Active Directory service again. This time, rootDSE is not used but rather the LDAP name of the schema that you discovered earlier. The property systemMayContain holds a collection of all attributes that are allowed in the class objectType:

```
private IEnumerable<string> GetSchemaProperties(string schemaNamingContext,
                                                string objectType)
{
    IEnumerable<string> data;
    using (var de = new DirectoryEntry())
    {
        de.Username = username;
        de.Password = password;

        de.Path = String.Format("LDAP://{0}CN={1},{2}", hostname, objectType,
                                schemaNamingContext);

        PropertyValueCollection values = de.Properties["systemMayContain"];
        data = from s in values.Cast<string>()
               orderby s
               select s;
    }
    return data;
}
```

Step 2 in the application is completed. The ListBox control has all the property names of the user objects.

Search for User Objects

The handler for the search button calls only the helper method FillResult():

```
private void OnSearch(object sender, RoutedEventArgs e)
{
    try
    {
        FillResult();
```

```
            }
            catch (Exception ex)
            {
                MessageBox.Show(String.Format("check your input! {0}", ex.Message));
            }
        }
```

code snippet UserSearch/MainWindow.xaml.cs

In `FillResult()`, you do a normal search in the complete Active Directory Domain as you saw earlier. `SearchScope` is set to `Subtree`, the `Filter` to the string you get from a `TextBox` object, and the properties that should be loaded into the cache are set by the values the user selected in the list box. The `PropertiesToLoad` property of the `DirectorySearcher` is of type `StringCollection` where the properties that should be loaded can be added using the `AddRange()` method that requires a string array. The properties that should be loaded are read from the `ListBox listBoxProperties` with the property `SelectedItems`. After setting the properties of the `DirectorySearcher` object, the properties are searched by calling the `SearchAll()` method. The result of the search inside the `SearchResultCollection` is used to generate summary information that is written to the text box `textBoxResults`:

```
        private void FillResult()
         {
            using (var root = new DirectoryEntry())
            {
                root.Username = username;
                root.Password = password;
                root.Path = String.Format("LDAP://{0}{1}",
                                          hostname, defaultNamingContext);
                using (var searcher = new DirectorySearcher())
                {
                    searcher.SearchRoot = root;
                    searcher.SearchScope = SearchScope.Subtree;
                    searcher.Filter = textFilter.Text;
                    searcher.PropertiesToLoad.AddRange(
                        listBoxProperties.SelectedItems.Cast<string>().ToArray());

                    SearchResultCollection results = searcher.FindAll();
                    var summary = new StringBuilder();
                    foreach (SearchResult result in results)
                    {
                        foreach (string propName in result.Properties.PropertyNames)
                        {
                            foreach (object p in result.Properties[propName])
                            {
                                summary.AppendFormat(" {0}: {1}", propName, p);
                                summary.AppendLine();
                            }
                        }
                        summary.AppendLine();
                    }
                    textResult.Text = summary.ToString();
                }
            }
```

Starting the application gives you a list of all objects where the filter is valid (see Figure 52-11).

FIGURE 52-11

ACCOUNT MANAGEMENT

Previous to .NET 3.5, it was difficult to create and modify user and group accounts. One way to do that was by using the classes from the `System.DirectoryServices` namespace, or by using the strongly typed native COM interfaces. New since .NET 3.5 is the assembly `System.DirectoryServices.AccountManagement` that offers an abstraction to the `System.DirectoryServices` classes by offering specific methods and properties to search, modify, create, and update users and groups.

The classes and their functionality are explained in the following table.

CLASS	DESCRIPTION
`PrincipalContext`	With the `PrincipalContext`, you configure the context of the account management. Here, you can define if an Active Directory Domain, the accounts from the local system, or an application directory should be used. You set this by setting the `ContextType` enumeration to one of the values `Domain, Machine,` or `ApplicationDirectory`. Depending on the context type, you can also define the name of the domain and specify a username and password that are used for access.
`Principal`	`Principal` is the base class of all principals. With the static method `FindByIdentity()`, you can get a `Principal` identity object. With a principal object, you have access to various properties such as name, description, distinguished name, and the object type from the schema. If you need more control over the principal than is available from the properties and methods of this class, you can use the method `GetUnderlyingType()`, which returns the underlying `DirectoryEntry` object.
`AuthenticablePrincipal`	`AuthenticablePrincipal` derives from `Principal` and is the base class for all principals that can be authenticated. There are several static methods to find principals, such as by logon or lockout times, by incorrect password attempts, or by password set time. Using instance methods, you can change the password and unlock an account.

continues

(continued)

CLASS	DESCRIPTION
`UserPrincipalComputer Principal`	`UserPrincipal` and `ComputerPrincipal` derive from the base class `AuthenticablePrincipal` and, thus, have all properties and methods the base class has. `UserPrincipal` is the object that maps to a user account, and `ComputerPrincipal` maps to a computer account. With `UserPrincipal`, you have many properties to get and set information about the user, for example, `EmployeeId`, `EmailAddress`, `GivenName`, and `VoiceTelephoneNumber`.
`GroupPrincipal`	Groups cannot authenticate; that's why `GroupPrincipal` derives directly from the `Principal` class. With `GroupPrincipal`, you can get members of the group with the `Members` property and the `GetMembers()` method.
`PrincipalCollection`	The `PrincipalCollection` contains a group of `Principal` objects; for example, the `Members` property from the `GroupPrincipal` class returns a `PrincipalCollection` object.
`PrincipalSearcher`	`PrincipalSearcher` is an abstraction of the `DirectorySearcher` class with special use for account management. With `PrincipalSearcher`, there's no need to know about the LDAP query syntax because this is created automatically.
`PrincipalSearchResult<T>`	Search methods from the `PrincipalSearcher` and `Principal` classes return a `PrincipalSearchResult<T>`.

The following sections look at some scenarios in which you can use the classes from the `System.DirectoryServices.AccountManagement` namespace.

Display User Information

The static property `Current` of the `UserPrincipal` class returns a `UserPrincipal` object with information about the currently logged-on user:

```
using (var user = UserPrincipal.Current)
{
   Console.WriteLine("Context Server: {0}", user.Context.ConnectedServer);
   Console.WriteLine(user.Description);
   Console.WriteLine(user.DisplayName);
   Console.WriteLine(user.EmailAddress);
   Console.WriteLine(user.GivenName);
   Console.WriteLine("{0:d}", user.LastLogon);
}
```

code snippet AccountManagementSamples/Program.cs

Running the application displays information about the user:

```
Context Server: Magellan.cninnovation.local
Developer, Author, Trainer, Consultant
Christian Nagel
Christian@ChristianNagel.com
Christian
2009/09/25
```

Create a User

You can use the `UserPrincipal` class to create a new user. First a `PrincipalContext` is required to define where the user should be created. With the `PrincipalContext`, you set the `ContextType` to an enumeration value of `Domain`, `Machine`, or `ApplicationDirectory`, depending on whether the directory service, the local accounts of the machine, or an application directory should be used. If the current user does not have access to add accounts to Active Directory, you can also set a user and password with the `PrincipalContext` that is used to access the server.

Next, you can create an instance of `UserPrincipal` passing the principal context, and setting all required properties. Here, the `GivenName` and `EmailAddress` properties are set. Finally, you must invoke the `Save()` method of the `UserPrincipal` to write the new user to the store:

```
using (var context = new PrincipalContext(ContextType.Domain, "cninnovation"))
using (var user = new UserPrincipal(context, "Tom", "P@ssw0rd", true)
      {
         GivenName = "Tom",
         EmailAddress = "test@test.com"
      })
 {
    user.Save();
 }
```

code snippet AccountManagementSamples/Program.cs

Reset a Password

To reset a password from an existing user, you can use the `SetPassword()` method from a `UserPrincipal` object:

```
using (var context = new PrincipalContext(ContextType.Domain, "cninnovation"))
using (var user = UserPrincipal.FindByIdentity(context, IdentityType.Name,
       "Tom"))
{
   user.SetPassword("Pa$$w0rd");
   user.Save();
}
```

code snippet AccountManagementSamples/Program.cs

The user running this code needs to have the privilege to reset a password. To change the password from an old one to a new one, you can use the method `ChangePassword()`.

Create a Group

A new group can be created in a similar way to creating a new user. Here, just the class `GroupPrincipal` is used instead of the class `UserPrincipal`. As in creating a new user, the properties are set, and the `Save()` method is invoked:

```
using (var ctx = new PrincipalContext(ContextType.Domain, "cninnovation"))
using (var group = new GroupPrincipal(ctx)
      {
         Description = "Sample group",
         DisplayName = "Wrox Authors",
         Name = "WroxAuthors"
      })
{
   group.Save();
}
```

code snippet AccountManagementSamples/Program.cs

Add a User to a Group

To add a user to a group, you can use a `GroupPrincipal` and add a `UserPrincipal` to the `Members` property of the group. To get an existing user and group, you can use the static method `FindByIdentity()`:

```
using (var context = new PrincipalContext(ContextType.Domain))
using (var group = GroupPrincipal.FindByIdentity(
      context, IdentityType.Name, "WroxAuthors"))
using (var user = UserPrincipal.FindByIdentity(
      context, IdentityType.Name, "Stephanie Nagel"))
{
   group.Members.Add(user);
   group.Save();
}
```

code snippet AccountManagementSamples/Program.cs

Finding Users

Static methods of the `UserPrincipal` object allow finding users based on some predefined criteria. The sample here shows finding users who didn't change their passwords within the last 30 days by using the method `FindPasswordSetTime()`. This method returns a `PrincipalSearchResult<UserPrincipal>` collection that is iterated to display the user name, the last logon time, and the time when the password was reset:

```
using (var context =  new PrincipalContext(ContextType.Domain, "explorer"))
using (var users = UserPrincipal.FindByPasswordSetTime(context,
      DateTime.Today—TimeSpan.FromDays(30), MatchType.LessThan))
{
   foreach (var user in users)
   {
      Console.WriteLine("{0}, last logon: {1}, " +
            "last password change: {2}", user.Name, user.LastLogon,
            user.LastPasswordSet);
   }
}
```

code snippet AccountManagementSamples/Program.cs

Other methods offered by the `UserPrincipal` class to find users are `FindByBadPasswordAttempt()`, `FindByExpirationTime()`, `FindByLockoutTime()`, and `FindByLogonTime()`.

You can get more flexibility in finding users by using the `PrincipalSearcher` class. This class is an abstraction of the `DirectorySearcher` class and uses this class behind the scenes. With the `PrincipalSearcher` class, you can assign any `Principal` object to the `QueryFilter` property.

In the example here, a `UserPrincipal` object with the properties `Surname` and `Enabled` is set to the `QueryFilter`. This way, all user objects starting with the surname Nag and that are enabled are returned with the `PrincipalSearchResult` collection. The `PrincipalSearcher` class creates an LDAP query string to do the search.

```
var context = new PrincipalContext(ContextType.Domain);

var userFilter = new UserPrincipal(context);
userFilter.Surname = "Nag*";
userFilter.Enabled = true;

using (var searcher = new PrincipalSearcher())
{
   searcher.QueryFilter = userFilter;
   var searchResult = searcher.FindAll();
   foreach (var user in searchResult)
```

```
                {
                   Console.WriteLine(user.Name);
                }
            }
```

code snippet AccountManagementSamples/Program.cs

DSML

With the namespace `System.DirectoryServices.Protocols`, you can access Active Directory through DSML (Directory Services Markup Language). DSML is a standard defined by the OASIS group (`www.oasis-open.org`) that allows you to access directory services through a Web service. To make Active Directory available through DSML, you must have at least Windows Server 2003 R2.

Figure 52-12 shows a configuration scenario with DSML. A system that offers DSML services accesses Active Directory via LDAP. On the client system, the DSML classes from the namespace `System.DirectoryServices.Protocols` are used to make SOAP requests to the DSML service.

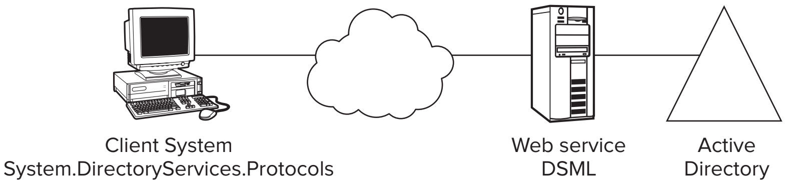

FIGURE 52-12

Classes in System.DirectoryServices.Protocols

The following table shows the major classes in the `System.DirectoryServices.Protocols` namespace.

CLASS	DESCRIPTION
`DirectoryConnection`	`DirectoryConnection` is the base class of all the connection classes that can be used to define the connection to the directory service. The classes that derive from `DirectoryConnection` are `LdapConnection` (for using the LDAP protocol), `DsmlSoapConnection`, and `DsmlSoapHttpConnection`. With the method `SendRequest`, a message is sent to the directory service.
`DirectoryRequest`	A request that can be sent to the directory service is defined by a class that derives from the base class `DirectoryRequest`. Depending on the request type, classes such as `SearchRequest`, `AddRequest`, `DeleteRequest`, and `ModifyRequest` can be used to send a request.
`DirectoryResponse`	The result that is returned with a `SendRequest` is of a type that derives from the base class `DirectoryResponse`. Examples for derived classes are `SearchResponse`, `AddResponse`, `DeleteResponse`, and `ModifyResponse`.

Searching for Active Directory Objects with DSML

This section looks at an example of how a search for directory services objects can be performed. As you can see in the code that follows, first a `DsmlSoapHttpConnection` object is instantiated that defines the connection to the DSML service. The connection is defined with the class `DsmlDirectoryIdentifier` that contains an `Uri` object. Optionally, the user credentials can be set with the connection:

```
Uri uri = new Uri("http://dsmlserver/dsml");
var identifier = new DsmlDirectoryIdentifier(uri);

var credentials = new NetworkCredential();
credentials.UserName = "cnagel";
credentials.Password = "password";
credentials.Domain = "explorer";

var dsmlConnection = new DsmlSoapHttpConnection(identifier, credentials);
```

code snippet DsmlSample/Program.cs

After the connection is defined, the search request can be configured. The search request consists of the directory entry where the search should start, an LDAP search filter, and the definition of what property values should be returned from the search. Here, the filter is set to `(objectClass=user)`, so that all user objects are returned from the search. `attributesToReturn` is set to `null`, and you can read all attributes that have values. `SearchScope` is an enumeration in the namespace `System.DirectoryServices.Protocols` that is similar to the `SearchScope` enumeration in the namespace `System.DirectoryServices` used to define how deep the search should go. Here, the `SearchScope` is set to `Subtree` to walk through the complete Active Directory tree.

The search filter can be defined with an LDAP string or by using an XML document contained in the `XmlDocument` class:

```
string distinguishedName = null;
string ldapFilter = "(objectClass=user)";
string[] attributesToReturn = null;// return all attributes

var searchRequest = new SearchRequest(distinguishedName,
      ldapFilter, SearchScope.Subtree, attributesToReturn);
```

After the search is defined with the `SearchRequest` object, the search is sent to the Web service by calling the method `SendRequest`. `SendRequest` is a method of the `DsmlSoapHttpConnection` class. `SendRequest` returns a `SearchResponse` object where the returned objects can be read.

As an alternative to invoking the synchronous `SendRequest` method, the `DsmlSoapHttpConnection` class also offers the asynchronous methods `BeginSendRequest` and `EndSendRequest`, which conform to the asynchronous .NET pattern.

```
SearchResponse searchResponse =
      (SearchResponse)dsmlConnection.SendRequest(searchRequest);
```

The returned Active Directory objects can be read within the `SearchResponse`. `SearchResponse.Entries` contains a collection of all entries that are wrapped with the type `SearchResultEntry`. The `SearchResultEntry` class has the `Attributes` property that contains all attributes. Each attribute can be read with help of the `DirectoryAttribute` class.

In the code example, the distinguished name of each object is written to the console. Next, the attribute values for the organizational unit (OU) are accessed, and the name of the organizational unit is written to the console. After this, all values of the `DirectoryAttribute` objects are written to the console:

```
Console.WriteLine("\r\nSearch matched {0} entries:",
      searchResponse.Entries.Count);
foreach (SearchResultEntry entry in searchResponse.Entries)
{
   Console.WriteLine(entry.DistinguishedName);

   // retrieve a specific attribute
   DirectoryAttribute attribute = entry.Attributes["ou"];
   Console.WriteLine("{0} = {1}", attribute.Name, attribute[0]);
```

```
            // retrieve all attributes
            foreach (DirectoryAttribute attr in entry.Attributes.Values)
            {
               Console.Write("{0}=", attr.Name);

               // retrieve all values for the attribute
               // the type of the value can be one of string, byte[] or Uri
               foreach (object value in attr)
               {
                  Console.Write("{0} ", value);
               }
               Console.WriteLine();
            }
         }
```

Adding, modifying, and deleting objects can be done similarly to searching objects. Depending on the action you want to perform, you can use the corresponding classes.

SUMMARY

This chapter discussed the architecture of Active Directory: the important concepts of domains, trees, and forests. You can access information in the complete enterprise. When writing applications that access Active Directory services, you must be aware that the data you read might not be up to date because of the replication latency.

The classes in the `System.DirectoryServices` namespaces give you easy ways to access Active Directory services by wrapping to the ADSI providers. The `DirectoryEntry` class makes it possible to read and write objects directly in the data store.

With the `DirectorySearcher` class, you can perform complex searches and define filters, timeouts, properties to load, and a scope. By using the global catalog, you can speed up the search for objects in the complete enterprise, because it stores a read-only version of all objects in the forest.

DSML is another API that allows accessing the Active Directory through a Web service interface.

Classes in `System.DirectoryServices.AccountManagement` offer an abstraction to make it easier to create and modify user, group, and computer accounts.

53

C#, Visual Basic, C++/CLI, and F#

WHAT'S IN THIS CHAPTER?

- Namespaces
- Defining types
- Methods
- Arrays
- Control statements
- Loops
- Exception handling
- Inheritance
- Resource management
- Delegates
- Events
- Generics
- LINQ queries
- C++/CLI mixing native and managed code

C# is *the* programming language designed for .NET. More than 50 languages exist for writing .NET applications — for example, Eiffel, Smalltalk, COBOL, Haskell, Pizza, Pascal, Delphi, Oberon, Prolog, and Ruby. Microsoft alone delivers the languages C#, Visual Basic, C++/CLI, J#, JScript.NET, and F#.

Every language has advantages and disadvantages; some things can be done easily with one language but are complicated with another one. The classes from the .NET Framework are always the same, but the syntax of the language abstracts various features from the framework. For example, the C# `using` statement makes it easy to use the objects implementing the `IDisposable` interface. Other languages need more code for the same functionality.

The most commonly used .NET languages from Microsoft are C# and Visual Basic. C# was newly designed for .NET with ideas from C++, Java, Pascal, and other languages. Visual Basic has its roots in Visual Basic 6 and was extended with object-oriented features for .NET.

C++/CLI is an extension to C++ that is an ECMA standard (ECMA 372). The big advantage of C++/CLI is the ability to mix native code with managed code. You can extend existing native C++ applications and add .NET functionality, and you can add .NET classes to native libraries so that they can be used from other .NET languages such as C#. It is also possible to write completely managed applications with C++/CLI.

F# is a new language within Visual Studio that offers special support for functional programming. It works well with .NET because it supports traditional object-oriented programming as well. To give you some information what functional programming with F# means: Functions can be used as values. This makes it easy to compose functions from multiple functions, and do function pipelining where functions are chained after each other.

This chapter shows you how to convert .NET applications from one language to another. If you see sample code with Visual Basic or C++/CLI, you can easily map this to C#, and the other way around. Don't assume you can learn F# or C++/CLI with this comparison because it mainly gives information about how the C# ideas map to the other languages, but not to the core concepts and ideas of the other languages.

NAMESPACES

.NET types are organized into namespaces. The syntax for defining and using namespaces is quite different between the four languages.

To import namespaces, C# uses the `using` keyword. C++/CLI is fully based on the C++ syntax with the `using namespace` statement. Visual Basic defines the `Imports` keyword, F# defines the `open` keyword, to import namespaces.

With C# and Visual Basic, you can define an alias to classes or other namespaces. With C++/CLI, an alias can reference other namespaces, but not classes. C++ requires the `namespace` keyword to define an alias — the same keyword is used to define a namespace. Visual Basic uses the `Imports` keyword again.

For defining namespaces, all four languages use the `namespace` keyword, but there's still a difference. With C++/CLI, you can't define hierarchical namespaces with one namespace statement; instead the namespaces must be nested. There's one important difference with the project settings: defining a namespace in the project settings of C# defines a default namespace that shows up in the code of all new items that you add to the project. With Visual Basic project settings, you define the root namespace that is used by all items in the project. Namespaces declared in the source code define only the sub-namespace inside the root namespace:

```
// C#
using System;
using System.Collections.Generic;
using Assm = Wrox.ProCSharp.Assemblies;
namespace Wrox.ProCSharp.Languages
{
}

// C++/CLI
using namespace System;
using namespace System::Collections::Generic;
namespace Assm = Wrox::ProCSharp::Assemblies;
namespace Wrox
{
   namespace ProCSharp
   {
      namespace Languages
      {
      }
   }
}

' Visual Basic
Imports System
Imports System.Collections.Generic
Imports Assm = Wrox.ProCSharp.Assemblies
Namespace Wrox.ProCSharp.Languages

End Namespace

// F#
namespace Wrox.ProCSharp.Languages
open System
open System.Collections.Generic
```

DEFINING TYPES

.NET differentiates between reference types and value types. With C#, reference types are defined with classes, and value types with structs. In addition to reference and value types, this section also shows you how to define an interface (a reference type) and an enumeration (a value type).

Reference Types

To declare a reference type, C# and Visual Basic use the `class` keyword. In C++/CLI, a class and a struct are nearly the same; you don't have the separation between a reference type and a value type as you do with C# and Visual Basic. C++/CLI has a `ref` keyword to define a managed class. You can create a reference type by defining `ref class` or `ref struct`.

Both with C# and C++/CLI the class is surrounded by curly brackets. With C++/CLI, don't forget the semicolon at the end of the class declaration. Visual Basic uses the `End Class` statement at the end of the class. F# creates classes and all other types with the `type` keyword followed by the name of the type and the optional `as` identifier, which defines the name of the instance identifier:

```
// C#
public class MyClass
{
}

// C++/CLI
public ref class MyClass
{
};
public ref struct MyClass2
{
};

' Visual Basic
Public Class MyClass2
End Class

// F# signature file
type MyClass() as this =
// ... members of the class
```

When using a reference type, a variable needs to be declared, and the object must be allocated on the managed heap. When declaring a handle to a reference type, C++/CLI defines the handle operator `^`, which is somewhat similar to the C++ pointer `*`. The `gcnew` operator allocates the memory on the managed heap. With C++/CLI, it is also possible to declare a variable locally, but for reference types, the object is still allocated on the managed heap. With Visual Basic, the variable declaration starts with the statement `Dim` followed by the name of the variable. With `new` and the object type, memory is allocated on the managed heap:

```
// C#
MyClass obj = new MyClass();
var obj2 = new MyClass()

// C++/CLI
MyClass^ obj = gcnew MyClass();
MyClass obj2;

' Visual Basic
Dim obj as New MyClass2()
```

If a reference type does not reference memory, different keywords are used: C# defines the `null` literal, C++/CLI defines `nullptr` (`NULL` is valid only for native objects), and Visual Basic defines `Nothing`. With F#, the `null` value is not normally used — it's not a value permitted with types that are defined with F#. By using types defined by languages other than F#, you might get `null` values.

Predefined reference types are listed in the following table. C++/CLI does not define the object and string type as is done with the other languages. Of course, you can use the classes defined by the framework.

.NET TYPE	C#	C++/CLI	VISUAL BASIC	F#
`System.Object`	`object`	Not defined	`Object`	`obj`
`System.String`	`string`	Not defined	`String`	`string`

Value Types

To declare a value type, C# uses the `struct` keyword; C++/CLI uses the keyword `value`; Visual Basic, `Structure`, and F#, use the `type` keyword with the attribute `[<Struct>]`. An alternative is to use the `struct` and `end` keywords:

```
// C#
public struct MyStruct
{
}

// C++/CLI
public value class MyStruct
{
};

' Visual Basic
Public Structure MyStruct
End Structure

// F#
[<Struct>]
type MyStruct =
    val x : int

type MyStruct2 =
    struct
        val x : int
    end
```

With C++/CLI, you can allocate a value type on the stack, on the native heap by using the `new` operator, and on the managed heap by using the `gcnew` operator. C# and Visual Basic do not have these options, but they become important when native and managed code is mixed with C++/CLI:

```
// C#
MyStruct ms;

// C++/CLI
MyStruct ms1;
MyStruct* pms2 = new MyStruct();
MyStruct^ hms3 = gcnew MyStruct();

' Visual Basic
Dim ms as MyStruct
```

Predefined value types for the different languages are listed in the following table. In C++/CLI, the `char` type has a size of just 1 byte for an ASCII character. In C#, `char` has a size of 2 bytes for Unicode characters; that's a `wchar_t` in C++/CLI. The ANSI standard for C++ just defines `short <= int <= long`. With 32-bit machines, `int` and `long` both have a size of 32 bits. To define a 64-bit variable in C++, you need `long long`.

.NET TYPE	C#	C++/CLI	VISUAL BASIC	F#	SIZE
`Char`	`char`	`wchar_t`	`Char`	`char`	2 bytes
`Boolean`	`bool`	`bool`	`Boolean`	`bool`	1 byte, contains `true` or `false`
`Int16`	`short`	`short`	`Short`	`int16`	2 bytes
`UInt16`	`ushort`	`unsigned short`	`UShort`	`uint16`	2 bytes with no sign
`Int32`	`int`	`int`	`Integer`	`int`	4 bytes
`UInt32`	`uint`	`unsigned int`	`UInteger`	`uint`	4 bytes with no sign
`Int64`	`long`	`long long`	`Long`	`int64`	8 bytes
`UInt64`	`ulong`	`unsigned long long`	`ULong`	`uint64`	8 bytes with no sign

Type Inference

C# allows you to define a local variable without an explicit data type declaration with the `var` keyword. The type is inferred from the initial value that is assigned. Visual Basic offers the same feature using the `Dim` keyword as long as *Option infer* is turned on. This can be done with the compiler option infer+ or by using the project configuration page with Visual Studio. With F#, the type of values, variables, parameters, and return types is inferred:

```
// C#
var x = 3;

' Visual Basic
Dim x = 3

// F#
let x = 3
```

Interfaces

Defining interfaces is very similar for the three languages that use the keyword `interface`. It's different with F#, because interfaces are defined with a `type` that contains only `abstract` members:

```
// C#
public interface IDisplay
{
   void Display();
}
```

code snippet CSharp/Person.cs

```
// C++/CLI
public interface class IDisplay
{
   void Display();
};
```

code snippet CPPCLI/Person.h

```
' Visual Basic
Public Interface IDisplay
   Sub Display
End Interface
```

code snippet VisualBasic/Person.vb

```
// F#
[<Interface>]
type public IDisplay
   abstract member Display : unit -> unit
```

code snippet FSharp/Person.fs

Implementing interfaces is different. C# and C++/CLI use a colon after the class name followed by the interface name. The methods defined with the interface are implemented. With C++/CLI, the methods must be declared `virtual`. Visual Basic uses the `Implements` keyword to implement an interface, and the methods that are defined by the interface also need the `Implements` keyword attached. F# lists the implemented interfaces in the section within the type definition. The interface is implemented with the `interface` and `with` keywords and implements all members of the following interface:

```
// C#
public class Person: IDisplay
{
   public void Display()
   {
   }
}
```

code snippet CSharp/Person.cs

```
// C# explicit interface implementation
public class Person: IDisplay
{
   void IDisplay.Display()
   {
   }
}

// C++/CLI
public ref class Person: IDisplay
{
public:
   virtual void Display() { }
};
```

code snippet CPPCLI/Person.h

```
' Visual Basic
Public Class Person
   Implements IDisplay
   Public Sub Display Implements IDisplay.Display
   End Sub
End Class
```

code snippet VisualBasic/Person.vb

```
// F#
type Person as this =
   interface IDisplay with
      member this.Display() = printfn "%s %s" this.FirstName this.LastName
```

code snippet FSharp/Person.fs

Enumerations

Enumerations are defined similarly in three languages with the `enum` keyword (only Visual Basic uses a new line instead of a comma to separate the elements). F# uses the `type` keyword and the match | expression:

```
// C#
public enum Color
{
   Red, Green, Blue
}
```

code snippet CSharp/Color.cs

```
// C++/CLI
public enum class Color
{
   Red, Green, Blue
};
```

code snippet CPPCLI/Color.h

```
' Visual Basic
Public Enum Color
   Red
   Green
   Blue
End Enum
```

code snippet VisualBasic/Color.vb

```
// F#
type Color =
| Red = 0
| Green = 1
| Blue = 2
```

code snippet FSharp/Color.fs

METHODS

With the exception of F#, methods are always declared within a class. The syntax from C++/CLI is very similar to C# except that the access modifier is not part of the method declaration but is written before that. The access modifier must end with a colon. With Visual Basic, the `Sub` keyword is used to define a method. With F#, a function can be defined with the `let` keyword. `Foo` has one parameter, *x*, and returns *x* plus `3`. The parameter types and the return type can be declared with a function, as shown. With the `add` function, *x* and *y* are of type `int`, and an `int` is returned. If the types are not declared, the types are inferred by the compiler. With the `Foo` function, *x* is `int` as well because 3 is added to *x*, and 3 is an `int`. Defining a method within a class is done with the `member` keyword. Instance methods have a prefix that is defined with the `as` identifier in the class definition. F# does not necessarily use `this`, `Me`, or `self` to access the current instance, but you can define any identifier you like:

```
// C#
public class MyClass
{
   public void Foo()
```

```
      {
      }
   }

   // C++/CLI
   public ref class MyClass
   {
   public:
      void Foo()
      {
      }
   };

   ' Visual Basic
   Public Class MyClass1
      Public Sub Foo
      End Sub
   End Class

   // F# function
   let foo x = x + 3
   let add (x : int, y : int) : int = x + y

   // method within a class
   type MyClass as this =
       member this.Foo() =
           printfn "MyClass.Foo"
```

Method Parameters and Return Types

With C# and C++/CLI, parameters that are passed to methods are defined inside a bracket. The type of the parameter is declared before the variable name. If a value is returned from a method, the method is defined with the type to return instead of `void`.

Visual Basic uses `Sub` statements to declare a method without returning a value, and the `Function` statement with a method that does have a return type. The return type is followed after the method name and the brackets. Visual Basic also has a different order with variable declaration and type in the parameter. The type follows the variable, which is the reverse direction from C# and C++/CLI.

With F#, if nothing is returned from a method, it is declared a `unit`. `unit` is similar to C# `void`. The method `Foo` is declared to receive an `int` parameter and returns an `int`:

```
// C#
public class MyClass
{
   public int Foo(int i)
   {
      return 2 * i;
   }
}

// C++/CLI
public ref class MyClass
{
public:
   int Foo(int i)
   {
      return 2 * i;
   }
};
```

```
' Visual Basic
Public Class MyClass2
   Public Sub Foo1(ByVal i as Integer)
   End Sub
   Public Function Foo(ByVal i As Integer) As Integer
      Return 2 * i
   End Sub
End Class

// F#
type MyClass as this =
    member this.Foo(i : int) : int = i * 2
```

Parameter Modifiers

By default, value types are passed by value, and reference types are passed by reference. If a value type that is passed as a parameter should be changed within a calling method, with C# you can use the parameter modifier `ref`.

C++/CLI defines a managed reference operator `%`. This operator is similar to the C++ reference operator `&` except that `%` can be used with managed types and the garbage collector can keep track of these objects in case they are moved within the managed heap.

With Visual Basic, the keyword `ByRef` is used for passing parameters by reference:

```
// C#
public class ParameterPassing
{
   public void ChangeVal(ref int i)
   {
      i = 3;
   }
}

// C++/CLI
public ref class ParameterPassing
{
public:
   int ChangeVal(int% i)
   {
      i = 3;
   }
};

' Visual Basic
Public Class ParameterPassing
   Public Sub ChangeVal(ByRef i as Integer)
      i = 3
   End Sub
End Class
```

When invoking a method with reference parameters, only the C# language requires you to apply a parameter modifier. C++/CLI and Visual Basic don't differentiate calling a method with or without the parameter modifier. C# has the advantage here because you can immediately see in the calling method that the parameter values can be changed.

Because of the caller syntax, which is not differentiated, Visual Basic does not allow you to overload methods just by changing the modifier. The C++/CLI compiler allows you to overload the method just by changing the modifier, but you cannot compile the caller because the resolved method is ambiguous.

With C# it is possible to overload and use methods with just the parameter modifier, but it's not good programming practice:

```
// C#
      ParameterPassing obj = new ParameterPassing();
      int a = 1;
      obj.ChangeVal(ref a);
      Console.WriteLine(a);      // writes 3

// C++/CLI
      ParameterPassing obj;
      int a = 1;
      obj.ChangeVal(a);
      Console.WriteLine(a);      // writes 3

' Visual Basic
      Dim obj as new ParameterPassing()
      Dim i as Integer = 1
      obj.ChangeVal(i)
      Console.WriteLine(i)      // writes 3
```

Constructors

With both C# and C++/CLI, the constructor has the same name as the class. Visual Basic uses a procedure named `New`. The `this` and `Me` keywords are used to access a member of this instance. When invoking another constructor within a constructor, a member initialization is required with C#. With C++/CLI and Visual Basic, it is possible to invoke the constructor as a method.

F# looks a little bit different. One constructor is defined with the type declaration. The constructor with the `Person` gets two `string` parameters. Other constructors are defined with the `new` keyword. `new()` defines a constructor without parameters. With the `Person` class, the constructor is invoked with two parameters:

```
// C#
public class Person
{
   public Person()
       : this("unknown", "unknown") { }
   public Person(string firstName, string lastName)
   {
      this.firstName = firstName;
      this.lastName = lastName;
   }
   private string firstName;
   private string lastName;
}
```

code snippet CSharp/Person.cs

```
// C++/CLI
public ref class Person
{
public:
   Person()
   {
      Person("unknown", "unknown");
   }
   Person(String^ firstName, String^ lastName)
   {
      this->firstName = firstName;
      this->lastName = lastName;
   }
private:
   String^ firstName;
   String^ lastName;
};
```

code snippet CPPCLI/Person.h

```
' Visual Basic
Public Class Person
   Public Sub New()
      Me.New("unknown", "unknown")
   End Sub
   Public Sub New(ByVal firstName As String, ByVal lastName As String)
      Me.MyFirstName = firstName
      Me.MyLastName = lastName
   End Sub
   Private MyFirstName As String
   Private MyLastName As String
End Class
```

code snippet VisualBasic/Person.vb

```
// F#
type Person(firstName0 : string, lastName0 : string) as this =
    let mutable firstName, lastName = firstName0, lastName0
    new () = Person("unknown", "unknown")
```

code snippet FSharp/Person.fs

Properties

To define a property, C# requires a get and set accessor within a property block. C#, C++/CLI, and Visual Basic also define a shorthand notation where a custom implementation is not needed if just a simple variable is returned or set by the get and set accessors. This is an automatic property. The syntax is different both with C++/CLI and Visual Basic. Both of these languages have a `property` keyword, and it is necessary to define a variable `value` with the set accessor. C++/CLI also requires a return type with the get accessor and a parameter type with the set accessor.

With the short version of writing a property with C++/CLI, you have to define the type and the name of the property; the get and set accessors are created automatically by the compiler. If nothing more than setting and returning a variable is needed, the short version is good enough. If the implementation of the accessors requires more — for example, checking the value or doing a refresh — you must write the full syntax for the properties.

F# defines properties as a member of the class using `with get()` for the set accessor and `and set (value)` for the set accessor:

```
// C#
public class Person
{
   private string firstName;
   public string FirstName
   {
      get { return firstName; }
      set { firstName = value; }
   }
   public string LastName { get; set; }
}
```

code snippet CSharp/Person.cs

```
// C++/CLI
public ref class Person
{
private:
    String^ firstName;
public:
   property String^ FirstName
   {
      String^ get()
      {
         return firstName;
      }
      void set(String^ value)
      {
         firstName = value;
      }
   }
   property String^ LastName;
};
```

code snippet CPPCLI/Person.h

```
' Visual Basic
Public Class Person
    Private myFirstname As String
    Public Property FirstName()
        Get
            Return myFirstName
        End Get
        Set(ByVal value)
            myFirstName = value
        End Set
    End Property
    Public Property LastName As String
End Class
```

code snippet VisualBasic/Person.vb

```
// F#
type Person(firstName0 : string, lastName0 : string) as this =
    let mutable firstName, lastName = firstName0, lastName0
    member this.FirstName
        with get() = firstName
        and set(value) = firstName <- value
    member this.LastName
        with get() = lastName
        and set(value) = lastName <- value
```

code snippet FSharp/Person.fs

With C# and C++/CLI, read-only properties just have a get accessor. With Visual Basic, you must also specify the ReadOnly modifier. Write-only properties must be defined with the WriteOnly modifier and a set accessor:

```
        ' Visual Basic
             Public ReadOnly Property Name()
            Get
                Return myFirstName & " " & myLastName
            End Get
        End Property
```

Object Initializers

With C# and Visual Basic, properties can be initialized using an object initializer. The properties can be initialized using curly brackets similar to an array initializer. The syntax from C# and Visual Basic is very similar; Visual Basic just uses the With keyword:

```
// C#
Person p = new Person { FirstName = "Tom", LastName = "Turbo" };

' Visual Basic
Dim p As New Person With { .FirstName = "Tom", .LastName = "Turbo" }
```

Extension Methods

Extension methods are the foundation of LINQ. With both C# and Visual Basic, it is possible to create extension methods. However, the syntax is different. C# marks an extension method with the this keyword in the first parameter, Visual Basic marks an extension method with the attribute <Extension>. With F#, the term for extension methods is type extension. Type extensions are done by specifying the fully qualified name of the type with the type declaration and extending it with the with keyword:

```
// C#
public static class StringExtension
{
   public static void Foo(this string s)
   {
      Console.WriteLine(""Foo {0}", s);
   }
}

' Visual Basic
Public Module StringExtension
   <Extension()> _
   Public Sub Foo(ByVal s As String)
      Console.WriteLine(""Foo {0}", s)
   End Sub
End Module

// F#
module Wrox.ProCSharp.Languages.StringExtension
type System.String with
    member this.Foo = printfn "String.Foo"
```

STATIC MEMBERS

A static field is instantiated only once for all objects of the type. C# and C++/CLI both use the static keyword; Visual Basic offers the same functionality with the Shared keyword.

To use static members, you use the name of the class followed by the . operator and the name of the static member. C++/CLI uses the : operator for accessing static members:

```
// C#
public class Singleton
{
   private static SomeData data = null;
   public static SomeData GetData()
   {
      if (data == null)
      {
         data = new SomeData();
      }
      return data;
   }
}
// use:
SomeData d = Singleton.GetData();
```

code snippet CSharp/Singleton.cs

```
// C++/CLI
public ref class Singleton
{
private:
   static SomeData^ hData;
public:
   static SomeData^ GetData()
   {
      if (hData == nullptr)
      {
         hData = gcnew SomeData();
      }
      return hData;
   }
};
// use:
SomeData^ d = Singleton::GetData();
```

code snippet CPPCLI/Singleton.h

```
' Visual Basic
Public Class Singleton
   Private Shared data As SomeData
   Public Shared Function GetData() As SomeData
      If data is Nothing Then
         data = new SomeData()
      End If
      Return data
   End Function
End Class
' Use:
Dim d as SomeData = Singleton.GetData()
```

code snippet VisualBasic/Singleton.fs

ARRAYS

Arrays are discussed in Chapter 6, “Arrays and Tuples.” The `Array` class is always behind the scenes of .NET arrays; declaring an array, the compiler creates a class that derives from the `Array` base class. When C# was designed, the designers of the C# language took the bracket syntax for arrays from C++ and extended it with array initializers:

```
// C#
int[] arr1 = new int[3] {1, 2, 3};
int[] arr2 = {1, 2, 3};
```

If you use brackets with C++/CLI, you create a native C++ array but not an array that is based on the `Array` class. To create .NET arrays, C++/CLI introduced the `array` keyword. This keyword uses a generic-like syntax with angle brackets. Within the angle brackets, the type of the elements is defined. C++/CLI supports array initializers with the same syntax as C#:

```
// C++/CLI
array<int>^ arr1 = gcnew array<int>(3) {1, 2, 3};
array<int>^ arr2 = {1, 2, 3};
```

Visual Basic uses braces for arrays. It requires the last element number instead of the number of elements with the array declaration. With every .NET language, arrays begin with element number 0. This is also the same for Visual Basic. To make that clearer, Visual Basic 9 introduced the `0 To number` expression with the array declaration. It always starts with 0; `0 To` just makes this more readable.

Visual Basic also supports array initializers if the array is initialized with the `New` operator:

```
' Visual Basic
Dim arr1(0 To 2) As Integer()
Dim arr2 As Integer() = New Integer(0 To 2) {1, 2, 3};
```

F# offers different ways to initialize an array. Small arrays can be created by using `[|` and `|]` as opening and closing braces and specifying all elements separated by semicolons. A sequence expression such as the `for in` statement can be used to initialize elements in the array as done with `arr2`. `arr3` is initialized with the `zeroCreate` type extension to the `Array` class to create and initialize 20 elements. Arrays can be accessed using an indexer. With slices it is possible to access a range from the array — `arr2.[4..]` accesses all elements starting with the fifth element to the last:

```
// F#
let arr1 = [| 1; 2; 3 |]
let arr2 = [| for i in 1..10 -> i |]
let arr3 : int aray = Array.zeroCreate 20

printfn "%d" arr1.[0]
// array slice
arr2.[4..]
```

CONTROL STATEMENTS

Control statements define what code should run. C# defines the `if` and `switch` statements, and the conditional operator.

if Statement

The C# `if` statement is the same as the C++/CLI version. Visual Basic uses `If-Then/Else/End If` instead of curly brackets:

```
// C# and C++/CLI
if (a == 3)
{
   // do this
}
else
{
   // do that
}

' Visual Basic
If a = 3 Then
 ' do this
Else
 ' do that
End If
```

Conditional Operator

C# and C++/CLI support the conditional operator, a lightweight version of the `if` statement. In C++/CLI, this operator is known as a *ternary* operator. The first argument has a Boolean result. If the result is true, the first expression is evaluated; otherwise, the second one is evaluated. Visual Basic has the `IIf` function in the Visual Basic Runtime Library, which offers the same functionality. With F#, `if`/`then`/`else` is used for the conditional operator:

```
// C#
string s = a > 3 ? "one": "two";

// C++/CLI
String^ s = a > 3 ? "one": "two";

' Visual Basic
Dim s As String = IIf(a > 3, "one", "two")

// F#
if a = 3 then printfn "do this" this else printfn "do that"
```

switch Statement

The `switch` statement looks very similar in C# and C++/CLI, but there are important differences. C# supports strings with the case selection. This is not possible with C++. With C++ you have to use `if-else` instead. C++/CLI supports an implicit fall-through from one case to the next. With C#, the compiler complains if there's not a `break` or a `goto` statement. C# has only implicit fall-through if there's not a statement for the case.

Visual Basic has a `Select`/`Case` statement instead of `switch`/`case`. A break is not only not needed but also not possible. An implicit fall-through from one case to the next is not possible, even if there's not a single statement following `Case`; instead, `Case` can be combined with `And`, `Or`, and `To` — for example, `3 To 5`.

F# has the match expressions with the `match` and `with` keywords. Every line of the matches starts with | followed by a pattern. The example uses the OR pattern with `Suit.Hear | Suit.Diamond`. The last pattern is the wildcard pattern:

```
// C#
string GetColor(Suit s)
{
   string color;
   switch (s)
   {
      case Suit.Heart:
      case Suit.Diamond:
         color = "Red";
         break;
      case Suit.Spade:
      case Suit.Club:
         color = "Black";
         break;
      default:
         color = "Unknown";
         break;
   }
   return color;
}

// C++/CLI
String^ GetColor(Suit s)
{
   String^ color;
```

```
    switch (s)
    {
       case Suit::Heart:
       case Suit::Diamond:
          color = "Red";
          break;
       case Suit::Spade:
       case Suit::Club:
          color = "Black";
          break;
       default:
          color = "Unknown";
          break;
    }
    return color;
 }

' Visual Basic
Function GetColor(ByVal s As Suit) As String
   Dim color As String = Nothing
   Select Case s
      Case Suit.Heart And Suit.Diamond
         color = "Red"
      Case Suit.Spade And Suit.Club
         color = "Black"
      Case Else
         color = "Unknown"
   End Select

   Return color
End Function

// F#
type SuitTest =
    static member GetColor(s : Suit) : string =
        match s with
        | Suit.Heart | Suit.Diamond -> "Red"
        | Suit.Spade | Suit.Club -> "Black"
        | _ -> "Unknown"
```

LOOPS

With loops, code is executed repeatedly until a condition is met. Loops with C# are discussed in Chapter 2, "Core C# ," including: `for`, `while`, `do.while`, and `foreach`. C# and C++/CLI are very similar with regard to looping statements; Visual Basic and F# defines different statements.

for Statement

The `for` statement is similar with C# and C++/CLI. With Visual Basic, you can't initialize a variable inside the `for/to` statement; you must initialize the variable beforehand. `for/to` doesn't require a `Step` to follow — `Step 1` is the default. Just in case you don't want to increment by 1, the `Step` keyword is required with `for/to`. F# uses the `for/to/do` and `for/downto/do` keywords:

```
// C#
for (int i = 0; i < 100; i++)
{
   Console.WriteLine(i);
}

// C++/CLI
```

```
for (int i = 0; i < 100; i++)
{
   Console::WriteLine(i);
}

' Visual Basic
Dim count as Integer
For count = 0 To 99 Step 1
   Console.WriteLine(count)
Next

// F#
for i = 1 to 10 do
    printfn i
for i = 10 downto 1 do
    printfn i
```

while and do . . . while Statements

The `while` and `do…while` statements are the same in C# and C++/CLI. Visual Basic has very similar constructs with `Do While/Loop` and `Do/Loop While`. F# doesn't have a `do/while` but a `while/do`:

```
// C#
int i = 0;
while (i < 3)
{
   Console.WriteLine(i++);
}
i = 0;
do
{
   Console.WriteLine(i++);
} while (i < 3);

// C++/CLI
int i = 0;
while (i < 3)
{
   Console::WriteLine(i++);
}
i = 0;
do
{
   Console::WriteLine(i++);
} while (i < 3);

' Visual Basic
Dim num as Integer = 0
Do While (num < 3)
   Console.WriteLine(num)
   num += 1
Loop
num = 0
Do
   Console.WriteLine(num)
   num += 1
Loop While (num < 3)

// F#
let i = 0
let mutable looping = true
while looping do
```

```
   printfn "%d" i
   i++
   if i >= 3
      looping <- false
```

foreach Statement

The `foreach` statement makes use of the interface `IEnumerable`. `foreach` doesn't exist with ANSI C++ but is an extension of ANSI C++/CLI. Unlike the C# `foreach`, in C++/CLI there's a blank space between `for` and `each`. F# uses this functionality for the `for`/`in`/`do` keywords:

```
// C#
int[] arr = {1, 2, 3};
foreach (int i in arr)
{
   Console.WriteLine(i);
}

// C++/CLI
array<int>^ arr = {1, 2, 3};
for each (int i in arr)
{
   Console::WriteLine(i);
}

' Visual Basic
Dim arr() As Integer = New Integer() {1, 2, 3}
Dim num As Integer
For Each num as Integer In arr
Console.WriteLine(num)
Next

// F#
for i in arr do
   printfn i
```

EXCEPTION HANDLING

Exception handling is discussed in Chapter 15, "Errors and Exceptions." This is extremely similar among three languages. All these languages use `try`/`catch`/`finally` for handling exceptions, and the `throw` keyword to create an exception. F# uses `raise` for throwing exceptions, and `try`/`with`/`finally` for handling exceptions:

```
// C#
public void Method(Object o)
{
   if (o == null)
      throw new ArgumentException("Error");
}
public void Foo()
{
   try
   {
      Method(null);
   }
   catch (ArgumentException ex)
   { }
   catch (Exception ex)
   { }
   finally
   { }
}
```

code snippet CSharp/ExceptionDemo.cs

```
// C++/CLI
public:
   void Method(Object^ o)
   {
      if (o == nullptr)
         throw gcnew ArgumentException("Error");
   }
   void Foo()
   {
      try
      {
         Method(nullptr);
      }
      catch (ArgumentException^ ex)
      { }
      catch (Exception^ ex)
      { }
      finally
      { }
   }
```

code snippet CPPCLI/ExceptionDemo.h

```
' Visual Basic
Public Sub Method(ByVal o As Object)
   If o = Nothing Then
      Throw New ArgumentException("Error")
End Sub
Public Sub Foo()
   Try
      Method(Nothing)
   Catch ex As ArgumentException
      '
   Catch ex As Exception
      '
   Finally
      '
   End Try
End Sub
```

code snippet VisualBasic/ExceptionDemo.vb

```
// F#
type ExceptionDemo() as this =
    member this.Method(o : obj) =
        if o = null then
            raise(ArgumentException("error"))
    member this.Foo =
        try
            try
            this.Method(null)
        with
            | :? ArgumentException as ex -> printfn "%s" ex.Message
            | :? IOException as ex -> printfn "%s" ex.Message
    finally
        printfn "finally"
```

code snippet FSharp/ExceptionDemo.fs

INHERITANCE

.NET languages offer many keywords to define polymorphic behavior, to override or hide methods, access modifiers to allow or not allow member access. For C#, this functionality is discussed in Chapter 4, “Inheritance.” The functionality of C#, C++/CLI, and Visual Basic is very similar, but the keywords are different.

Access Modifiers

The access modifiers of C++/CLI, Visual Basic, and F# are very similar to C#, with some notable differences. Visual Basic uses the `Friend` access modifier instead of `internal` for accessing the types in the same assembly. C++/CLI has one more access modifier: `protected private`. An `internal protected` modifier allows accessing the members from within the same assembly, and also from other assemblies if the type is derived from the base type. C# and Visual Basic don’t have a way to allow only derived types within the same assembly. This is possible with `protected private` from C++/CLI. Here `private` means that outside the assembly there’s no access, but from inside the assembly protected access is possible. The order — whether you write `protected private` or `private protected` — does not matter. The access modifier allowing more is always located within the assembly, and the access modifier allowing less is always outside the assembly. F# uses three access modifiers but also allows the protected modifier if the type should be used from other .NET languages. Access modifiers can be declared in F# within signature files.

The following table lists the access modifiers for each of the languages.

C#	C++/CLI	VISUAL BASIC	F#
`public`	`Public`	`Public`	`public`
`protected`	`Protected`	`Protected`	
`private`	`Private`	`Private`	`private`
`internal`	`Internal`	`Friend`	`internal`
`internal protected`	`internal protected`	`Protected Friend`	
`not possible`	`protected private`	`not possible`	

F# signature files have the file extension `.fsi` and define the signature of the members. They can be automatically created from code files with the --sig compiler option. According to the requirements, only the access modifiers need to be changed:

```
// F#
type public Person =
  class
    interface IDisplay
    public new : unit -> Person
    public new : firstName:string * lastName:string -> Person
    override ToString : unit -> string
    member public FirstName : string
    member public LastName : string
    member public FirstName : string with set
    member public LastName : string with set
  end
```

Keywords

Keywords important for inheritance are mapped in the following table.

C#	C++/CLI	VISUAL BASIC	F#	FUNCTIONALITY
`:`	`:`	`Implements`	`interface with`	Implement an interface
`:`	`:`	`Inherits`	`inherit`	Inherits from a base class
`virtual`	`virtual`	`Overridable`	`abstract`	Declare a method to support polymorphism
`overrides`	`override`	`Overrides`	`override`	Override a virtual method
`new`	`new`	`Shadows`		Hide a method from a base class
`abstract`	`abstract`	`MustInherit`	`[<AbstractClass]`	Abstract class
`sealed`	`sealed`	`NotInheritable`	`[<Sealed>]`	Sealed class
`abstract`	`abstract`	`MustOverride`	`abstract`	Abstract method
`sealed`	`sealed`	`NotOverridable`		Sealed method
`this`	`this`	`Me`		Reference the current object
`base`	`Classname::`	`MyBase`	`base`	Reference the base class

The order in which you place the keywords is important in the languages. In the code example, an abstract base class `Base` with one abstract method and one implemented method that is virtual are defined. The class `Base` is derived from the class `Derived`, where the abstract method is implemented, and the virtual method is overridden:

```
// C#
public abstract class Base
{
   public virtual void Foo()
   {
   }
   public abstract void Bar();
}
public class Derived: Base
{
   public override void Foo()
   {
      base.Foo();
   }
   public override void Bar()
   {
   }
}
```

code snippet CSharp/InheritanceDemo.cs

```
// C++/CLI
public ref class Base abstract
{
public:
   virtual void Foo()
   {
   }
   virtual void Bar() abstract;
};
public ref class Derived: public Base
{
```

```
public:
   virtual void Foo() override
   {
      Base::Foo();
   }
   virtual void Bar() override
   {
   }
};
```

code snippet CPPCLI/InheritanceDemo.h

```
' Visual Basic
Public MustInherit Class Base
   Public Overridable Sub Foo()
   End Sub
   Public MustOverride Sub Bar()
End Class
Public class Derived
   Inherits Base
   Public Overrides Sub Foo()
      MyBase.Foo()
   End Sub
   Public Overrides Sub Bar()
   End Sub
End Class
```

code snippet VisualBasic/InheritanceDemo.vb

```
// F#
[<AbstractClass>]
type Base() as this =
    abstract Foo : unit -> unit
    default this.Foo() = printfn "Base.Foo"
    abstract Bar : unit -> unit

type Derived() as this =
    inherit Base()
    override this.Foo() =
        base.Foo()
        printfn "Derived.Foo"
    override this.Bar() = printfn "Derived.Bar"
```

code snippet FSharp/InheritanceDemo.fs

RESOURCE MANAGEMENT

Working with resources is covered in Chapter 13, "Memory Management and Pointers," both implementing the `IDisposable` interface and implementing a finalizer. How this looks in C++/CLI, Visual Basic, and F# is covered in this section.

IDisposable Interface Implementation

For freeing resources, the interface `IDisposable` defines the `Dispose()` method. Using C#, Visual Basic, and F# you have to implement the interface `IDisposable`. With C++/CLI the interface `IDisposable` is implemented as well, but this is done by the compiler if you just write a destructor:

```
// C#
public class Resource: IDisposable
{
   public void Dispose()
   {
      // release resource
   }
}
```

code snippet CSharp/Resource.cs

```
// C++/CLI
public ref class Resource
{
public:
   ~Resource()
   {
      // release resource
   }
};
```

code snippet CPPCLI/Resource.h

```
' Visual Basic
Public Class Resource
   Implements IDisposable
   Public Sub Dispose() Implements IDisposable.Dispose
      ' release resource
   End Sub
End Class
```

code snippet VisualBasic/Resource.vb

```
// F#
type Resource() as this =
    interface IDisposable with
        member this.Dispose() = printfn "release resource"
```

code snippet FSharp/Resource.fs

With C++/CLI, the `Dispose()` *method is invoked by using the* `delete` *statement.*

using Statement

The C# `using` statement implements an acquire/use/release pattern to release a resource as soon as it is no longer used, even in the case of an exception. The compiler creates a `try`/`finally` statement and invokes the `Dispose` method inside the `finally`. Visual Basic supports the `using` statement just as C# does. C++/CLI has an even more elegant approach to this problem. If a reference type is declared locally, the compiler creates a `try`/`finally` statement to invoke the `Dispose()` method at the end of the block. F# offers two different constructs to easily support resource management. The `use` binding automatically invokes the `Dispose()` method when the value goes out of scope. The `using` expression creates an object that must be disposed and it is disposed at the end of the function that is called. Here, the function `bar` is called after the `Resource` object is created:

```
// C#
using (Resource r = new Resource())
{
   r.Foo();
}

// C++/CLI
{
   Resource r;
   r.Foo();
}

' Visual Basic
Using r As New Resource
   r.Foo()
End Using

// F# use binding
let rs =
    use r = new Resource()
    r.Foo()
    // r.Dispose called implicitly
// F# using expression
let bar (r : Resource) =
    r.Foo()

using (new Resource()) bar
```

Override Finalize

If a class contains native resources that must be freed, the class must override the `Finalize()` method from the `Object` class. With C#, this is done by writing a destructor. C++/CLI has a special syntax with the `!` prefix to define a finalizer. Within a finalizer, you cannot dispose contained objects that have a finalizer as well because the order of finalization is not guaranteed. That's why the Dispose pattern defines an additional `Dispose()` method with a Boolean parameter. With C++/CLI, it is not necessary to implement this pattern in the code because this is done by the compiler. The C++/CLI destructor implements both `Dispose()` methods. With Visual Basic, both `Dispose()` and the finalizer must be implemented manually. However, most Visual Basic classes do not use native resources directly, just with the help of other classes. With Visual Basic, usually it is not necessary to override the `Finalize()` method, but an implementation of the `Dispose()` method is often required.

Writing a destructor with C# overrides the `Finalize()` *method of the base class. A C++/CLI destructor implements the* `IDisposable` *interface.*

```
// C#
public class Resource: IDisposable
{
   ~Resource // override Finalize
   {
      Dispose(false);
   }
   protected virtual void Dispose(bool disposing)
   {
      if (disposing) // dispose embedded members
      {
      }
      // release resources of this class
      GC.SuppressFinalize(this);
   }
   public void Dispose()
   {
      Dispose(true);
   }
}
```

code snippet CSharp/Resource.cs

```
// C++/CLI
public ref class Resource
{
public:
   ~Resource() // implement IDisposable
   {
      this->!Resource();
   }
   !Resource()  // override Finalize
   {
      // release resource
   }
};
```

***code snippet** CPPCLI/Resource.h*

```
' Visual Basic
Public Class Resource
   Implements IDisposable
   Public Sub Dispose() Implements IDisposable.Dispose
      Dispose(True)
      GC.SuppressFinalize(Me)
   End Sub
   Protected Overridable Sub Dispose(ByVal disposing)
      If disposing Then
         ' Release embedded resources
      End If
      ' Release resources of this class
   End Sub
   Protected Overrides Sub Finalize()
      Try
         Dispose(False)
      Finally
         MyBase.Finalize()
      End Try
   End Sub
End Class
```

***code snippet** VisualBasic/Resource.vb*

DELEGATES

Delegates — type-safe pointers to methods — are discussed in Chapter 8, "Delegates, Lambdas, and Events." In all four languages, the keyword `delegate` can be used to define a delegate. The difference is with using the delegate.

The sample code shows a class `Demo` with a static method `Foo()` and an instance method `Bar()`. Both of these methods are invoked by delegate instances of type `DemoDelegate`. `DemoDelegate` is declared to invoke a method with `void` return type and an `int` parameter.

When using the delegate, C# supports delegate inference, where the compiler creates a delegate instance and passes the address of the method.

With C# and C++/CLI, two delegates can be combined into one by using the + operator:

```
// C#
public delegate void DemoDelegate(int x);
public class Demo
{
   public static void Foo(int x) { }
   public void Bar(int x) { }
}
```

```
Demo d = new Demo();
DemoDelegate d1 = Demo.Foo;
DemoDelegate d2 = d.Bar;
DemoDelegate d3 = d1 + d2;
d3(11);
```

code snippet CSharp/DelegateSample.cs

Delegate inference is not possible with C++/CLI. With C++/CLI, you must create a new instance of the delegate type and pass the address of the method to the constructor:

```
// C++/CLI
public delegate void DemoDelegate(int x);
public ref class Demo
{
public:
   static void Foo(int x) { }
   void Bar(int x) { }
};
Demo^ d = gcnew Demo();
DemoDelegate^ d1 = gcnew DemoDelegate(&Demo::Foo);
DemoDelegate^ d2 = gcnew DemoDelegate(d, &Demo::Bar);
DemoDelegate^ d3 = d1 + d2;
d3(11);
```

code snippet CPPCLI/DelegateSample.h

Similarly to C++/CLI, Visual Basic does not support delegate inference. You have to create a new instance of the delegate type and pass the address of a method. Visual Basic has the `AddressOf` operator to pass the address of a method.

Visual Basic doesn't overload the + operator for delegates, so it is necessary to invoke the `Combine()` method from the `Delegate` class. The `Delegate` class is written inside brackets because `Delegate` is a Visual Basic keyword, and thus it is not possible to use a class with the same name. Putting brackets around `Delegate` ensures that the class is used instead of the `Delegate` keyword:

```
' Visual Basic
Public Delegate Sub DemoDelegate(ByVal x As Integer)
Public Class Demo
   Public Shared Sub Foo(ByVal x As Integer)
      '
   End Sub
   Public Sub Bar(ByVal x As Integer)
      '
   End Sub
End Class
Dim d As New Demo()
Dim d1 As New DemoDelegate(AddressOf Demo.Foo)
Dim d2 As New DemoDelegate(AddressOf d.Bar)
Dim d3 As DemoDelegate = [Delegate].Combine(d1, d2)
d3(11)
```

code snippet VisualBasic/DelegateDemo.vb

Functions as objects are first-class citizens with F#. Just as with interoperability with other .NET languages, delegates are needed — therefore the syntax seems more complex. With F#, a delegate is declared assigning the delegate keyword to the type name and defining the parameters and return type. With `DemoDelegate`, the parameter is of type `int` and the return type `unit` which is similar to `void` in C#.

The `Demo` type is defined with a static member `Foo` and an instance member `Bar`. Both of these members fulfill the requirements of the delegate type.

The variable *d1* is a delegate variable that references the `Demo.Foo` method, and *d2* references the instance method `Bar`. The function `invokeDelegate,` with parameters `DemoDelegate` and `int,` is declared to invoke the functions referenced by the delegate. It calls the `Invoke` method of the `Delegate` class and passes the `int` parameter. After the `invokeDelegate` function is declared, it is invoked by passing the delegate instance *d1* and the value `33`. To combine delegates, you need to invoke the `Delegate.Combine()` method. Because `Combine()` requires two `Delegate` parameters and returns a `Delegate` type, upcasting and downcasting is required. Here, the F# syntax `:>` is used to cast *d1* to the base type `Delegate`, and `:?>` to cast the `Delegate` type *d33* to the derived class `DemoDelegate`. Instead of using `:>` and `:?>` it is also legal to use the keywords `upcast` and `downcast`:

```
// F#
type DemoDelegate = delegate of int -> unit

type Demo() as this =
    static member Foo(x : int) =
        printfn "Foo %d" x
    member this.Bar(x : int) =
        printfn "Bar %d" x

// F# using delegate
let d = Demo()
let d1 : DemoDelegate = new DemoDelegate(Demo.Foo)
let invokeDelegate (dlg : DemoDelegate) (x : int) =
    dlg.Invoke(x)
(invokeDelegate d1 33)
let d2 : DemoDelegate = new DemoDelegate(d.Bar)
let d11 = d1 :> Delegate
let d22 = d2 :> Delegate
let d33 : Delegate = Delegate.Combine(d11, d22)
let d3 : d33 :?> DemoDelegate
(invokeDelegate d3 11)
```

code snippet FSharp/DelegateDemo.fs

EVENTS

With the `event` keyword, a subscription mechanism can be done that is based on delegates. Again, all languages define an `event` keyword for offering events from a class. The class `EventDemo` fires events with the name `DemoEvent` of type `DemoDelegate`.

In C#, the syntax for firing the event looks similar to a method call of the event. The event variable is `null` as long as nobody is registered to the event, so a check for not `null` must be done before firing the event. The handler method is registered by using the `+=` operator and passing the address of the handler method with the help of delegate inference:

```
// C#
   public class EventDemo
   {
      public event DemoDelegate DemoEvent;
      public void FireEvent()
      {
         if (DemoEvent != null)
            DemoEvent(44);
      }
   }
   public class Subscriber
   {
      public void Handler(int x)
      {
            // handler implementation
         }
      }
   //...
   EventDemo evd = new EventDemo();
   Subscriber subscr = new Subscriber();
   evd.DemoEvent += subscr.Handler;
   evd.FireEvent();
```

code snippet CSharp/EventDemo.cs

C++/CLI is very similar to C# except that when firing the event, you do not need to first see that the event variable is not `null`. This is automatically done by the IL code created from the compiler.

Both C# and C++/CLI use the `+=` *operator to unregister from an event.*

```
   // C++/CLI
      public ref class EventDemo
      {
      public:
         event DemoDelegate^ DemoEvent;
         public void FireEvent()
         {
            DemoEvent(44);
         }
      }
      public class Subscriber
      {
      public:
         void Handler(int x)
         {
            // handler implementation
         }
      }
   //...
   EventDemo^ evd = gcnew EventDemo();
   Subscriber^ subscr = gcnew Subscriber();
   evd->DemoEvent += gcnew DemoDelegate(subscr, &Subscriber::Handler);
   evd->FireEvent();
```

code snippet CPPCLI/EventDemo.h

Visual Basic has a different syntax. The event is declared with the `Event` keyword, which is the same as in C# and C++/CLI. However, the event is raised with the `RaiseEvent` statement. The `RaiseEvent` statement checks whether the event variable is initialized by a subscriber. To register a handler, the `AddHandler` statement has the same functionality as the `+=` operator in C#. `AddHandler` requires two parameters: the first defines the event, the second the address of the handler. The `RemoveHandler` statement is used to unregister a handler from the event:

```
      ' Visual Basic
         Public Class EventDemo
         Public Event DemoEvent As DemoDelegate
         public Sub FireEvent()
            RaiseEvent DemoEvent(44);
         End Sub
      End Class
      Public Class Subscriber
         Public Sub Handler(ByVal x As Integer)
            ' handler implementation
      End Sub
   End Class
'...
Dim evd As New EventDemo()
Dim subscr As New Subscriber()
AddHandler evd.DemoEvent, AddressOf subscr.Handler
evd.FireEvent()
```

code snippet VisualBasic/EventDemo.vb

Visual Basic offers another syntax that is not available with the other languages: you can also use the `Handles` keyword with the method that subscribes to the event. The requirement for this is to define a variable with the `WithEvents` keyword:

```
Public Class Subscriber
    Public WithEvents evd As EventDemo
    Public Sub Handler(ByVal x As Integer) Handles evd.DemoEvent
        ' Handler implementation
    End Sub
    Public Sub Action()
        evd = New EventDemo()
        evd.FireEvent()
    End Sub
End Class
```

GENERICS

All four languages support the creation and use of generics. Generics are discussed in Chapter 5, “Generics.”

To use generics, C# borrowed the syntax from C++ templates to define the generic type with angle brackets. C++/CLI uses the same syntax. In Visual Basic, the generic type is defined with the `Of` keyword in braces. Here, F# looks very similar to C#:

```
// C#
List<int> intList = new List<int>();
intList.Add(1);
intList.Add(2);
intList.Add(3);
```

code snippet CSharp/GenericsDemo.cs

```
// C++/CLI
List<int>^ intList = gcnew List<int>();
intList->Add(1);
intList->Add(2);
intList->Add(3);
```

code snippet CPPCLI/GenericsDemo.h

```
' Visual Basic
Dim intList As List(Of Integer) = New List(Of Integer)()
intList.Add(1)
intList.Add(2)
intList.Add(3)
```

code snippet VisualBasic/GenericsDemo.vb

```
// F#
let intList =
    new List<int>()
intList.Add(1)
intList.Add(2)
intList.Add(3)
```

code snippet FSharp/GenericsDemo.fs

Because you use angle brackets with the class declaration, the compiler knows to create a generic type. Constraints are defined with the `where` clause:

```
public class MyGeneric<T>
   where T: IComparable<T>
{
   private List<T> list = new List<T>();
   public void Add(T item)
   {
      list.Add(item);
   }
   public void Sort()
   {
      list.Sort();
   }
}
```

code snippet CSharp/GenericsDemo.cs

Defining a generic type with C++/CLI is similar to defining a template with C++. Instead of the `template` keyword, with generics the `generic` keyword is used. The `where` clause is similar to that in C#; however, C++/CLI does not support a constructor constraint:

```
generic <typename T>
where T: IComparable<T>
ref class MyGeneric
{
private:
   List<T>^ list;
public:
   MyGeneric()
   {
      list = gcnew List<T>();
   }
   void Add(T item)
   {
      list->Add(item);
   }
   void Sort()
   {
      list->Sort();
   }
};
```

code snippet CPPCLI/GenericsDemo.h

Visual Basic defines a generic class with the `Of` keyword. Constraints can be defined with `As`:

```
Public Class MyGeneric(Of T As IComparable(Of T))
   Private myList = New List(Of T)
   Public Sub Add(ByVal item As T)
      myList.Add(item)
   End Sub
   Public Sub Sort()
      myList.Sort()
   End Sub
End Class
```

code snippet VisualBasic/GenericsDemo.vb

F# defines a generic type with angle brackets. The generic type is marked with an apostrophe. Constraints are defined with the `when` keyword. A constraint follows `when`. In the example, a type constraint with `:>` is used. This defines that the generic type must derive from the interface or base class. You can also define value type constraints (`: struct`), reference type constraints (`: not struct`), and default constructor constraints (`'a : (new : unit -> 'a)`). A constraint that is not available with other languages is the null constraint (`'a : null`). This constraint defines that the ‘a generic type needs to be nullable. This allows all .NET reference types, but not F# types that are not nullable:

```
type MyGeneric<'a> when 'a :> IComparable<'a>() as this =
    let list = new List<'a>()
    member this.Add(item : 'a) = list.Add(item)
    member this.Sort() = list.Sort()
```

code snippet FSharp/GenericsDemo.fs

LINQ QUERIES

Language-integrated queries are a feature of C# and Visual Basic. The syntax is very similar between these two languages:

```
// C#
var query = from r in racers
            where r.Country == "Brazil"
            orderby r.Wins descending
            select r;
```

code snippet CSharp/LinqSample.cs

```
' Visual Basic
Dim query = From r in racers _
            Where r.Country = "Brazil" _
            Order By r.Wins Descending _
            Select r
```

code snippet VisualBasic/LinqSample.vb

C++/CLI does not support LINQ queries.

C++/CLI MIXING NATIVE AND MANAGED CODE

One of the big advantages of C++/CLI is the capability to mix native and managed code. You use native code from C# through a mechanism known as *platform invoke,* which is discussed in Chapter 26, “Interop.” Using native code from C++/CLI is known as *It just works*.

In a managed class, you can use both native and managed code, as you can see here. The same is true for a native class. You can mix native and managed code as well within a method:

```
#pragma once
#include <iostream>      // include this header file for cout
using namespace std;     // the iostream header defines the namespace std
using namespace System;
```

```
public ref class Managed
{
public:
   void MixNativeAndManaged()
   {
      cout << "Native Code" << endl;
      Console::WriteLine("Managed Code");
   }
};
```

code snippet CPPCLI/Mixing.h

In a managed class, you can also declare a field of a native type or a pointer to a native type. Doing the same the other way around is not possible to accomplish directly. You must take care that an instance of a managed type can be moved by the garbage collector when cleaning up memory.

To use managed classes as a member within native classes, C++/CLI defines the keyword `gcroot`, which is defined in the header file `gcroot.h`. The `gcroot` keyword wraps a `GCHandle` that keeps track of a CLR object from a native reference:

```
#pragma once
#include "gcroot.h"
using namespace System;
public ref class Managed
{
public:
   Managed() { }
   void Foo()
   {
      Console::WriteLine("Foo");
   }
};
public class Native
{
private:
   gcroot<Managed^> m_p;
public:
   Native()
   {
      m_p = gcnew Managed();
   }
   void Foo()
   {
      m_p->Foo();
   }
};
```

C# SPECIFICS

Some C# syntax features were not covered in this chapter. C# defines the `yield` statement, which makes it easy to create enumerators. This statement is not available with C++/CLI and Visual Basic; with these languages an enumerator must be implemented manually. Also, C# defines a special syntax for nullable types, whereas with the other languages you have to use the generic struct `Nullable<T>` instead.

C# allows for unsafe code blocks where you can use pointers and pointer arithmetic. This feature can be extremely helpful for invoking methods from native libraries. Visual Basic does not have this capability; this is a real advantage of C#. C++/CLI does not need the `unsafe` keyword to define unsafe code blocks. It's very natural with C++/CLI to mix native and managed code.

SUMMARY

In this chapter, you learned how to map the syntax from C# to Visual Basic, C++/CLI, and F#. C++/CLI defines extensions to C++ for writing .NET applications and draws on C# for the syntax extensions. Although C# and C++/CLI have the same roots, there are many important differences. Visual Basic does not use curly brackets, but is chattier instead. The syntax from F# is very different as its major focus is on functional programming.

With the syntax mapping, you've seen how to map the C# syntax to C++/CLI, Visual Basic, and F#; how the other three languages look, with defining types, methods, and properties; what keywords are used for OO features; how resource management is done; and how delegates, events, and generics are implemented with the four languages.

Although it is possible to map most of the syntax, the languages are still different in their functionality.

54

.NET Remoting

WHAT'S IN THIS CHAPTER?

- An overview of .NET Remoting
- Contexts, which are used to group objects with similar execution requirements
- Implementing a simple remote object, client, and server
- The .NET Remoting architecture
- .NET Remoting configuration files
- Hosting .NET Remoting objects in ASP.NET
- Using Soapsuds to access the metadata of remote objects
- Calling .NET Remoting methods asynchronously
- Calling methods in the client with the help of events
- Using the `CallContext` to automatically pass data to the server

This chapter explores .NET Remoting. .NET Remoting can be used for accessing objects in another application domain (for example, on another server). It provides a faster format for communication between .NET applications on both the client and the server side.

In this chapter, you develop .NET Remoting objects, clients, and servers by using the HTTP, TCP, and IPC channels. First, you configure the client and server programmatically before you change the application to use configuration files instead, where only a few .NET Remoting methods are required. You also write small programs to use .NET Remoting asynchronously and for calling event handlers in the client application.

The .NET Remoting classes can be found in the namespace `System.Runtime.Remoting` and its subnamespaces. Many of these classes are in the core assembly `mscorlib`, and some needed only for cross-network communication are available in the assembly `System.Runtime.Remoting`.

WHY USE .NET REMOTING?

.NET Remoting is a technology for communication between different application domains. Using .NET Remoting for communication between application domains can happen inside the same process, between processes on a single system, or between processes on different systems.

Several different technologies can be used for communication with a client and a server application. You can program your application by using sockets, or you can use some helper classes from the `System.Net` namespace that make it easier to deal with protocols, IP addresses, and port numbers (see Chapter 24, "Networking," for details). Using this technology, you always have to send data across the network. The data you send can be your own custom protocol where the packet is interpreted by the server, so that the server knows what methods should be invoked. You not only have to deal with the data that is sent but also have to create threads yourself.

Using ASP.NET Web services, you can send messages across the network. With ASP.NET Web services you get platform independence. You also get a loose coupling between client and server, which means that it's easier to deal with versioning issues. See Chapter 55, "Web Services with ASP.NET," for information on ASP.NET Web services.

With .NET Remoting you always have a tight coupling between client and server, because the same object types are shared. .NET Remoting brings CLR object functionality to methods that are invoked across different application domains.

The functionality of .NET Remoting can be described with the application types and protocols that are supported, and by looking at *CLR Object Remoting*.

CLR Object Remoting is an importing aspect of .NET Remoting. All the language constructs (such as constructors, delegates, interfaces, methods, properties, and fields) can be used with remote objects. .NET Remoting extends the CLR object functionality across the network. It deals with activation, distributed identities, lifetimes, and call contexts. This is a major difference from XML Web services. With XML Web services, the objects are abstracted and the client doesn't need to know the object types of the server.

Today, the best choice for network communication is explained in Chapter 43, "Windows Communication Foundation." WCF gives features of both ASP.NET Web services, such as its platform independence, as well as performance and flexibility as is offered by .NET Remoting for .NET to .NET communication. A place where .NET Remoting still has the advantage is in communication between application domains within a process. The MAF technology (System.AddIn) that is discussed in Chapter 50, "Managed Add-In Framework," uses .NET Remoting behind the scenes. And of course there are a lot of existing .NET solutions based on .NET Remoting that wouldn't take advantage of rewriting it to a newer technology.

.NET Remoting is an extremely flexible architecture that can be used in *any application type* over *any transport*, using *any payload encoding*.

Using SOAP and HTTP is just one way to call remote objects. The transport channel is pluggable and can be replaced. With .NET 4 you get HTTP, TCP, and IPC channels represented by the classes `HttpChannel`, `TcpChannel`, and `IpcChannel`, respectively. You can build transport channels to use UDP, IPX, SMTP, a shared memory mechanism, or message queuing — the choice is entirely yours.

The payload is used to transport the parameters of a method call. This payload encoding can also be replaced. Microsoft delivers SOAP and binary encoding mechanisms. You can use either the SOAP formatter with the HTTP channel or HTTP with the binary formatter. Of course, both of these formatters can also be used with the TCP channel.

Although SOAP is used with .NET Remoting, you should be aware that only the SOAP RPC style is supported, whereas ASP.NET Web services supports both the DOC style (default) and the RPC style. The RPC style is obsolete in the new SOAP versions.

.NET Remoting not only enables you to use server functionality in every .NET application, but you can use this technology anywhere (regardless of whether you are building a console or a Windows application, a Windows service, or a COM+ component). .NET Remoting is also a good technology for peer-to-peer communication.

.NET REMOTING TERMS EXPLAINED

.NET Remoting can be used for accessing objects in another application domain. This technology can always be used whether the two objects live inside a single process, in separate processes, or on separate systems.

Remote assemblies can be configured to work locally in the application domain or as part of a remote application. If the assembly is part of the remote application, the client receives a proxy to talk to instead of the real object. The proxy is a representative of the remote object in the client process used by the client application to call methods. When the client calls a method in the proxy, the proxy sends a message into the channel that is passed on to the remote object.

.NET applications usually work within an application domain. An application domain can be seen as a subprocess within a process. Traditionally, processes were used as an isolation boundary. An application running in one process cannot access and destroy memory in another process. Cross-process communication is needed for applications to communicate with each other. With .NET, the application domain is the new safety boundary inside a process, because the MSIL code is type-safe and verifiable. As discussed in Chapter 18, different applications can run inside the same process but within different application domains. Objects inside the same application domain can interact directly. A proxy is needed to access objects in a different application domain.

The following list provides an overview of the key elements of this architecture:

- A *remote object* is an object that's running on the server. The client doesn't call methods on this object directly, but uses a proxy instead. With .NET it's easy to distinguish remote objects from local objects: any class that's derived from `MarshalByRefObject` never leaves its application domain. The client can call methods of the remote object via a proxy.
- A *channel* is used for communication between the client and the server. There are client and server parts of the channel. .NET Framework 4 offers channel types that communicate via TCP, HTTP, or IPC. You can also create a custom channel that communicates by using a different protocol.
- *Messages* are sent into the channel; they are created for communication between the client and the server. These messages hold the information about the remote object, the method name called, and all the arguments.
- The *formatter* defines how messages are transferred into the channel. .NET 4 has SOAP and binary formatters. The SOAP formatter can be used to communicate with Web services that are not based on the .NET Framework. Binary formatters are much faster and can be used efficiently in an intranet environment. Of course, you also have the option to create a custom formatter.
- A *formatter provider* is used to associate a formatter with a channel. By creating a channel, you can specify the formatter provider to be used, and this in turn defines the formatter that is used to transfer the data into the channel.
- The client calls methods on a proxy instead of the remote object. Two types of proxies exist: the *transparent proxy* and the *real proxy*. For the client, the transparent proxy looks like the remote object. On the transparent proxy, the client can call the methods implemented by the remote objects. In turn, the transparent proxy calls the `Invoke()` method on the real proxy. The `Invoke()` method uses the message sink to pass the message to the channel.

- A *message sink*, or *sink* for short, is an interceptor object. Interceptors are used on both the client and the server. A sink is associated with the channel. The real proxy uses the message sink to pass the message into the channel, so the sink can do some interception before the message goes into the channel. Depending on where the sink is used, it is known as an envoy sink, a server-context sink, an object-context sink, and so on.
- The client can use an *activator* to create a remote object on the server or to get a proxy of a server-activated object.
- `RemotingConfiguration` is a utility class to configure remote servers and clients. This class can be used either to read configuration files or to configure remote objects dynamically.
- `ChannelServices` is a utility class used to register channels and then to dispatch messages to them.

Figure 54-1 shows a conceptual picture of how these pieces fit together.

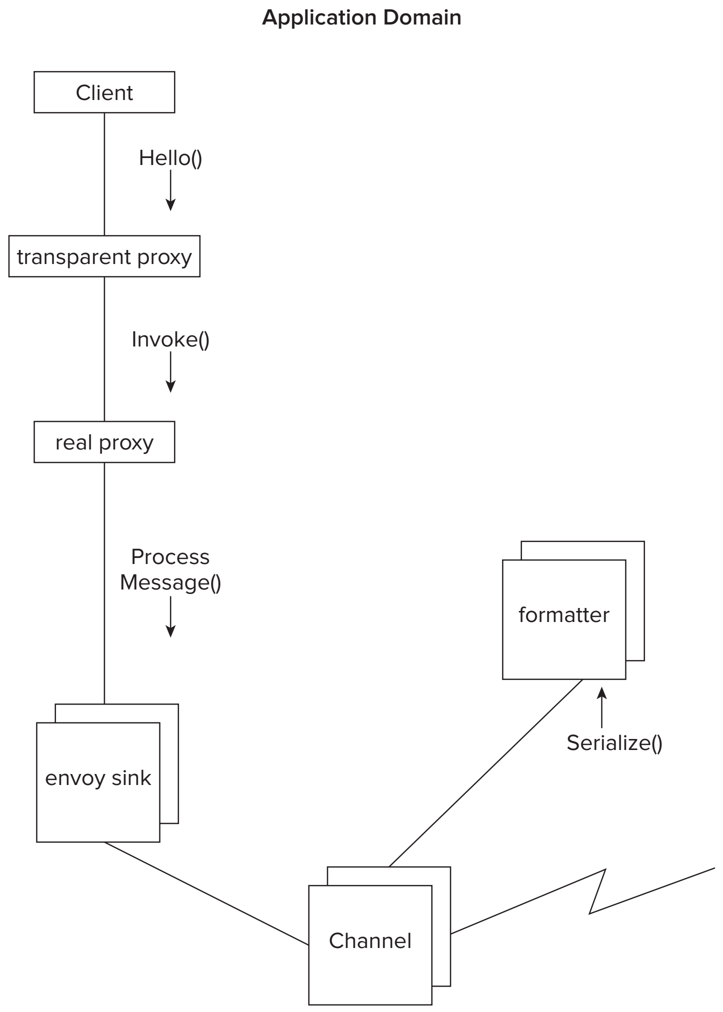

FIGURE 54-1

Client-Side Communication

When the client calls methods on a remote object, it actually calls them on a transparent proxy instead of the real object. The transparent proxy looks like the real object — it implements the public methods of the real object. The transparent proxy knows about the public methods of the real object by using the reflection mechanism to read the metadata from the assembly.

In turn, the transparent proxy calls the real proxy. The real proxy is responsible for sending the message to the channel. This proxy is pluggable: it can be replaced with a custom implementation. Such a custom implementation can be used to write a log, to use another way to find a channel, and so on. The default implementation of the real proxy locates the collection (or chain) of envoy sinks and passes the message to the first envoy sink. An envoy sink can intercept and change the message. Examples of such sinks are debugging sinks, security sinks, and synchronization sinks.

The last envoy sink sends the message into the channel. The formatter defines how the messages are sent over the wire. As previously stated, SOAP and binary formatters are available with .NET Framework 4. The formatter, however, is also pluggable. The channel is responsible for either connecting to a listening socket on the server or sending the formatted data. With a custom channel you can do something different; you just have to implement the code and to do what's necessary to transfer the data to the other side.

Server-Side Communication

Let's continue with the server side as shown in Figure 54-2:

- The channel receives the formatted messages from the client and uses the formatter to unmarshal the SOAP or binary data into messages. Then the channel calls server-context sinks.
- The server-context sinks are a chain of sinks, where the last sink in the chain continues the call to the chain of object-context sinks.
- The last object-context sink then calls the method in the remote object.

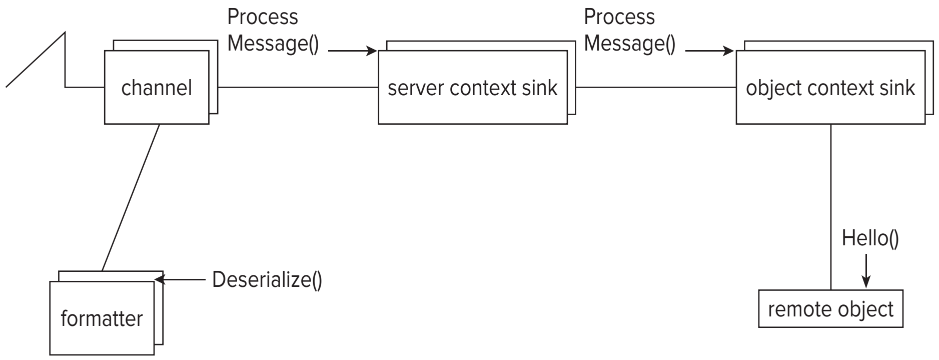

FIGURE 54-2

Note that the object-context sinks are confined to the object context, and the server-context sinks are confined to the server context. A single server-context sink can be used to access a number of object sinks.

A logging sink is one example where a sink can be useful. With a logging sink you can log messages sent and received. Examining if the server is available and dynamically changing to a different server can be done with a sink on the client system.

> *.NET Remoting is extremely customizable: you can replace the real proxy, add sink objects, or replace the formatter and channel. Of course, you can also use what's already provided.*

Going through these layers, you may be wondering about the overhead, but there's not much overhead left if nothing is happening in there. If you add your own functionality, the overhead will depend on that.

CONTEXTS

Before you look at using .NET Remoting to build servers and clients that communicate across a network, this section turns to the cases where a channel is needed inside an application domain: calling objects across contexts.

If you've previously written COM+ components, you already know about COM+ contexts. Contexts in .NET are very similar. A context is a boundary containing a collection of objects. Likewise, with a COM+ context, the objects in such a collection require the same usage rules that are defined by the context attributes.

As you already know, a single process can have multiple application domains. An application domain is something like a subprocess with security boundaries. Application domains are discussed in Chapter 18.

An application domain can have different contexts. A context is used to group objects with similar execution requirements. Contexts are composed from a set of properties and are used for interception: when a *context-bound object* is accessed by a different context, an *interceptor* can do some work before the call reaches the object. This can be used for thread synchronization, transactions, and security management, for example.

A class derived from `MarshalByRefObject` is bound to the application domain. Outside the application domain a proxy is needed to access the object. A class derived from `ContextBoundObject`, which itself derives from `MarshalByRefObject`, is bound to a context. Outside the context, a proxy is needed to access the object.

Context-bound objects can have *context attributes*. A context-bound object without context attributes is created in the context of the creator. A context-bound object with context attributes is created in a new context or in the creator's context if the attributes are compatible.

To further understand contexts, you must be familiar with these terms:

- Creating an application domain creates the *default context* in this application domain. If a new object is instantiated that needs different context properties, a new context is created.
- *Context attributes* can be assigned to classes derived from `ContextBoundObject`. You can create a custom attribute class by implementing the interface `IContextAttribute`. The .NET Framework has one context attribute class in the namespace `System.Runtime.Remoting.Contexts`: `SynchronizationAttribute`.
- Context attributes define *context properties* that are needed for an object. A context property class implements the interface `IContextProperty`. Active properties contribute message sinks to the call chain. The class `ContextAttribute` implements both `IContextProperty` and `IContextAttribute`, and can be used as a base class for custom attributes.
- A *message sink* is an interceptor for a method call. With a message sink, method calls can be intercepted. Properties can contribute to message sinks.

Activation

A new context is created if an instance of a class that's created needs a context different from the calling context. The attribute classes that are associated with the target class are asked if all the properties of the current context are acceptable. If any of these properties are unacceptable, the runtime asks for all property classes associated with the attribute class and creates a new context. The runtime then asks the property classes for the sinks they want to install. A property class can implement one of the `IContributeXXXSink` interfaces to contribute sink objects. Several of these interfaces are available to go with the variety of sinks.

Attributes and Properties

The properties of a context are defined with context attributes. A context attribute class is primarily an attribute — you can find out more about attributes in Chapter 14, "Reflection." Context attribute classes must implement the interface `IContextAttribute`. A custom context attribute class can derive from the class `ContextAttribute`, because this class already has a default implementation of this interface.

The .NET Framework includes two context attribute classes: `System.Runtime.Remoting.Contexts.SynchronizationAttribute` and `System.Runtime.Remoting.Activation.UrlAttribute`. The `Synchronization` attribute defines synchronization requirements; it specifies the synchronization property that is needed by the object. With this attribute you can specify that multiple threads cannot access the object concurrently, but the thread accessing the object can change.

With the constructor of this attribute, you can set one of four values:

- ➤ `NOT_SUPPORTED` defines that the class should not be instantiated in a context where the synchronization is set.
- ➤ `REQUIRED` specifies that a synchronization context is required.
- ➤ `REQUIRES_NEW` always creates a new context.
- ➤ `SUPPORTED` means that it doesn't matter what context you get; the object can live in it.

Communication between Contexts

How does the communication between contexts happen? The client uses a proxy instead of the real object. The proxy creates a message that is transferred to a channel, and sinks can intercept. Does this sound familiar? It ought to. The same mechanism is used for communication across different application domains or different systems. A TCP or HTTP channel is not required for the communication across contexts, but a channel is used here too. `CrossContextChannel` can use the same virtual memory in both the client and server sides of the channel, and formatters are not required for crossing contexts.

REMOTE OBJECTS, CLIENTS, AND SERVERS

Before stepping into the details of the .NET Remoting architecture, this section looks briefly at a remote object and a very small, simple server and client application that uses this remote object. After that the required steps and options are discussed in more detail.

Figure 54-3 shows the major .NET Remoting classes in the client and server application. The remote object that will be implemented is called `Hello`. `HelloServer` is the main class of the application on the server, and `HelloClient` is used for the client.

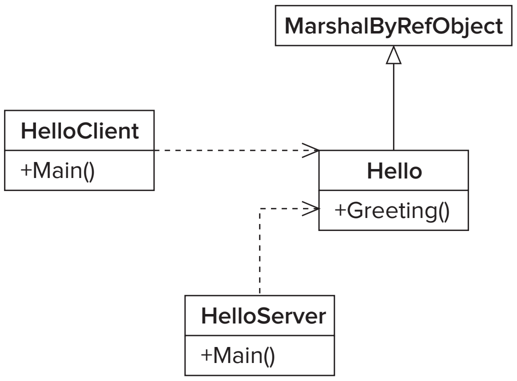

FIGURE 54-3

Remote Objects

Remote objects are required for distributed computing. An object that should be called remotely from a different system must be derived from `System.MarshalByRefObject`. `MarshalByRefObject` objects are *confined to the application domain* in which they were created. This means that they are never passed across application domains; instead, a proxy object is used to access the remote object from another application domain. The other application domain can live inside the same process, in another process, or on another system.

A remote object has *distributed identity*. Because of this, a reference to the object can be passed to other clients, and they will still access the same object. The proxy knows about the identity of the remote object.

The `MarshalByRefObject` class has, in addition to the inherited methods from the `Object` class, methods to initialize and to get the lifetime services. The lifetime services define how long the remote object lives. Lifetime services and leasing features are dealt with later in this chapter.

To see .NET Remoting in action, create a Class Library for the remote object. The class `Hello` derives from `System.MarshalByRefObject`. In the constructor a message is written to the console that provides information about the object's lifetime. In addition, add the method `Greeting()` that will be called from the client.

To distinguish easily between the assembly and the class in the following sections, give them different names in the arguments of the method calls used. The name of the assembly is `RemoteHello`, and the class is named `Hello`:

```
using System;

namespace Wrox.ProCSharp.Remoting
{

   public class Hello : System.MarshalByRefObject
   {
      public Hello()
      {
         Console.WriteLine("Constructor called");
      }

      public string Greeting(string name)
      {
         Console.WriteLine("Greeting called");
         return "Hello, " + name;
      }
   }
}
```

code snippet RemoteHello/RemoteHello/Hello.cs

A Simple Server Application

For the server, create a new C# console application called `HelloServer`. To use the `TcpServerChannel` class, you have to reference the `System.Runtime.Remoting` assembly. It's also required that you reference the `RemoteHello` assembly that was created earlier in the "Remote Objects" section.

In the `Main()` method, an object of type `System.Runtime.Remoting.Channels.Tcp.TcpServerChannel` is created with the port number `8086`. This channel is registered with the `System.Runtime.Remoting.Channels.ChannelServices` class to make it available for remote objects. The remote object type is registered by calling the method `RemotingConfiguration.RegisterWellKnownServiceType()`.

In the example, the URI type of the remote object class used by the client and a mode are specified. The mode `WellKnownObjectMode.SingleCall` means that a new instance is created for every method call; in the sample application no state is held in the remote object.

.NET Remoting allows creating stateless and stateful remote objects. In the first example, well-known single-call objects that don't hold state are used. The other object type is called client-activated. Client-activated objects hold state. Later in this chapter, when looking at the object activation sequence, you learn more details about these differences and how these object types can be used.

After registration of the remote object, it is necessary to keep the server running until a key is pressed:

```
using System;
using System.Collections.Generic;
using System.Runtime.Remoting;
using System.Runtime.Remoting.Channels;
using System.Runtime.Remoting.Channels.Tcp;

namespace Wrox.ProCSharp.Remoting
{
   class Program
   {
      static void Main()
      {
         var channel = new TcpServerChannel(8086);
         ChannelServices.RegisterChannel(channel, true);
         RemotingConfiguration.RegisterWellKnownServiceType(
               typeof(Hello), "Hi", WellKnownObjectMode.SingleCall);
         Console.WriteLine("Press return to exit");
         Console.ReadLine();
      }
   }
}
```

code snippet RemoteHello /HelloServer/Program.cs

A Simple Client Application

The client is again a C# console application: `HelloClient`. With this project, you also have to reference the `System.Runtime.Remoting` assembly so that the `TcpClientChannel` class can be used. In addition, you have to reference the `RemoteHello` assembly. Although the object will be created on the remote server, the assembly is needed on the client for the proxy to read the type information during runtime.

In the client program, create a `TcpClientChannel` object that's registered in `ChannelServices`. For the `TcpChannel`, you can use the default constructor, so a free port is selected. Next, the `Activator` class is used to return a proxy to the remote object. The proxy is of type `System.Runtime.Remoting.Proxies.__TransparentProxy`. This object looks like the real object because it offers the same methods. The transparent proxy uses the real proxy to send messages to the channel:

```
using System;
using System.Runtime.Remoting.Channels;
using System.Runtime.Remoting.Channels.Tcp;

namespace Wrox.ProCSharp.Remoting
{
   class Program
   {
        static void Main()
        {
           Console.WriteLine("Press return after the server is started");
           Console.ReadLine();

           ChannelServices.RegisterChannel(new TcpClientChannel(), true);
           Hello obj = (Hello)Activator.GetObject(
                                 typeof(Hello), "tcp://localhost:8086/Hi");
           if (obj == null)
           {
              Console.WriteLine("could not locate server");
              return;
           }
           for (int i=0; i< 5; i++)
           {
              Console.WriteLine(obj.Greeting("Stephanie"));
           }
        }
     }
  }
```

code snippet RemoteHello/HelloClient/Program.cs

A proxy is an object used by the client application in place of the remote object. Proxies that are used in Chapter 55 have a similar functionality to the proxies in this chapter. The implementation of proxies for Web services and proxies for .NET Remoting is very different.

Now you can start the server and then the client. Within the client console, the text `Hello, Stephanie` appears five times. With your server console window you can see the output shown. With every method call a new instance gets created because the `WellKnownObjectMode.SingleCall` activation mode was selected:

```
Press return to exit
Constructor called
Greeting called
Constructor called
Greeting called
Constructor called
Greeting called
Constructor called
Greeting called
Constructor called
Greeting called
```

.NET REMOTING ARCHITECTURE

Now that you've seen a simple client and server application in action, let's take a look at the .NET Remoting architecture before we dive into the details. Based on the previously created program, you look at the architecture and the mechanisms for extensibility.

This section explores the following topics:

- ➤ The functionality of a channel and how a channel can be configured
- ➤ Formatters and how they are used
- ➤ The utility classes `ChannelServices` and `RemotingConfiguration`

- ➤ Different ways to activate remote objects, and how stateless and stateful objects can be used with .NET Remoting
- ➤ Functionality of message sinks
- ➤ How to pass objects by value and by reference
- ➤ Lifetime management of stateful objects with .NET Remoting leasing mechanisms

Channels

A channel is used to communicate between a .NET client and a server. .NET Framework 4 ships with channel classes that communicate using TCP, HTTP, or IPC. You can create custom channels for other protocols.

The HTTP channel uses the HTTP protocol for communication. Because firewalls usually have port 80 open so clients can access web servers, .NET Remoting Web services can listen to port 80 so they can easily be used by these clients.

It's also possible to use the TCP channel on the Internet, but here the firewalls must be configured so that clients can access a specified port that's used by the TCP channel. The TCP channel can be used to communicate more efficiently in an intranet environment compared to the HTTP channel.

The IPC channel is best for communication on a single system across different processes. It uses the Windows interprocess communication mechanism and thus it is faster than the other channels.

Performing a method call on the remote object causes the client channel object to send a message to the remote channel object.

Both the server and the client application must create a channel. This code shows how a `TcpServerChannel` can be created on the server side:

```
using System.Runtime.Remoting.Channels.Tcp;
  ...
TcpServerChannel channel = new TcpServerChannel(8086);
```

The port on which the TCP socket is listening is specified in the constructor argument. The server channel must specify a well-known port, and the client must use this port when accessing the server. To create a `TcpClientChannel` on the client, however, it isn't necessary to specify a well-known port. The default constructor of `TcpClientChannel` chooses an available port, which is passed to the server at connection time so that the server can return data to the client.

Creating a new channel instance immediately switches the socket to the listening state, which can be verified by typing **netstat –a** at the command line.

A very useful tool for testing to see what data is sent across the network is `tcpTrace`. `tcpTrace` *can be downloaded from* `www.pocketsoap.com/tcptrace`.

The HTTP channels can be used similarly to the TCP channels. You can specify the port where the server can create the listening socket.

A server can listen to multiple channels. This code creates and registers HTTP, TCP, and IPC channels:

```
var tcpChannel = new TcpServerChannel(8086);
var httpChannel = new HttpServerChannel(8085);
var ipcChannel = new IpcServerChannel("myIPCPort");

// register the channels
ChannelServices.RegisterChannel(tcpChannel, true);
ChannelServices.RegisterChannel(httpChannel, false);
ChannelServices.RegisterChannel(ipcChannel, true);
```

A channel class must implement the IChannel interface. The IChannel interface has these two properties:

- ChannelName is a read-only property that returns the name of the channel. The name of the channel depends on the type; for example, the HTTP channel is named HTTP.
- ChannelPriority is a read-only property. More than one channel can be used for communication between a client and a server. The priority defines the order of the channel. On the client, the channel with the higher priority is chosen first to connect to the server. The bigger the priority value, the higher the priority. The default value is 1, but negative values are allowed to create lower priorities.

Additional interfaces are implemented depending on whether the channel is a client channel or a server channel. The server versions of the channels implement the IChannelReceiver interface; the client versions implement the IChannelSender interface.

The HttpChannel, TcpChannel, and IPCChannel classes can be used for both the client and the server. They implement IChannelSender and IChannelReceiver. These interfaces derive from IChannel.

The client-side IChannelSender has, in addition to IChannel, a single method called CreateMessageSink(), which returns an object that implements IMessageSink. The IMessageSink interface can be used for putting synchronous as well as asynchronous messages into the channel. With the server-side interface IChannelReceiver, the channel can be put into listening mode using StartListening(), and stopped again with StopListening(). The property ChannelData can be used to access the received data.

You can get information about the configuration of the channels using properties of the channel classes. For both channels, the properties ChannelName, ChannelPriority, and ChannelData are offered. The ChannelData property can be used to get information about the URIs that are stored in the ChannelDataStore class. With the HttpServerChannel there's also a Scheme property. The following code shows a helper method, ShowChannelProperties(), in the file that displays this information:

```
static void ShowChannelProperties(IChannelReceiver channel)
{
   Console.WriteLine("Name: {0}", channel.ChannelName);
   Console.WriteLine("Priority: {0}", channel.ChannelPriority);
   if (channel is HttpServerChannel)
   {
      HttpServerChannel httpChannel = channel as HttpServerChannel;
      Console.WriteLine("Scheme: {0}", httpChannel.ChannelScheme);
   }
   if (channel is TcpServerChannel)
   {
      TcpServerChannel tcpChannel = channel as TcpServerChannel;
      Console.WriteLine("Is secured: {0}", tcpChannel.IsSecured);
   }

   ChannelDataStore data = (ChannelDataStore)channel.ChannelData;
   if (data != null)
   {
      foreach (string uri in data.ChannelUris)
      {
         Console.WriteLine("URI: {0}", uri);
      }
   }
   Console.WriteLine();
}
```

Setting Channel Properties

You can set all the properties of a channel in a list using the constructor HttpServerChannel(IDictionary, IServerChannelSinkProvider). The generic Dictionary class implements IDictionary, so you can set the Name, Priority, and Port property with the help of this class. To use the Dictionary class, you have to import the System.Collections.Generic namespace.

With the constructor of the class HttpServerChannel, you can pass an object that implements the interface IServerChannelSinkProvider in addition to the IDictionary parameter. In the example, a BinaryServerFormatterSinkProvider is set instead of the SoapServerFormatterSinkProvider, which is the default of the HttpServerChannel. The default implementation of the BinaryServerFormatterSinkProvider class associates a BinaryServerFormatterSink class with the channel that uses a BinaryFormatter object to convert the data for the transfer:

```
var properties = new Dictionary<string, string>();
properties["name"] = "HTTP Channel with a Binary Formatter";
properties["priority"] = "15";
properties["port"] = "8085";
var sinkProvider = new BinaryServerFormatterSinkProvider();
var httpChannel = new HttpServerChannel(properties, sinkProvider);
```

Depending on the channel types, different properties can be specified. Both the TCP and the HTTP channels support the name and priority channel property used in the example. These channels also support other properties such as bindTo, which specifies an IP address for binding that can be used if the computer has multiple IP addresses configured. rejectRemoteRequests is supported by the TCP server channel to allow client connections only from the local computer.

Pluggability of a Channel

A custom channel can be created to send the messages by using a transport protocol other than HTTP, TCP, or IPC, or the existing channels can be extended to offer more functionality:

- The sending part must implement the IChannelSender interface. The most important part is the CreateMessageSink() method, with which the client sends a URL, and here a connection to the server can be instantiated. A message sink must be created, which is then used by the proxy to send messages to the channel.
- The receiving part must implement the IChannelReceiver interface. You have to start the listening in the ChannelData get property. Then you can wait in a separate thread to receive data from the client. After unmarshaling the message, you can use ChannelServices.SyncDispatchMessage() to dispatch the message to the object.

Formatters

The .NET Framework delivers two formatter classes:

- System.Runtime.Serialization.Formatters.Binary.BinaryFormatter
- System.Runtime.Serialization.Formatters.Soap.SoapFormatter

Formatters are associated with channels through formatter sink objects and formatter sink providers.

Both of these formatter classes implement the interface System.Runtime.Remoting.Messaging.IRemotingFormatter, which defines the methods Serialize() and Deserialize() to transfer the data to and from the channel.

The formatter is also pluggable. When you're writing a custom formatter class, an instance must be associated with the channel you want to use. This is done by using a formatter sink and a formatter sink provider. The formatter sink provider, for example, SoapServerFormatterSinkProvider, can be passed as an argument when creating a channel as shown earlier. A formatter sink provider implements the interface IServerChannelSinkProvider for the server and IClientChannelSinkProvider for the client. Both of these interfaces define a CreateSink() method where a formatter sink must be returned. The SoapServerFormatterSinkProvider returns an instance of the class SoapServerFormatterSink.

On the client side, the `SoapClientFormatterSink` class uses the `SyncProcessMessage()` and `AsyncProcessMessage()` methods of the `SoapFormatter` class to serialize the message. The `SoapServerFormatterSink` class deserializes the message, again using the `SoapFormatter` class.

All these sink and provider classes can be extended and replaced with custom implementations.

ChannelServices and RemotingConfiguration

The `ChannelServices` utility class is used to register channels into the .NET Remoting runtime. With this class, you can also access all registered channels. This is extremely useful if configuration files are used to configure the channel, because here the channel is created implicitly, as you see later.

A channel is registered using the static method `ChannelServices.RegisterChannel()`. The first parameter of this method requires the channel. Setting the second parameter to `true` verifies if security is available with the channel. The `HttpChannel` class doesn't have security support, so the checking is set to `false` for this channel.

Here you can see the server code to register the HTTP, TCP, and IPC channels:

```
var tcpChannel = new TcpChannel(8086);
var httpChannel = new HttpChannel(8085);
var ipcChannel = new IpcChannel("myIPCPort");
ChannelServices.RegisterChannel(tcpChannel, true);
ChannelServices.RegisterChannel(httpChannel, false);
ChannelServices.RegisterChannel(ipcChannel, true);
```

The `ChannelServices` utility class can now be used to dispatch synchronous and asynchronous messages, and to unregister specific channels. The `RegisteredChannels` property returns an `IChannel` array of all the channels you registered. You can also use the `GetChannel()` method to get to a specific channel by its name. With the help of `ChannelServices` you can write a custom administration utility that manages your channels. Here is a small example to show how the server channel can be stopped from listening to incoming requests:

```
HttpServerChannel channel =
(HttpServerChannel)ChannelServices.GetChannel("http");
channel.StopListening(null);
```

The `RemotingConfiguration` class is another .NET Remoting utility class. On the server side it's used to register remote object types for server-activated objects, and to marshal remote objects to a marshaled object reference class `ObjRef`. `ObjRef` is a serializable representation of an object that's sent over the wire. On the client side, `RemotingServices` is used to unmarshal a remote object to create a proxy from the object reference.

Server for Well-Known Objects

Here is the server-side code to register a well-known remote object type to the `RemotingServices`:

```
RemotingConfiguration.RegisterWellKnownServiceType(
                              typeof(Hello),                  // Type
                              "Hi",                           // URI
                              WellKnownObjectMode.SingleCall); // Mode
```

The first argument of `RegisterWellKnownServiceType()`, `typeof(Hello)`, specifies the type of the remote object. The second argument, "`Hi`", is the uniform resource identifier of the remote object, used by the client to access the remote object. The last argument is the mode of the remote object. The mode can be a value of the `WellKnownObjectMode` enumeration: `SingleCall` or `Singleton`.

- `SingleCall` means that the object holds no state. With every call to the remote object a new instance is created. A single-call object is created from the server with the `RemotingConfiguration.RegisterWellKnownServiceType()` method and a `WellKnownObjectMode.SingleCall` argument. This is very efficient on the server, because it means that you needn't hold any resources for maybe thousands of clients.
- With a `singleton` the object is shared for all clients of the server; typically, such object types can be used if you want to share some data between all clients. This shouldn't be a problem for read-only data, but with read-write data you have to be aware of locking issues and scalability. A singleton object is created by the server with the `RemotingConfiguration.RegisterWellKnownServiceType()` method and a `WellKnownObjectMode.Singleton` argument. You have to pay attention to the locking of resources held by the singleton object; you have to make sure that data can't be corrupted when clients are accessing the singleton object concurrently, but you also have to check that the locking is done efficiently enough to reach the required scalability.

Server for Client-Activated Objects

If a remote object should hold state for a specific client, you can use client-activated objects. The "Object Activation" section looks at how to call server-activated or client-activated objects on the client side. On the server side, client-activated objects must be registered in a different way from server-activated objects.

Instead of calling `RemotingConfiguration.RegisterWellKnownServiceType()`, you have to call `RemotingConfiguration.RegisterActivatedServiceType()`. With this method, only the type is specified, not the URI. The reason for this is that for client-activated objects, the clients can instantiate different object types with the same URI. The URI for all client-activated objects must be defined using `RemotingConfiguration.ApplicationName`:

```
RemotingConfiguration.ApplicationName = "HelloServer";
RemotingConfiguration.RegisterActivatedServiceType(typeof(Hello));
```

Object Activation

Clients can use and create a remote `Activator` class. You can get a proxy to a server-activated or well-known remote object by using the `GetObject()` method. The `CreateInstance()` method returns a proxy to a client-activated remote object.

Instead of using the `Activator` class, the `new` operator can also be used to activate remote objects. To make this possible, the remote object must also be configured within the client using the `RemotingConfiguration` class.

Application URL

In all activation scenarios, you have to specify a URL to the remote object. This URL is the same one you'd use when browsing with a web browser. The first part specifies the protocol followed by the server name or IP address, the port number, and a Uniform Resource Identifier (URI) that was specified when registering the remote object on the server in this form:

```
protocol://server:port/URI
```

In the code samples, three URL examples are used continuously in the code. With the URL, the protocol is specified with `http`, `tcp`, or `ipc`. With the HTTP and TCP channels the server name is `localhost` and the port numbers are `8085` and `8086`. With the IPC channel there's no need to define a hostname, because IPC is possible only on a single system. With all protocols the URI is `Hi`, as follows:

```
http://localhost:8085/Hi
tcp://localhost:8086/Hi
ipc://myIPCPort/Hi
```

Activating Well-Known Objects

In the previous simple client example in the "A Simple Client Application" section, well-known objects have been activated. Here, you take a more detailed look at the activation sequence:

```
TcpClientChannel channel = new TcpClientChannel();
ChannelServices.RegisterChannel(channel);

Hello obj = (Hello)Activator.GetObject(typeof(Hello),
                                       "tcp://localhost:8086/Hi");
```

`GetObject()` is a static method of the class `System.Activator` that calls `RemotingServices.Connect()` to return a proxy object to the remote object. The first argument of this method specifies the type of the remote object. The proxy implements all public and protected methods and properties, so that the client can call these methods as it would do on the real object. The second argument is the URL to the remote object. Here, the string `tcp://localhost:8086/Hi` is used. `tcp` defines the protocol that is used, the hostname, and the port number is `localhost:8086`, and finally `Hi` is the URI of the object that is specified on the server with the `method.RemotingConfiguration.RegisterWellKnownServiceType()`.

Instead of using `Activator.GetObject()`, you can also use `RemotingServices.Connect()` directly:

```
Hello obj = (Hello)RemotingServices.Connect(typeof(Hello),
                                            "tcp://localhost:8086/Hi");
```

If you prefer to use the `new` operator to activate well-known remote objects, the remote object can be registered on the client using `RemotingConfiguration.RegisterWellKnownClientType()`. The arguments are similar: the type of the remote object and the URI. `new` doesn't really create a new remote object, it returns a proxy similar to `Activator.GetObject()` instead. If the remote object is registered with a flag, `WellKnownObjectMode.SingleCall`, the rule always stays the same — the remote object is created with every method call:

```
RemotingConfiguration.RegisterWellKnownClientType(typeof(Hello),
"tcp://localhost:8086/Hi");
Hello obj = new Hello();
```

Activating Client-Activated Objects

Remote objects can hold state for a client. `Activator.CreateInstance()` creates a client-activated remote object. Using the `Activator.GetObject()` method, the remote object is created on a method call, and is destroyed when the method is finished. The object doesn't hold state on the server. The situation is different with `Activator.CreateInstance()`. With the static `CreateInstance()` method an activation sequence is started to create the remote object. This object lives until the lease time is expired and a garbage collection occurs. The leasing mechanism is discussed later in the "Lifetime Management" section.

Some of the overloaded `Activator.CreateInstance()` methods can only be used to create local objects. To create remote objects a method is needed where it's possible to pass activation attributes. One of these overloaded methods is used in the example. This method accepts two string parameters and an array of objects. The first parameter is the name of the assembly, and the second is the type of the remote object class. With the third parameter it is possible to pass arguments to the constructor of the remote object class. The channel and the object name are specified in the object array with the help of a `UrlAttribute`. To use the `UrlAttribute` class, the namespace `System.Runtime.Remoting.Activation` must be imported:

```
object[] attrs = {new UrlAttribute("tcp://localhost:8086/HelloServer") };
ObjectHandle handle = Activator.CreateInstance(
             "RemoteHello", "Wrox.ProCSharp.Remoting.Hello", attrs);
if (handle == null)
{
   Console.WriteLine("could not locate server");
   return;
}

Hello obj = (Hello)handle.Unwrap();
Console.WriteLine(obj.Greeting("Christian"));
```

Of course, for client-activated objects, it's again possible to use the new operator instead of the Activator class, but then you have to register the client-activated object using RemotingConfiguration .RegisterActivatedClientType(). In the architecture of client-activated objects, the new operator not only returns a proxy but also creates the remote object:

```
RemotingConfiguration.RegisterActivatedClientType(typeof(Hello),
                                       "tcp://localhost:8086/HelloServer");
Hello obj = new Hello();
```

Proxy Objects

The Activator.GetObject() and Activator.CreateInstance() methods return a proxy to the client. Actually, two proxies are used: the transparent proxy and the real proxy. The transparent proxy looks like the remote object — it implements all public methods of the remote object. These methods just call the Invoke() method of the RealProxy, where a message containing the method to call is passed. The real proxy sends the message to the channel with the help of message sinks.

With RemotingServices.IsTransparentProxy(), you can check if your object is really a transparent proxy. You can also get to the real proxy using RemotingServices.GetRealProxy(). Using the Visual Studio debugger, it's now easy to see all the properties of the real proxy:

```
ChannelServices.RegisterChannel(new TCPChannel());
Hello obj = (Hello)Activator.GetObject(typeof(Hello),
                                       "tcp://localhost:8086/Hi");
if (obj == null)
{
   Console.WriteLine("could not locate server");
   return;
}
if (RemotingServices.IsTransparentProxy(obj))
{
   Console.WriteLine("Using a transparent proxy");
   RealProxy proxy = RemotingServices.GetRealProxy(obj);

  // proxy.Invoke(message);
}
```

Pluggability of a Proxy

The real proxy can be replaced with a custom proxy. A custom proxy can extend the base class System .Runtime.Remoting.Proxies.RealProxy. The type of the remote object is received in the constructor of the custom proxy. Calling the constructor of the RealProxy creates a transparent proxy in addition to the real proxy. In the constructor, the registered channels can be accessed with the ChannelServices class to create a message sink, IChannelSender.CreateMessageSink(). Besides implementing the constructor, a custom channel has to override the Invoke() method. In Invoke() a message is received that can be analyzed and sent to the message sink.

Messages

The proxy sends a message into the channel. On the server side, a method call can be made after analyzing the message. This section takes a closer look at the messages.

The .NET Framework has some message classes for method calls, responses, return messages, and so on. What all the message classes have in common is that they implement the IMessage interface. This interface has a single property: Properties. This property represents a dictionary with the IDictionary interface, which packages the URI to the object, MethodName, MethodSignature, TypeName, Args, and CallContext.

Figure 54-4 shows the hierarchy of the message classes and interfaces. The message that is sent to the real proxy is an object of type MethodCall. With the interfaces IMethodCallMessage and IMethodMessage, you can have easier access to the properties of the message than through the IMessage interface. Instead of using the `IDictionary` interface, you have direct access to the method name, the URI, the arguments, and so on. The real proxy returns a `ReturnMessage` to the transparent proxy.

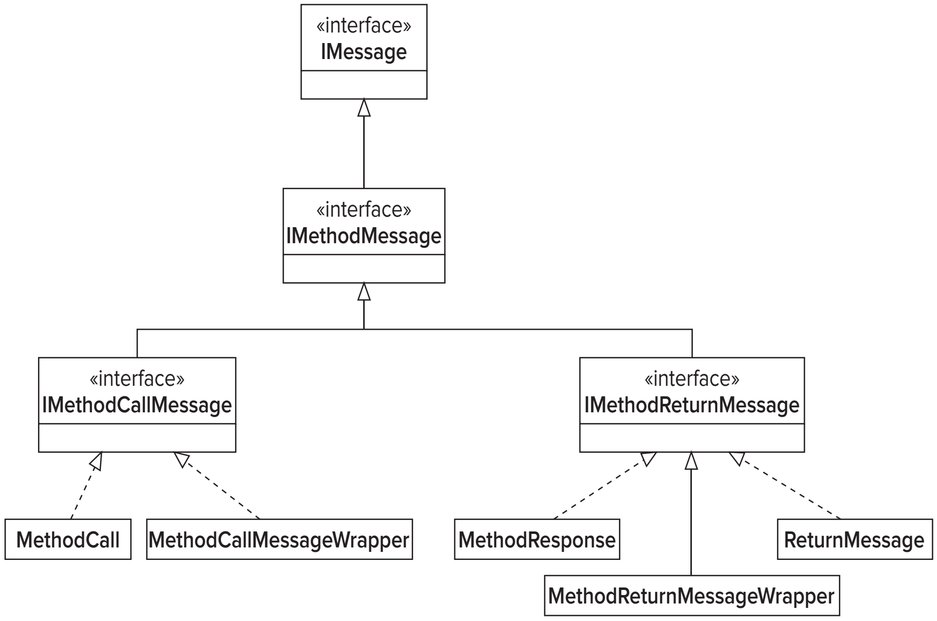

FIGURE 54-4

Message Sinks

The `Activator.GetObject()` method calls `RemotingServices.Connect()` to connect to a well-known object. In the `Connect()` method, an `Unmarshal()` happens where not only the proxy, but also envoy sinks are created. The proxy uses a chain of envoy sinks to pass the message to the channel. All the sinks are interceptors that can change the messages and perform some additional actions such as creating a lock, writing an event, performing security checks, and so on.

All message sinks implement the interface `IMessageSink`. This interface defines one property and two methods:

- ➤ The property `NextSink` is used by a sink to get to the next sink and pass the message along.
- ➤ For synchronous messages, `SyncProcessMessage()` is invoked by a previous sink or by the remoting infrastructure. It has an `IMessage` parameter to send a message and to return a message.
- ➤ For asynchronous messages, `AsyncProcessMessage()` is invoked by a previous sink in the chain, or by the remoting infrastructure. `AsyncProcessMessage()` has two parameters: a message and a message sink that receives the reply.

The following sections look at the three different message sinks available for use.

Envoy Sink

You can get to the chain of envoy sinks using the `IEnvoyInfo` interface. The marshaled object reference `ObjRef` has the `EnvoyInfo` property, which returns the `IEnvoyInfo` interface. The envoy list is created from the server context, so the server can inject functionality into the client. Envoys can collect identity information about the client and pass that information to the server.

Server Context Sink

When the message is received on the server side of the channel, it is passed to the server-context sinks. The last of the server-context sinks routes the message to the object sink chain.

Object Sink

The object sink is associated with a particular object. If the object class defines particular context attributes, context sinks are created for the object.

Passing Objects in Remote Methods

The parameter types of remote method calls aren't limited only to basic data types but can also be classes that you define yourself. For remoting, three types of classes must be differentiated:

Marshal-by-value classes — These classes are serialized through the channel. Classes that should be marshaled must be marked with the `Serializable` attribute. Objects of these classes don't have a remote identity, because the complete object is marshaled through the channel, and the object that is serialized to the client is independent of the server object (or the other way around). Marshal-by-value classes are also called *unbound classes* because they don't have data that depends on the application domain. Serialization is discussed in detail in Chapter 29, "Manipulating Files and the Registry."

Marshal-by-reference classes — These classes have a remote identity. The objects are not passed across the wire, but a proxy is returned instead. A class marshaled by reference must derive from `MarshalByRefObject`. `MarshalByRefObject`s are known as *application domain–bound objects*. A specialized version of `MarshalByRefObject` is `ContextBoundObject`: the abstract class `ContextBoundObject` is derived from `MarshalByRefObject`. If a class is derived from `ContextBoundObject`, a proxy is needed even in the same application domain when context boundaries are crossed. Such objects are called *context-bound objects*, and they are only valid in the creation context.

- **Nonremotable classes** — These classes are not serializable and don't derive from `MarshalByRefObject`. Classes of these types cannot be used as parameters in a remote object's public methods. These classes are bound to the application domain where they are created. Nonremotable classes should be used if the class has a data member that is only valid in the application domain, such as a Win32 file handle.

To see marshaling in action, change the remote object to send an object to the client: the class `MySerialized` will be sent marshal-by-value. In the method a message is written to the console so that you can verify whether the call was made on the client or on the server. In addition, the `Hello` class is extended to return a `MySerialized` instance:

```
using System;

namespace Wrox.ProCSharp.Remoting
{

   [Serializable]
   public class MySerialized
   {
      public MySerialized(int val)
      {
         a = val;
      }
      public void Foo()
      {
         Console.WriteLine("MySerialized.Foo called");
      }
      public int A
```

```
         {
            get
            {
               Console.WriteLine("MySerialized.A called");
               return a;
            }
            set
            {
               a = value;
            }
         }
         protected int a;
      }

      public class Hello : MarshalByRefObject
      {
         public Hello()
         {
            Console.WriteLine("Constructor called");
         }
         public string Greeting(string name)
         {
            Console.WriteLine("Greeting called");
            return "Hello, " + name;
         }
         public MySerialized GetMySerialized()
         {
            return new MySerialized(4711);
         }
      }
   }
```

code snippet PassingObjects/RemoteHello/Hello.cs

The client application also needs to be changed to see the effects when using marshaled-by-value and marshaled-by-reference objects. Invoke the methods `GetMySerialized()` and `GetMyRemote()` to retrieve the new objects. Also make use of the method `RemotingServices.IsTransparentProxy()` to check whether or not the returned object is a proxy:

```
         ChannelServices.RegisterChannel(new TcpClientChannel(), false);
         Hello obj = (Hello)Activator.GetObject(typeof(Hello),
               "tcp://localhost:8086/Hi");
         if (obj == null)
         {
            Console.WriteLine("could not locate server");
            return;
         }
         MySerialized ser = obj.GetMySerialized();
         if (!RemotingServices.IsTransparentProxy(ser))
         {
            Console.WriteLine("ser is not a transparent proxy");
         }
         ser.Foo();
```

code snippet PassingObjects /HelloClient/Program.cs

In the client console window, you can see that the `ser` object is called on the client. This object is not a transparent proxy because it's serialized to the client:

```
Press return after the server is started

ser is not a transparent proxy
MySerialized.Foo called
```

Security and Serialized Objects

One important difference with .NET Remoting and ASP.NET Web services is how objects are marshaled. With ASP.NET Web services, only the public fields and properties are transferred across the wire. .NET Remoting uses a different serialization mechanism to serialize all data, including all private data. Malicious clients could use the serialization and deserialization phases to harm the application.

To take this problem into account, two automatic deserialization levels are defined when passing objects across .NET Remoting boundaries: low and full.

By default, low-level deserialization is used. With low-level deserialization it is not possible to pass `ObjRef` objects and objects that implement the `ISponsor` interface. To make this possible, you can change the deserialization level to full. You can do this programmatically by creating a formatter sink provider, and assign the property `TypeFilterLevel`. For the binary formatter, the provider class is `BinaryServerFormatterSinkProvider`, whereas for the SOAP formatter the provider class is `SoapServerFormatterSinkProvider`.

The following code shows how you can create a TCP channel with full serialization support:

```
var serverProvider = new BinaryServerFormatterSinkProvider();
serverProvider.TypeFilterLevel = TypeFilterLevel.Full;

var clientProvider = new BinaryClientFormatterSinkProvider();

var properties = new Dictionary<string, string>();
properties["port"] = 6789;

var channel = new TcpChannel(properties, clientProvider, serverProvider);
```

code snippet PassingObjects/HelloServer/Program.cs

At first, a `BinaryServerFormatterSinkProvider` is created where the property `TypeFilterLevel` is set to `TypeFilterLevel.Full`. The enumeration `TypeFilterLevel` is defined in the namespace `System.Runtime.Serialization.Formatters`, so you have to declare this namespace. For the client side of the channel, a `BinaryClientFormatterSinkProvider` is created. Both the client-side and the server-side formatter sink provider instances are passed to the constructor of the `TcpChannel`, as well as the `IDictionary` properties that define the attributes of the channel.

Directional Attributes

Remote objects are never transferred over the wire, whereas value types and serializable classes are transferred. Sometimes the data should be sent in one direction only. This can be especially important when the data is transferred over the network. For example, if you want to send data in a collection to the server for the server to perform some calculation on this data and return a simple value to the client, it would not be very efficient to send the collection back to the client. With COM it was possible to declare the directional attributes `[in]`, `[out]`, and `[in, out]` to the arguments if the data should be sent to the server, to the client, or in both directions.

C# has similar attributes as part of the language: `ref` and `out` method parameters. The `ref` and `out` method parameters can be used for value types and for reference types that are serializable. Using the `ref` parameter, the argument is marshaled in both directions, and with the `out` parameter the data is sent from the server to the client. With no parameters the data is sent to the server.

Lifetime Management

How do a client and a server detect if the other side is not available anymore, and what are the problems you might get into?

For a client the answer can be simple. As soon as the client does a call to a method on the remote object, you get an exception of type `System.Runtime.Remoting.RemotingException`. You just have to handle this exception and do what's necessary; for example, perform a retry, write to a log, inform the user, and so on.

What about the server? When does the server detect if the client is not around anymore, meaning that the server can go ahead and clean up any resources it's holding for the client? You could wait until the next method call from the client — but maybe it will never arrive. In the COM realm, the DCOM protocol used a ping mechanism. The client sent a ping to the server with the information about the object referenced. A client can have hundreds of objects referenced on the server, so the information in the ping can be very large. To make this mechanism more efficient, DCOM didn't send all the information about all objects, just what is different from the previous ping.

This ping mechanism was efficient on a LAN, but it is not suitable for scalable solutions — imagine thousands of clients sending ping information to the server! .NET Remoting has a much more scalable solution for lifetime management: the *Leasing Distributed Garbage Collector* (*LDGC*).

This lifetime management is only active for *client-activated objects* and well-known singleton objects. Single-call objects can be destroyed after every method call because they don't hold state. Client-activated objects do state and you should be aware of the resources used. A lease is created for client-activated objects that are referenced outside the application domain. A lease has a lease time, and when the lease time reaches zero, the lease expires, the remote object is disconnected, and finally, it is garbage collected.

Lease Renewals

If the client calls a method on the object when the lease has expired, an exception is thrown. If you have a client where the remote object could be needed for more than 300 seconds (the default value for lease times), you have three ways to renew a lease:

- **Implicit renewal** — This renewal of the lease is automatically done when the client calls a method on the remote object. If the current lease time is less than the `RenewOnCallTime` value, the lease is set to `RenewOnCallTime`.
- **Explicit renewal** — With this renewal, the client can specify the new lease time. This is done with the `Renew()` method of the `ILease` interface. You can get to the `ILease` interface by calling the `GetLifetimeService()` method of the transparent proxy.
- **Sponsoring renewal** — In the case of this renewal, the client can create a sponsor that implements the `ISponsor` interface and registers the sponsor in the leasing services using the `Register()` method of the `ILease` interface. The sponsor defines the lease extension time. When a lease expires, the sponsor is asked for an extension of the lease. The sponsoring mechanism can be used if you want long-lived remote objects on the server.

Leasing Configuration Values

The values that can be configured are the following:

- `LeaseTime` defines the time until a lease expires.
- `RenewOnCallTime` is the time the lease is set on a method call if the current lease time has a lower value.
- If a sponsor is not available within the `SponsorshipTimeout`, the remoting infrastructure looks for the next sponsor. If there are no more sponsors, the lease expires.
- The `LeaseManagerPollTime` defines the time interval at which the lease manager checks for expired objects.

The default values are listed in the following table.

LEASE CONFIGURATION	DEFAULT VALUE (SECONDS)
`LeaseTime`	300
`RenewOnCallTime`	120
`SponsorshipTimeout`	120
`LeaseManagerPollTime`	10

Classes Used for Lifetime Management

The `ClientSponsor` class implements the `ISponsor` interface. It can be used on the client side for lease extension. With the `ILease` interface you can get all information about the lease, all the lease properties, and the current lease time and state. The state is specified with the `LeaseState` enumeration. With the `LifetimeServices` utility class, you can get and set the properties for the lease of all remote objects in the application domain.

Getting Lease Information Example

In this small code example, the lease information is accessed by calling the `GetLifetimeService()` method of the transparent proxy. For the `ILease` interface, you have to declare the namespace `System.Runtime.Remoting.Lifetime`. For the class `UrlAttribute` you have to import the namespace `System.Runtime.Remoting.Activation`.

The leasing mechanism can only be used with stateful (client-activated and singleton) objects. Single-call objects are instantiated with every method call anyway, so the leasing mechanism doesn't apply.
To offer client-activated objects with the server, you can change the remoting configuration to a call to `RegisterActivatedServiceType()`:

```
RemotingConfiguration.ApplicationName = "Hello";
RemotingConfiguration.RegisterActivatedServiceType(typeof(Hello));
```

In the client application, the instantiation of the remote object must be changed, too. Instead of using the method `Activator.GetObject()`, `Activator.CreateInstance()` is used to invoke client-activated objects:

```
ChannelServices.RegisterChannel(new TcpClientChannel(), true);

object[] attrs = {new UrlAttribute("tcp://localhost:8086/Hi") };
Hello obj = (Hello)Activator.CreateInstance(typeof(Hello), null, attrs);
```

To show the leasing time, you can use the `ILease` interface returned by calling `GetLifetimeService()` from the proxy object:

```
ILease lease = (ILease)obj.GetLifetimeService();
if (lease != null)
{
   Console.WriteLine("Lease Configuration:");
   Console.WriteLine("InitialLeaseTime: {0}", lease.InitialLeaseTime);
   Console.WriteLine("RenewOnCallTime: {0}", lease.RenewOnCallTime);
   Console.WriteLine("SponsorshipTimeout: {0}", lease.SponsorshipTimeout);
   Console.WriteLine(lease.CurrentLeaseTime);
}
```

Changing Default Lease Configurations

The server itself can change the default lease configuration for all remote objects of the server using the `System.Runtime.Remoting.Lifetime.LifetimeServices` utility class:

```
LifetimeServices.LeaseTime = TimeSpan.FromMinutes(10);
LifetimeServices.RenewOnCallTime = TimeSpan.FromMinutes(2);
```

If you want different default lifetimes depending on the type of the remote object, you can change the lease configuration of the remote object by overriding the `InitializeLifetimeService()` method of the base class `MarshalByRefObject`:

```
public class Hello : System.MarshalByRefObject
{
   public override Object InitializeLifetimeService()
   {
      ILease lease = (ILease)base.InitializeLifetimeService();
      lease.InitialLeaseTime = TimeSpan.FromMinutes(10);
      lease.RenewOnCallTime = TimeSpan.FromSeconds(40);
      return lease;
   }
```

The lifetime services configuration can also be done by using a configuration file that is discussed next.

CONFIGURATION FILES

Instead of writing the channel and object configuration in the source code, you can use configuration files. This way the channel can be reconfigured, additional channels can be added, and so on, without changing the source code. Like all the other configuration files on the .NET platform, XML is used. The same application and configuration files that you read about in Chapter 18 and in Chapter 21, "Security," are used here, too. For .NET Remoting, there are some more XML elements and attributes to configure the channel and the remote objects. The difference with the remoting configuration file is that this configuration needn't be in the application configuration file itself; the file can have any name. To make the build process easier, in this chapter, the remoting configuration is written inside the application configuration files named with a `.config` file extension after the filename of the executable.

The code download (from `www.wrox.com`) contains the following example configuration files in the root directory of the client and the server examples: `clientactivated.config` and `wellknown.config`. With the client example, you will also find the file `wellknownhttp.config` that specifies an HTTP channel to a well-known remote object. To use these configurations, the files must be renamed to the name that is used with the parameter of the `RemotingConfiguration.Configure()` method and placed in the directory containing the executable file.

Here is just one example of how such a configuration file might look:

```
<configuration>
   <system.runtime.remoting>
      <application name="Hello">
         <service>
            <wellknown mode="SingleCall"
               type="Wrox.ProCSharp.Remoting.Hello, RemoteHello"
                     objectUri="Hi" />
         </service>
         <channels>
            <channel ref="tcp" port="6791" />
            <channel ref="http" port="6792" />
            <channel ref="ipc" portName="myIPCPort" />
         </channels>
      </application>
   </system.runtime.remoting>
</configuration>
```

code snippet ConfigurationFiles/HelloServer/app.config

`<configuration>` is the XML root element for all .NET configuration files. All the remoting configurations can be found in the subelement `<system.runtime.remoting>`. `<application>` is a subelement of `<system.runtime.remoting>`.

The following list describes the main elements and attributes of the parts within `<system.runtime.remoting>`:

- With the `<application>` element, you can specify the name of the application using the attribute `name`. On the server side, this is the name of the server, and on the client side it's the name of the client application. As an example for a server configuration, `<application name="Hello">` defines the remote application name Hello, which is used as part of the URL by the client to access the remote object.
- On the server, the element `<service>` is used to specify a collection of remote objects. It can have `<wellknown>` and `<activated>` subelements that specify the type of the remote object as well-known or client-activated.
- The client part of the `<service>` element is `<client>`. As with the `<service>` element, it can have `<wellknown>` and `<activated>` subelements to specify the type of the remote object. Unlike the `<service>` counterpart, `<client>` has a `url` attribute to specify the URL to the remote object.
- `<wellknown>` is an element that's used on the server and the client to specify well-known remote objects. The server part could look like this:

```
<wellknown mode="SingleCall"
   type="Wrox.ProCSharp.Remoting.Hello, RemoteHello"
         objectURI="Hi" />
```

- Although the `mode` attribute `SingleCall` or `Singleton` can be specified, the type is the type of the remote class, including the namespace `Wrox.ProCSharp.Remoting.Hello`. It is followed by the assembly name `RemoteHello`. `objectURI` is the name of the remote object that's registered in the channel.
- On the client, the `type` attribute is the same as it is for the server version. `mode` and `objectURI` are not needed, but the `url` attribute is used to define the path to the remote object instead: protocol, hostname, port number, application name, and the object URI:

```
<wellknown type="Wrox.ProCSharp.Remoting.Hello, RemoteHello"
                 url="tcp://localhost:6791/Hello/Hi" />
```

- The `<activated>` element is used for client-activated objects. With the `type` attribute the type and the assembly must be defined for both the client and the server application:

```
<activated type="Wrox.ProCSharp.Remoting.Hello, RemoteHello" />
```

- To specify the channel, the `<channel>` element is used. It's a subelement of `<channels>` so that a collection of channels can be configured for a single application. Its use is similar for clients and servers. With the XML attribute `ref`, you reference a preconfigured channel name. For the server channel, you have to set the port number with the XML attribute `port`. The XML attribute `displayName` is used to specify a name for the channel that is used from the .NET Framework Configuration tool, as discussed later in this chapter:

```
<channels>
   <channel ref="tcp" port="6791" displayName="TCP Channel" />
   <channel ref="http" port="6792" displayName="HTTP Channel" />
   <channel ref="ipc" portName="myIPCPort" displayName="IPC Channel"
       />
</channels>
```

Server Configuration for Well-Known Objects

This example file, `Wellknown_Server.config`, has the value `Hello` for the `name` property. In the following configuration file, the TCP channel is set to listen on port 6791 and the HTTP channel is set to listen on port 6792. The IPC channel is configured with the port name `myIPCPort`. The remote object class is `Wrox.ProCSharp.Remoting.Hello` in the assembly `RemoteHello`, the object is called `Hi` in the channel, and the object mode is `SingleCall`:

```
<configuration>
   <system.runtime.remoting>
      <application name="Hello">
         <service>
            <wellknown mode="SingleCall"
                       type="Wrox.ProCSharp.Remoting.Hello, RemoteHello"
                       objectUri="Hi" />
          </service>
          <channels>
             <channel ref="tcp" port="6791"
                displayName="TCP Channel (HelloServer)" />
             <channel ref="http" port="6792"
                displayName="HTTP Channel (HelloServer)" />
             <channel ref="ipc" portName="myIPCPort"
                displayName="IPC Channel (HelloServer)" />
          </channels>
      </application>
   </system.runtime.remoting>
</configuration>
```

code snippet ConfigurationFiles/HelloServer/Wellknown.config

Client Configuration for Well-Known Objects

For well-known objects, you have to specify the assembly and the channel in the client configuration file `Wellknown_Client.config`. The types for the remote object are in the `RemoteHello` assembly, `Hi` is the name of the object in the channel, and the URI for the remote type `Wrox.ProCSharp.Remoting.Hello` is `ipc://myIPCPort/Hello/Hi`. In the client, an IPC channel is used as well, but no port is specified, so a free port is selected. The channel that is selected with the client must correspond to the URL:

```
<configuration>
   <system.runtime.remoting>
      <application name="Client">
         <client displayName="Hello client for well-known objects">
            <wellknown type = "Wrox.ProCSharp.Remoting.Hello, RemoteHello"
                               url="ipc://myIPCPort/Hello/Hi" />
         </client>
         <channels>
            <channel ref="ipc" displayName="IPC Channel (HelloClient)" />
         </channels>
      </application>
   </system.runtime.remoting>
</configuration>
```

code snippet ConfigurationFiles/HelloClient/Wellknown_Client.config

After a small change in the configuration file, you're using the HTTP channel (as you can see in `WellknownHttp_Client.config`):

```
         <client>
            <wellknown type="Wrox.ProCSharp.Remoting.Hello, RemoteHello"
                             url="http://localhost:6792/Hello/Hi" />
         </client>
         <channels>
            <channel ref="http" displayName="HTTP Channel (HelloClient)" />
         </channels>
```

code snippet ConfigurationFiles/HelloClient/WellknownHttp_Client.config

Server Configuration for Client-Activated Objects

By changing only the configuration file (located in `ClientActivated_Server.config`), you can change the server configuration from server-activated to client-activated objects. Here the `<activated>` subelement of the `<service>` element is specified. With the `<activated>` element for the server configuration, only the `type` attribute must be specified. The `name` attribute of the `application` element defines the URI:

```
<configuration>
   <system.runtime.remoting>
      <application name="HelloServer">
         <service>
            <activated type="Wrox.ProCSharp.Remoting.Hello, RemoteHello" />
         </service>
         <channels>
            <channel ref="http" port="6788"
                     displayName="HTTP Channel (HelloServer)" />
            <channel ref="tcp" port="6789"
               displayName="TCP Channel (HelloServer)" />
            <channel ref="ipc" portName="myIPCPort"
                     displayName="IPC Channel (HelloServer)" />
         </channels>
      </application>
   </system.runtime.remoting>
</configuration>
```

code snippet ConfigurationFiles/HelloServer/ClientActivated.config

Client Configuration for Client-Activated Objects

The `ClientActivated_Client.config` file defines the client-activated remote object using the `url` attribute of the `<client>` element and the `type` attribute of the `<activated>` element:

```
<configuration>
   <system.runtime.remoting>
      <application>
         <client url="http://localhost:6788/HelloServer"
                displayName="Hello client for client-activated objects">
            <activated type="Wrox.ProCSharp.Remoting.Hello, RemoteHello" />
         </client>
         <channels>
            <channel ref="http" displayName="HTTP Channel (HelloClient)" />
            <channel ref="tcp" displayName="TCP Channel (HelloClient)" />
            <channel ref="ipc" displayName="IPC Channel (HelloClient)" />
         </channels>
      </application>
   </system.runtime.remoting>
</configuration>
```

code snippet ConfigurationFiles/HelloClient/ClientActivated_Client.config

Server Code Using Configuration Files

In the server code, you have to configure remoting using the static method `Configure()` from the `RemotingConfiguration` class. Here all channels that are defined in the configuration file are created and configured with the .NET Remoting runtime. Maybe you also want to know about the channel configurations from the server application — that's why the static methods `ShowActivatedServiceTypes()` and `ShowWellKnownServiceTypes()` were created; they are called after loading and starting the remoting configuration:

```
public static void Main()
{
   RemotingConfiguration.Configure("HelloServer.exe.config", false);
   Console.WriteLine("Application: {0}", RemotingConfiguration.ApplicationName);
   ShowActivatedServiceTypes();
   ShowWellKnownServiceTypes();
   System.Console.WriteLine("press return to exit");
   System.Console.ReadLine();
}
```

code snippet ConfigurationFiles/HelloServer/Program.cs

These two functions show configuration information of well-known and client-activated types:

```
public static void ShowWellKnownServiceTypes()
{
   WellKnownServiceTypeEntry[] entries =
       RemotingConfiguration.GetRegisteredWellKnownServiceTypes();
   foreach (var entry in entries)
   {
      Console.WriteLine("Assembly: {0}", entry.AssemblyName);
      Console.WriteLine("Mode: {0}", entry.Mode);
      Console.WriteLine("URI: {0}", entry.ObjectUri);
      Console.WriteLine("Type: {0}", entry.TypeName);
   }
}
public static void ShowActivatedServiceTypes()
{
   ActivatedServiceTypeEntry[] entries =
   RemotingConfiguration.GetRegisteredActivatedServiceTypes();
   foreach (var entry in entries)
   {
      Console.WriteLine("Assembly: {0}", entry.AssemblyName);
      Console.WriteLine("Type: {0}", entry.TypeName);
   }
}
```

Client Code Using Configuration Files

In the client code, it is only necessary to configure the remoting services using the configuration file `client.exe.config`. After that, you can use the `new` operator to create new instances of the remote class `Hello`, no matter whether you work with server-activated or client-activated remote objects. However, there's a small difference — with client-activated objects, it's now possible to use *nondefault constructors* with the `new` operator. This isn't possible for server-activated objects. Single-call objects can have no state because they are destroyed with every call; singleton objects are created just once. Calling nondefault constructors is only possible with client-activated objects because this is the only type whereby invoking the `new` operator the remote object is instantiated.

In the `Main()` method of the file `HelloClient.cs`, you can now change the remoting code to use the configuration file with `RemotingConfiguration.Configure()` and create the remote object with the `new` operator:

```
RemotingConfiguration.Configure("HelloClient.exe.config", false);
Hello obj = new Hello();
if (obj == null)
{
   Console.WriteLine("could not locate server");
```

```
      return;
   }
   for (int i=0; i < 5; i++)
   {
      Console.WriteLine(obj.Greeting("Stephanie"));
   }
```

code snippet ConfigurationFiles/HelloClient/Program.cs

Delayed Loading of Client Channels

With .NET Remoting, three channels are configured by default that can be used automatically if the client doesn't configure a channel:

```
<system.runtime.remoting>
   <application>
      <channels>
         <channel ref="http client" displayName="http client (delay loaded)"
                  delayLoadAsClientChannel="true" />
         <channel ref="tcp client" displayName="tcp client (delay loaded)"
                  delayLoadAsClientChannel="true" />
         <channel ref="ipc client" displayName="ipc client (delay loaded")"
                  delayLoadAsClientChannel="true" />
      </channels>
   </application>
</system.runtime.remoting>
```

The XML attribute `delayLoadAsClientChannel` with a value `true` specifies that the channel should be used from a client that doesn't configure a channel. The runtime tries to connect to the server using the delay-loaded channels. So, it is not necessary to configure a channel in the client configuration file, and a client configuration file for the well-known object you have used earlier can look as simple as this:

```
<configuration>
   <system.runtime.remoting>
      <application name="Client">
         <client url="tcp:/localhost:6791/Hello">
            <wellknown type = "Wrox.ProCSharp.Remoting.Hello, RemoteHello"
                       url="tcp://localhost:6791/Hello/Hi" />
         </client>
      </application>
   </system.runtime.remoting>
</configuration>
```

Debugging Configuration

If you have a misconfigured server configuration file (for example, by specifying the wrong name of the remote assembly), the error is not detected when the server starts. Instead, the error is detected when the client instantiates a remote object and invokes a method. The client gets the exception that the remote object assembly cannot be found. By specifying the configuration `<debug loadTypes="true" />`, the remote object is loaded and instantiated on the server when the server starts up. This way you get an error on the server if the configuration file is misconfigured:

```
<configuration>
   <system.runtime.remoting>
      <application name="Hello">
         <service>
            <wellknown mode="SingleCall"
                       type="Wrox.ProCSharp.Remoting.Hello, RemoteHello"
                       objectUri="Hi" />
         </service>
         <channels>
```

```
              <channel ref="tcp" port="6791"
                 displayName="TCP Channel (HelloServer)" />
          </channels>
       </application>
       <debug loadTypes="true" />
    </system.runtime.remoting>
</configuration>
```

Lifetime Services in Configuration Files

Leasing configuration for remote servers can also be done with the application configuration files. The `<lifetime>` element has the attributes `leaseTime`, `sponsorshipTimeOut`, `renewOnCallTime`, and `pollTime`, as shown in this example:

```
<configuration>
   <system.runtime.remoting>
      <application>
         <lifetime leaseTime = "15M" sponsorshipTimeOut = "4M"
                   renewOnCallTime = "3M" pollTime = "30s"/>
      </application>
   </system.runtime.remoting>
</configuration>
```

Using configuration files, it is possible to change the remoting configuration by editing files instead of working with source code. You can easily change the channel to use HTTP instead of TCP, change a port, the name of the channel, and so on. With the addition of a single line, the server can listen to two channels instead of one.

Formatter Providers

Earlier in this chapter we discussed where properties of the formatter provider need to be changed to support marshaling of all objects across the network. Instead of doing this programmatically, as was done earlier, you can configure the properties of a formatter provider in a configuration file.

The following server configuration file is changed within the `<channel>` element, insofar as `<serverProviders>` and `<clientProviders>` are defined as child elements. With the `<serverProviders>`, the built-in providers `wsdl`, `soap`, and `binary` are referenced, and with the soap and binary providers the property `typeFilterLevel` is set to `Full`:

```
<configuration>
   <system.runtime.remoting>
      <application name="HelloServer">
         <service>
            <activated type="Wrox.ProCSharp.Remoting.Hello, RemoteHello" />
         </service>
         <channels>
            <channel ref="tcp" port="6789" displayName="TCP Channel (HelloServer)">
              <serverProviders>
                <provider ref="wsdl" />
                <provider ref="soap" typeFilterLevel="Full" />
                <provider ref="binary" typeFilterLevel="Full" />
              </serverProviders>
              <clientProviders>
                <provider ref="binary" />
              </clientProviders>
            </channel>
         </channels>
      </application>
   </system.runtime.remoting>
</configuration>
```

HOSTING SERVERS IN ASP.NET

Up to this point, all the sample servers have been running in self-hosted .NET servers. A self-hosted server must be launched manually. A .NET Remoting server can also be started in a lot of other application types. In a Windows Service, the server can be automatically started at boot time, and in addition the process can run with the credentials of the system account. For more details on Windows Services, see Chapter 25, "Windows Services."

There's special support for .NET Remoting servers for ASP.NET. ASP.NET can be used for the automatic startup of remote servers. ASP.NET-hosted Remoting uses a different file for configuration than EXE-hosted applications, but it has the same syntax.

To use the infrastructure from the Internet Information Services (IIS) and ASP.NET, you have to create a class that derives from `System.MarshalByRefObject` and has a default constructor. The code used earlier for the server to create and register the channel is no longer necessary; that's done by the ASP.NET runtime. You have to create only a virtual directory on the Web server that maps a directory into which you put the configuration file `Web.config`. The assembly of the remote class must reside in the bin subdirectory.

To configure a virtual directory on the web server, you can use the IIS MMC. Selecting the Default Web Site and opening the Action menu creates a new Virtual Directory.

The configuration file `Web.config` on the web server must be put in the home directory of the virtual web site. With the default IIS configuration, the channel that will be used listens to port 80:

```
<configuration>
   <system.runtime.remoting>
      <application>
         <service>
            <wellknown mode="SingleCall"
               type="Wrox.ProCSharp.Remoting.Hello, RemoteHello"
               objectUri="HelloService.soap" />
         </service>
      </application>
   </system.runtime.remoting>
</configuration>
```

If the remoting object is hosted within IIS, the name of the remote object must end either with `.soap` *or* `.rem`*, depending on the type of formatter that is used (SOAP or the binary).*

The client can now connect to the remote object using the following configuration file. The URL that must be specified for the remote object here is the web server `localhost`, followed by the web application name `RemoteHello` (specified when creating the virtual web site), and the URI of the remote object `HelloService.soap` that is defined in the file `Web.config`. It's not necessary to specify the port number 80, because that's the default port for the HTTP protocol. Not specifying a `<channels>` section means that the delay-loaded HTTP channel from the configuration file `machine.config` is used:

```
<configuration>
   <system.runtime.remoting>
      <application>
         <client url="http:/localhost/RemoteHello">
            <wellknown type="Wrox.ProCSharp.Remoting.Hello, RemoteHello"
                       url="http://localhost/RemoteHello/HelloService.soap" />
         </client>
      </application>
   </system.runtime.remoting>
</configuration>
```

CLASSES, INTERFACES, AND SOAPSUDS

In the .NET Remoting examples you have seen so far, you have always copied the assembly of the remote object not only to the server but also to the client application. This way the MSIL code of the remote object is on both the client and the server system, although in the client application only the metadata is needed. However, copying the remoting object assembly means that it's not possible for the client and the server to be programmed independently. A much better way to use just the metadata is to use interfaces or the `Soapsuds.exe` utility instead.

Interfaces

You get a cleaner separation of the client and server code by using interfaces. An interface simply defines the methods without implementation. This way the contract (the interface) is separated from the implementation, and just the contract is needed on the client system. Here are the necessary steps for using an interface:

1. Define an interface that will be placed in a separate assembly.
2. Implement the interface in the remote object class. To do this, the assembly of the interface must be referenced.
3. On the server side no more changes are required. The server can be programmed and configured in the usual way.
4. On the client side, reference the assembly of the interface instead of the assembly of the remote class.
5. The client can now use the interface of the remote object rather than the remote object class. The object can be created using the `Activator` class as it was done earlier. You can't use the `new` operator in this way, because the interface itself cannot be instantiated.

The interface defines the contract between the client and server. The two applications can now be developed independently of each other. If you also stick to the old COM rules about interfaces (that interfaces should never be changed), you will not have any versioning problems.

Soapsuds

You can also use the Soapsuds utility to get the metadata from an assembly if an HTTP channel and the SOAP formatter are used. Soapsuds can convert assemblies to XML schemas and XML schemas to wrapper classes — it also works in the other direction.

The following command converts the type `Hello` from the assembly `RemoteHello` to the assembly `HelloWrapper`, where a transparent proxy is generated that calls the remote object:

```
soapsuds -types:Wrox.ProCSharp.Remoting.Hello,RemoteHello -oa:HelloWrapper.dll
```

With Soapsuds you can also get the type information directly from a running server, if the HTTP channel and the SOAP formatter are used:

```
soapsuds -url:http://localhost:6792/hello/hi?wsdl -oa:HelloWrapper.dll
```

In the client, you can now reference the generated assembly instead of the original one. Some of the Soapsuds options are listed in the following table.

OPTION	DESCRIPTION
`-url`	Retrieve schema from the specified URL
`-proxyurl`	If a proxy server is required to access the server, specify the proxy with this option
`-types`	Specify a type and assembly to read the schema information from it
`-is`	Input schema file
`-ia`	Input assembly file
`-os`	Output schema file
`-oa`	Output assembly file

ASYNCHRONOUS REMOTING

If server methods take some time to complete and the client needs to do some different work at the same time, it isn't necessary to start a separate thread to make the remote call. By making an asynchronous call, you cause the method to start but return immediately to the client. Asynchronous calls can be made on a remote object, as they are made on a local object with the help of a delegate. With methods that don't return a value, you can also use the `OneWay` attribute.

Using Delegates with .NET Remoting

To make an asynchronous method, you can use a delegate with the same argument and return value as the `Greeting()` method of the remote object. The generic `Func<T>` and `Action<T>` delegates are very helpful with this. The `Greeting()` method requires a `string` parameter that returns a `string` type, `Func<string, string>`. This is the delegate definition to invoke this method. You start the `Greeting()` call using the `BeginInvoke()` method of the delegate. The second argument of `BeginInvoke()` is an `AsyncCallback` instance that defines the method `HelloClient.Callback()`. It is called when the remote method is finished. In the `Callback()` method, the remote call is finished using `EndInvoke()`:

```
using System;
using System.Runtime.Remoting;
namespace Wrox.ProCSharp.Remoting
{
   public class HelloClient
   {
      private static string greeting;

      public static void Main()
      {
         RemotingConfiguration.Configure("HelloClient.exe.config");
         Hello obj = new Hello();
         if (obj == null)
         {
            Console.WriteLine("could not locate server");
            return;
         }
         Func<string, string> d = new Func<string, string>(obj.Greeting);
         IAsyncResult ar = d.BeginInvoke("Stephanie", null, null);

         // do some work and then wait
         ar.AsyncWaitHandle.WaitOne();
         string greeting = null;
         if (ar.IsCompleted)
```

```
            {
               greeting = d.EndInvoke(ar);
            }

            Console.WriteLine(greeting);
         }
      }
   }
```

You can find more information about delegates in Chapter 8, "Delegates, Lambdas, and Events," and about using delegates asynchronously in Chapter 20, "Threads, Tasks, and Synchronization."

OneWay Attribute

A method that has a `void` return and only input parameters can be marked with the `OneWay` attribute. The `OneWay` attribute (defined within the namespace `System.Runtime.Remoting.Messaging`) makes a method automatically asynchronous, regardless of how the client calls it. Adding the method `TakeAWhile()` to your remote object class `RemoteHello` creates a fire-and-forget method. If the client calls it by the proxy, the proxy immediately returns to the client. On the server, the method finishes some time later:

```
[OneWay]
public void TakeAWhile(int ms)
{
   Console.WriteLine("TakeAWhile started");
   System.Threading.Thread.Sleep(ms);
   Console.WriteLine("TakeAWhile finished");
}
```

SECURITY WITH .NET REMOTING

.NET Remoting has supported security since .NET 2.0. .NET Remoting offers confidentiality of the data that is transferred across the wire as well as authentication of the user.

Security can be configured with every channel. TCP, HTTP, and IPC channels support security configuration. With the server configuration you have to define the minimum security requirement of the communication, while the client configuration defines the capabilities regarding security. If the client defines a security configuration that is lower than the minimum requirements defined by the server, the communication fails.

Let's start with the server configuration. The following extract of the configuration file shows how the security can be defined for the server.

With the XML attribute `protectionLevel`, you can specify whether the server requires encrypted data to be sent across the network. The possible values that can be set with the `protectionLevel` attribute are `None`, `Sign`, and `EncryptAndSign`. With the value `Sign` a signature is created that is used to verify whether the data that is sent didn't change on its way across the network. However, it is still possible to read the data with a sniffer that reads all the data on the network. With the value `EncryptAndSign`, the data that is sent is also encrypted to make it impossible that systems not officially participating with the message transfer can read the data.

The attribute `impersonate` can be set to `true` or `false`. If `impersonate` is set to `true`, the server can impersonate the user of the client to access resources in its name:

```
<channels>
   <channel ref="tcp" port="9001"
      secure="true"
      protectionLevel="EncryptAndSign"
      impersonate="false" />
</channels>
```

With the client configuration, the capabilities of the network communication are defined. If the capabilities don't fulfill the server requirements, the communication fails. You can see `protectionLevel` and `TokenImpersonationLevel` configured in the following sample configuration.

`protectionLevel` can be set to the same options as you have seen with the server configuration file.

The `TokenImpersonationLevel` can be set to `Anonymous`, `Identification`, `Impersonation`, and `Delegation`. With the `Anonymous` value, the server cannot identify the user of the client. If the value is set to `Identification`, the server can find out the user identity of the server. If the server is configured with `impersonate` set to `true`, the communication fails if the client is only configured with `Anonymous` or `Identification`. Setting `TokenImpersonationLevel` to `Impersonation` allows the server to impersonate the client. Setting `TokenImpersonationLevel` to `Delegation` allows the server to impersonate the client not only to access resources local on the server but also to use the user identification to access resources on other servers. Delegation is only possible if Kerberos is used for logging on the user, as is possible with Active Directory:

```
<channels>
   <channel ref="tcp"
      secure="true"
      protectionLevel="EncryptAndSign"
      TokenImpersonationLevel="Impersonate" />
</channels>
```

If you create the channel programmatically instead of using configuration files, you can define the security setting programmatically as well. A collection that contains all security settings can be passed to the constructor of the channel as shown. The collection class must implement the interface `IDictionary`, for example the generic `Dictionary` class or the `Hashtable` class:

```
var dict = new Dictionary<string, string>();
dict.Add("secure", "true");

var clientChannel = new TcpClientChannel(dict, null);
```

You can read more about security in Chapter 21.

REMOTING AND EVENTS

Not only can the client invoke methods on the remote object across the network but the server can do the same — invoking methods in the client. For this, a mechanism that you already know from the basic language features is used: *delegates and events*.

In principle, the architecture is simple. The server has a remotable object that the client can call, and the client has a remotable object that the server can call:

- ➤ The remote object in the server must declare an external function (a delegate) with the signature of the method that the client will implement in a handler.
- ➤ The arguments that are passed with the handler function to the client must be marshalable, so all the data sent to the client must be serializable.
- ➤ The remote object must also declare an instance of the delegate function modified with the `event` keyword; the client will use this to register a handler.
- ➤ The client must create a sink object with a handler method that has the same signature as the delegate defined, and it has to register the sink object with the event in the remote object.

Take a look at an example. To see all the parts of event handling with .NET Remoting, create five classes: `Server`, `Client`, `RemoteObject`, `EventSink`, and `StatusEventArgs`. The dependencies of these classes are shown in Figure 54-5.

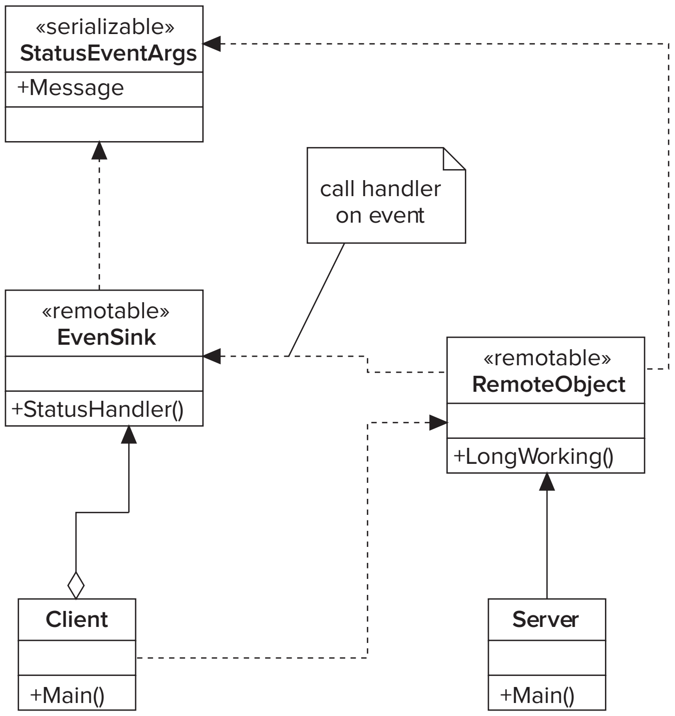

FIGURE 54-5

The `Server` class is a remoting server such as the one you are already familiar with. The `Server` class will create a channel based on information from a configuration file and register the remote object that's implemented in the `RemoteObject` class in the remoting runtime. The remote object declares the arguments of a delegate and fires events in the registered handler functions. The argument that's passed to the handler function is of type `StatusEventArgs`. The class `StatusEventArgs` must be serializable so that it can be marshaled to the client.

The `Client` class represents the client application. This class creates an instance of the `EventSink` class and registers the `StatusHandler()` method of this class as a handler for the delegate in the remote object. `EventSink` must be remotable like the `RemoteObject` class, because this class will also be called across the network.

Remote Object

The remote object class is implemented in the file `RemoteObject.cs`. The remote object class must be derived from `MarshalByRefObject`, as you already know from the previous examples. To enable the client to register an event handler that can be called from within the remote object, you have to declare an external function with the `delegate` keyword. Declare the delegate `StatusEvent()` with two arguments: the `sender` (so the client knows about the object that fired the event) and a variable of type `StatusEventArgs`. Into the argument class you can put all the additional information that you want to send to the client.

The method that will be implemented in the client has some strict requirements. It can only have input parameters — return types, `ref`, and `out` parameters are not allowed — and the argument types must be either `[Serializable]` or remotable (derived from `MarshalByRefObject`). These requirements are fulfilled by the parameters that are defined with the `EventHandler<StatusEventArgs>` delegate.

Within the `RemoteObject` class, declare an event name `Status` of type `EventHandler<StatusEventArgs>`. The client must add an event handler to the `Status` event to receive status information from the remote object:

```
public class RemoteObject : MarshalByRefObject
{
   public RemoteObject()
   {
      Console.WriteLine("RemoteObject constructor called");
   }
   public event EventHandler<StatusEventArgs> Status;
```

code snippet RemotingAndEvents/RemoteObject/RemoteObject.cs

The `LongWorking()` method checks whether an event handler is registered before the event is fired by calling `Status(this, e)`. To verify that the event is fired asynchronously, fire an event at the start of the method before doing the `Thread.Sleep()` and after the sleep:

```
public void LongWorking(int ms)
{
   Console.WriteLine("RemoteObject: LongWorking() Started");
   StatusEventArgs e = new StatusEventArgs(
                           "Message for Client: LongWorking() Started");
   // fire event
   if (Status != null)
   {
      Console.WriteLine("RemoteObject: Firing Starting Event");
       Status(this, e);
   }
   System.Threading.Thread.Sleep(ms);
   e.Message = "Message for Client: LongWorking() Ending";
   // fire ending event
   if (Status != null)
   {
      Console.WriteLine("RemoteObject: Firing Ending Event");
      Status(this, e);
   }
   Console.WriteLine("RemoteObject: LongWorking() Ending");
}
```

Event Arguments

As you've seen in the `RemoteObject` class, the class `StatusEventArgs` is used as an argument for the delegate. With the `Serializable` attribute an instance of this class can be transferred from the server to the client. Here is a simple property of type `string` to send a message to the client:

```
[Serializable]
public class StatusEventArgs : EventArgs
{
   public StatusEventArgs(string message)
   {
      this.Message = message;
   }
   public string Message { get; set; }
}
```

code snippet RemotingAndEvents/RemoteObject/RemoteObject.cs

Server

The server is implemented within a console application. With `RemotingConfiguration.Configure()`, the configuration file is read and thus the channel and remote objects are set up. With the `Console.ReadLine()` the server waits until the user stops the application:

```
using System;
using System.Runtime.Remoting;
namespace Wrox.ProCSharp.Remoting
{
   class Server
   {
      static void Main()
      {
         RemotingConfiguration.Configure("Server.exe.config", true);
         Console.WriteLine("press return to exit");
         Console.ReadLine();
      }
   }
}
```

code snippet RemotingAndEvents/RemoteServer/Program.cs

Server Configuration File

The server configuration file, `Server.exe.config`, is also created as already discussed. There is just one important point: the remote object must keep state for the client because the client at first registers the event handler and calls the remote method afterward. You cannot use single-call objects with events, so the `RemoteObject` class is configured as a client-activated type. Also, to support delegates, you have to enable full serialization by specifying the `typeFilterLevel` attribute with the `<provider>` element:

```
<configuration>
   <system.runtime.remoting>
      <application name="CallbackSample">
         <service>
            <activated type="Wrox.ProCSharp.Remoting.RemoteObject,
                             RemoteObject" />
         </service>
         <channels>
            <channel ref="tcp" port="6791">
               <serverProviders>
                  <provider ref="binary" typeFilterLevel="Full" />
               </serverProviders>
            </channel>
         </channels>
      </application>
   </system.runtime.remoting>
</configuration>
```

code snippet RemotingAndEvents/RemoteServer/app.config

Event Sink

An event sink library is required for use by the client and is invoked by the server. The event sink implements the handler `StatusHandler()` that's defined with the delegate. As previously noted, the method can only have input parameters and only a void return. The `EventSink` class must also inherit from the class `MarshalByRefObject` to make it remotable, because it will be called remotely from the server:

```
using System;
using System.Runtime.Remoting.Messaging;

namespace Wrox.ProCSharp.Remoting
{
   public class EventSink : MarshalByRefObject
   {
      public EventSink()
      {
      }
      public void StatusHandler(object sender, StatusEventArgs e)
      {
         Console.WriteLine("EventSink: Event occurred: " + e.Message);
      }
   }
}
```

code snippet RemotingAndEvents/EventSink/EventSink.cs

Client

The client reads the client configuration file with the `RemotingConfiguration` class, which is not different from the clients that have been discussed so far. The client creates an instance of the remotable sink class `EventSink` locally. The method that should be called from the remote object on the server is passed to the remote object:

```
using System;
using System.Runtime.Remoting;

namespace Wrox.ProCSharp.Remoting
{
   class Client
   {
      static void Main()
      {
         RemotingConfiguration.Configure("Client.exe.config", true);
         Console.WriteLine("wait for server...");
         Console.ReadLine();
```

code snippet RemotingAndEvents/RemoteClient/Program.cs

The differences start here. You have to create an instance of the remotable sink class `EventSink` locally. Because this class will not be configured with the `<client>` element, it's instantiated locally. Next, the remote object class `RemoteObject` is instantiated. This class is configured in the `<client>` element, so it's instantiated on the remote server:

```
         var sink = new EventSink();
         var obj = new RemoteObject();
         if (!RemotingServices.IsTransparentProxy(obj))
         {
            Console.WriteLine("check your remoting configuration");
            return;
         }
```

Now you can register the handler method of the `EventSink` object in the remote object. `StatusEvent` is the name of the delegate that was defined in the server. The `StatusHandler()` method has the same arguments as defined in the `StatusEvent`.

By calling the `LongWorking()` method, the server will call back into the method `StatusHandler()` at the beginning and at the end of the method:

```
            // register client sink in server - subscribe to event
            obj.Status += sink.StatusHandle;
            obj.LongWorking(5000);
```

Now you are no longer interested in receiving events from the server, so you are unsubscribing from the event. The next time you call `LongWorking()`, no events will be received:

```
            // unsubscribe from event
            obj.Status -= sink.StatusHandler;
            obj.LongWorking(5000);
            Console.WriteLine("press return to exit");
            Console.ReadLine();
         }
      }
   }
```

Client Configuration File

The configuration file for the client, `client.exe.config`, is nearly the same configuration file for client-activated objects that we've already seen. The difference is in defining a port number for the channel. Because the server must reach the client with a known port, you have to define the port number for the channel as an attribute of the `<channel>` element. It isn't necessary to define a `<service>` section for your `EventSink` class, because this class will be instantiated from the client with the `new` operator locally. The server does not access this object by its name; it will receive a marshaled reference to the instance instead:

```
<configuration>
   <system.runtime.remoting>
      <application name="Client">
         <client url="tcp://localhost:6791/CallbackSample">
            <activated type="Wrox.ProCSharp.Remoting.RemoteObject,
                             RemoteObject" />
         </client>
         <channels>
             <channel ref="tcp" port="0">
                <serverProviders>
                   <provider ref="binary" typeFilterLevel="Full" />
                </serverProviders>
             </channel>
         </channels>
      </application>
   </system.runtime.remoting>
</configuration>
```

code snippet RemotingAndEvents/RemoteClient/app.config

Running Programs

Here is the resulting output of the server. The constructor of the remote object is called once because you have a client-activated object. Next, you can see that the call to `LongWorking()` has started and an event is fired to the client. The next start of the `LongWorking()` method doesn't fire events, because the client has already unregistered its interest in the event:

```
press return to exit
RemoteObject constructor called
RemoteObject: LongWorking() Started
RemoteObject: Firing Starting Event
RemoteObject: Firing Ending Event
```

```
RemoteObject: LongWorking() Ending
RemoteObject: LongWorking() Started
RemoteObject: LongWorking() Ending
```

With the client output you can see the events that made it across the network:

```
wait for server...

EventSink: Event occurred: Message for Client: LongWorking() Started
EventSink: Event occurred: Message for Client: LongWorking() Ending
```

CALL CONTEXTS

Client-activated objects can hold state for a specific client. With client-activated objects the server allocates resources for every client. With server-activated `SingleCall` objects, a new instance is created for every instance call, and no resources are held on the server; these objects can't hold state for a client. For state management, you can keep state on the client side; the state information is sent with every method call to the server. To implement such a state management, it is not necessary to change all method signatures to include an additional parameter that passes the state to the server; this is automatically done by the *call context*.

A call context flows with a logical thread and is passed with every method call. A *logical thread* is started from the calling thread and flows through all method calls that are started from the calling thread, passing through different contexts, different application domains, and different processes.

You can assign data to the call context using `CallContext.SetData()`. The class of the object that's used as data for the `SetData()` method must implement the interface `ILogicalThreadAffinative`. You can get this data again in the same logical thread (but possibly a different physical thread) using `CallContext.GetData()`.

For the data of the call context, create a new C# Class Library with the class `CallContextData`. This class will be used to pass some data from the client to the server with every method call. The class that's passed with the call context must implement the `System.Runtime.Remoting.Messaging.ILogicalThreadAffinative` interface. This interface doesn't have a method; it's just a markup for the runtime to define that instances of this class should flow with a logical thread. The `CallContextData` class must also be marked with the `Serializable` attribute so it can be transferred through the channel:

```
using System;
using System.Runtime.Remoting.Messaging;
namespace Wrox.ProCSharp.Remoting
{
   [Serializable]
   public class CallContextData : ILogicalThreadAffinative
   {
      public CallContextData()
      {
      }
      public string Data { get; set; }
   }
}
```

In the remote object class `Hello`, change the `Greeting()` method to access the call context. To use the `CallContextData` class, you have to reference the previously created assembly `CallContextData` in the file `CallContextData.dll`. To work with the `CallContext` class, the namespace `System.Runtime.Remoting.Messaging` must be opened. The variable cookie holds the data that is sent from the client to the server. The name "cookie" is chosen because the context works similarly to a browser-based cookie, where the client automatically sends data to the web server:

```
      public string Greeting(string name)
      {
         Console.WriteLine("Greeting started");
         CallContextData cookie = (CallContextData)CallContext.GetData("mycookie");
```

```
            if (cookie != null)
            {
               Console.WriteLine("Cookie: " + cookie.Data);
            }
            Console.WriteLine("Greeting finished");
            return "Hello, " + name;
         }
```

In the client code, the call context information is set by calling `CallContext.SetData()`. With this method an instance of the class `CallContextData` is assigned to be passed to the server. Now every time the method `Greeting()` is called in the `for` loop, the context data is automatically passed to the server:

```
            CallContextData cookie = new CallContextData();
            cookie.Data = "information for the server";
            CallContext.SetData("mycookie", cookie);
            for (int i=0; i < 5; i++)
            {
               Console.WriteLine(obj.Greeting("Christian"));
            }
```

You can use such a call context to send information about the user, the name of the client system, or simply a unique identifier used on the server side to get some state information from a database.

SUMMARY

In this chapter, you've seen that .NET Remoting facilitates the task of invoking methods across the network. A remote object has to inherit form `MarshalByRefObject`. In the server application, only a single method is needed to load the configuration file so that the channels and remote objects are both set up and running. Within the client, you load the configuration file and can use the `new` operator to instantiate the remote object.

You also used .NET Remoting without the help of configuration files. On the server, you simply created a channel and registered a remote object. On the client, you created a channel and used the remote object.

Furthermore, you learned that the .NET Remoting architecture is flexible and can be extended. All parts of this technology such as channels, proxies, formatters, message sinks, and so on are pluggable and can be replaced with custom implementations.

You used HTTP, TCP, and IPC channels for communication across the network, and SOAP and binary formatters to format the parameters before sending them.

You learned about the stateless and stateful object types that are used by well-known and client-activated objects. With client-activated objects you have seen how the leasing mechanism is used to specify the lifetime of remote objects.

You have also seen that .NET Remoting is very well-integrated in other parts of the .NET Framework, such as calling asynchronous methods, performing callbacks using the delegate and event keywords, and so on.

55 Web Services with ASP.NET

WHAT'S IN THIS CHAPTER

- The syntax of SOAP and WSDL
- How SOAP and WSDL are used by web services
- Exposing and consuming web services
- The use of web services
- Exchanging data by using SOAP headers

Web services are a way of performing remote method calls over HTTP that can make use of *Simple Object Access Protocol* (SOAP). In the past, this issue was fraught with difficulty, as anyone who has any DCOM (Distributed COM) experience knows. Using older technologies, the act of instantiating an object on a remote server, calling a method, and obtaining the result is far from simple, and the necessary configuration is even trickier.

SOAP simplifies matters immensely. This technology is an XML-based standard that details how method calls can be made over HTTP in a reproducible manner. A remote SOAP server is capable of understanding these calls and performing all the hard work for you, such as instantiating the required object, making the call, and returning a SOAP-formatted response to the client.

The .NET Framework makes it very easy for you to do this. As with ASP.NET, you are able to use the full array of C# and .NET techniques on the server, but (perhaps more importantly) the simple consumption of web services can be achieved from any platform with HTTP access to the server. In other words, it is conceivable that Linux code could, for example, use ASP.NET web services, or even Internet-enabled fridges. To quote a real-world example, in the past I have had great success combining ASP.NET web services with Macromedia Flash to create data-enabled flash content.

In addition, web services can be completely described using *Web Service Description Language* (WSDL), allowing the dynamic discovery of web services at runtime. WSDL provides descriptions of all methods (along with the types required to call them) using XML with XML schemas. A wide variety of types are available to web services, which range from simple primitive types to full `DataSet` objects; this makes it possible to marshal full in-memory databases to a client. This can result in a dramatic reduction in load on a database server.

SOAP

As mentioned, one way to exchange data with web services is SOAP. This technology had a lot of press when it was first released, especially as Microsoft decided to adopt it for use in the .NET Framework. When you think about it, finding out exactly how SOAP works is a bit like finding out about how HTTP works — interesting, but not essential. Most of the time you don't have to worry about the format of the exchanges made with web services; they just happen, you get the results you want, and everyone is happy.

For this reason, this section won't go into a huge amount of depth, but you will see some simple SOAP requests and responses so you can get a feel for what is going on under the hood.

Imagine that you want to call a method in a web service with the following signature:

```
int DoSomething(string stringParam, int intParam)
```

The SOAP headers and body required for this are shown in the following code, with the address of the web service (more on this later) at the top:

```
POST /SomeLocation/myWebService.asmx HTTP/1.1
Host: hostname
Content-Type: text/xml; charset=utf-8
Content-Length: length
SOAPAction: "http://tempuri.org/DoSomething"
<?xml version="1.0" encoding="utf-8"?>
<soap:Envelope xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
               xmlns:xsd="http://www.w3.org/2001/XMLSchema"
               xmlns:soap="http://schemas.xmlsoap.org/soap/envelope/">
  <soap:Body>
    <DoSomething xmlns="http://tempuri.org/">
      <stringParam>string</stringParam>
      <intParam>int</intParam>
    </DoSomething>
  </soap:Body>
</soap:Envelope>
```

The `length` parameter here specifies the total byte size of the content and varies depending on the values sent in the *`string`* and *`int`* parameters. `Host` will also vary, depending on where the web service is located.

The `soap` namespace referenced here defines various elements that you use to build your message. When you send this over HTTP, the actual data sent is slightly different (but related). For example, you could call the preceding method using the simple `GET` method:

```
GET /SomeLocation/myWebService.asmx/DoSomething?stringParam=string&intParam=int
  HTTP/1.1
Host: hostname
```

The SOAP response of this method is as follows:

```
HTTP/1.1 200 OK
Content-Type: text/xml; charset=utf-8
Content-Length: length
<?xml version="1.0" encoding="utf-8"?>
<soap:Envelope xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
               xmlns:xsd="http://www.w3.org/2001/XMLSchema"
               xmlns:soap="http://schemas.xmlsoap.org/soap/envelope/">
  <soap:Body>
    <DoSomethingResponse xmlns="http://tempuri.org/">
```

```
        <DoSomethingResult>int</DoSomethingResult>
      </DoSomethingResponse>
    </soap:Body>
  </soap:Envelope>
```

where `length` varies depending on the contents, in this case *`int`*.

The actual response over HTTP is simpler, as shown in this example:

```
HTTP/1.1 200 OK
Content-Type: text/xml; charset=utf-8
Content-Length: length
<?xml version="1.0"?>
<int xmlns="http://tempuri.org/">int</int>
```

This is a far simpler XML format.

As discussed at the start of this section, the beauty of all this is that you can ignore it completely. Only if you want to do something really odd does the exact syntax become important.

WSDL

WSDL completely describes web services, the methods available, and the various ways of calling these methods. The exact details of this process won't really benefit you that much, but a general understanding is useful.

WSDL is another fully XML-compliant syntax, and specifies web services by the methods available, the types used by these methods, the formats of request and response messages sent to and from methods via various protocols (pure SOAP, HTTP GET, and so on), and various bindings between these specifications. WSDL is understood by a variety of clients — not just .NET ones, but others such as Macromedia Flash, as mentioned in the introduction to this chapter.

Perhaps the most important part of a WSDL file is the type-definition section. This section uses XML schemas to describe the format for data exchange with the XML elements that can be used and their relationships.

For example, the web service method used as an example in the last section:

```
int DoSomething(string stringParam, int intParam)
```

would have types declared for the request as follows:

```
<?xml version="1.0" encoding="utf-8"?>
<definitions xmlns:http="http://schemas.xmlsoap.org/wsdl/http/"
             xmlns:soap="http://schemas.xmlsoap.org/wsdl/soap/"
             xmlns:s="http://www.w3.org/2001/XMLSchema"
             xmlns:wsdl="http://schemas.xmlsoap.org/wsdl"
             ...other namespaces...>
  <wsdl:types>
    <s:schema elementFormDefault="qualified"
              targetNamespace="http://tempuri.org/">
      <s:element name="DoSomething">
        <s:complexType>
          <s:sequence>
            <s:element minOccurs="0" maxOccurs="1" name="stringParam"
                       type="s:string" />
            <s:element minOccurs="1" maxOccurs="1" name="intParam"
                       type="s:int" />
          </s:sequence>
        </s:complexType>
      </s:element>
      <s:element name="DoSomethingResponse">
        <s:complexType>
          <s:sequence>
            <s:element minOccurs="1" maxOccurs="1" name="DoSomethingResult"
                       type="s:int" />
          </s:sequence>
        </s:complexType>
      </s:element>
      </s:schema>
    </wsdl:types>
    ...other definitions...
  </definitions>
```

These types are all that are required for the SOAP and HTTP requests and responses you saw earlier, and are bound to these operations later in the file. All the types are specified using standard XML schema syntax, for example:

```
<s:element name="DoSomethingResponse">
  <s:complexType>
    <s:sequence>
      <s:element minOccurs="1" maxOccurs="1" name="DoSomethingResult"
                 type="s:int" />
    </s:sequence>
  </s:complexType>
</s:element>
```

This specifies that an element called `DoSomethingResponse` has a child element called `DoSomethingResult` that contains an integer. This integer must occur between 1 and 1 times, meaning that it must be included.

If you have access to the WSDL for a web service, you can use it. As you see shortly, this isn't that difficult to do.

After this brief look at SOAP and WSDL, it's time to move on to discuss how you create and consume web services.

WEB SERVICES

The information about web services in this chapter is divided into two subsections:

➤ "Exposing Web Services," which addresses writing web services and placing them on web servers.

➤ "Consuming Web Services," which covers using web services in a client application.

Exposing Web Services

Web services are exposed by placing code either directly into `.asmx` files or by referencing web service classes from these files. As with ASP.NET pages, creating a web service in Visual Studio .NET uses the latter method, and you will too for demonstration purposes.

Create a web service project (via File ➪ New ➪ Web Site . . .) in the `C:\ProCSharp\Chapter55` directory and call it `PCSWebService1` (see Figure 55-1). Creating a web service project generates a similar set of files as creating a web application project, and you have the same location options for creating the project. In fact, the only difference is that instead of a file called `Default.aspx`, a file called `Service.asmx` is created, with code-behind in `App_Code/Service.cs`.

FIGURE 55-1

The code in `Service.asmx` is as follows:

```
<%@ WebService Language="C#" CodeBehind="~/App_Code/Service.cs" Class="Service" %>
```

This references the code file `/App_Code/Service.cs`. The following listing shows the generated code:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Services;

[WebService(Namespace = "http://tempuri.org/")]
[WebServiceBinding(ConformsTo = WsiProfiles.BasicProfile1_1)]
// To allow this Web Service to be called from script, using ASP.NET AJAX,
// uncomment the following line.
// [System.Web.Script.Services.ScriptService]
public class Service : System.Web.Services.WebService
{
   public Service()
   {
      //Uncomment the following line if using designed components
      //InitializeComponent();
   }

   [WebMethod]
   public string HelloWorld()
   {
      return "Hello World";
   }
}
```

code snippet PCSWebService1\App_Code\Service.cs

This code contains several standard namespace references, and defines the web service class `Service` (referenced in `Service.asmx`), which inherits from `System.Web.Services.WebService`. The `WebService` attribute specifies the namespace for the web service, which enables client applications to differentiate between web service methods with the same name, but on different web services. The `WebServiceBinding` attribute relates to web service interoperability, as defined in the WS-I Basic Profile 1.1 specification. Put simply, this attribute can declare that a web service supports a standard WSDL description for one or more of its web methods, or, as is the case here, defines a new set of WSDL definitions. There is also a commented out `ScriptService` attribute, which if uncommented makes it possible to call web methods using ASP.NET AJAX script. It is now up to you to provide additional methods on this web service class.

Adding a method accessible through the web service simply requires defining the method as `public` and giving it the `WebMethod` attribute. This attribute simply labels the methods you want to be accessible through the web service. You look at the types you can use for the return type and parameters shortly, but for now replace the autogenerated `HelloWorld()` method with the following one:

```
   [WebMethod]
   public string CanWeFixIt()
   {
      return "Yes we can!";
   }
```

Now compile the project.

To see whether everything works, run the application with Ctrl+F5 and you'll be taken straight to the test interface for the web service, as shown in Figure 55-2.

Service

The following operations are supported. For a formal definition, please review the Service Description.

- CanWeFixIt

This web service is using http://tempuri.org/ as its default namespace.

Recommendation: Change the default namespace before the XML Web service is made public.

Each XML Web service needs a unique namespace in order for client applications to distinguish it from other services on the Web. http://tempuri.org/ is available for XML Web services that are under development, but published XML Web services should use a more permanent namespace.

Your XML Web service should be identified by a namespace that you control. For example, you can use your company's Internet domain name as part of the namespace. Although many XML Web service namespaces look like URLs, they need not point to actual resources on the Web. (XML Web service namespaces are URIs.)

For XML Web services creating using ASP.NET, the default namespace can be changed using the WebService attribute's Namespace property. The WebService attribute is an attribute applied to the class that contains the XML Web service methods. Below is a code example that sets the namespace to "http://microsoft.com/webservices/":

C#

```
[WebService(Namespace="http://microsoft.com/webservices/")]
public class MyWebService {
    // implementation
}
```

Visual Basic

```
<WebService(Namespace:="http://microsoft.com/webservices/")> Public Class MyWebService
    ' implementation
End Class
```

C++

```
[WebService(Namespace="http://microsoft.com/webservices/")]
public ref class MyWebService {
    // implementation
};
```

For more details on XML namespaces, see the W3C recommendation on Namespaces in XML.

For more details on WSDL, see the WSDL Specification.

For more details on URIs, see RFC 2396.

FIGURE 55-2

Note that, by default, this test page is only available to callers from the local computer, even when your web service is hosted in Internet Information Services (IIS).

Most of the text shown in the browser concerns the fact that the web service namespace is set to `http://tempuri.org`. This isn't a problem during development, although (as the text on the web page says) it should be changed later on. This can be done using the `WebService` attribute as shown. For now, though, you can leave things as they are.

Clicking the method name gives you information about the SOAP request and response, as well as examples of how the request and response will look using the HTTP GET and HTTP POST methods. You can also test the method by clicking the Invoke button. If the method requires simple parameters, you can enter these on this form as well (for more complex parameters, this form won't allow you to test the method in this way). If you do this you will see XML returned by the method call:

```
<?xml version="1.0" encoding="utf-8"?>
<string xmlns="http://tempuri.org/">Yes we can!</string>
```

This demonstrates that your method is working perfectly.

Following the Service Description link, from the browser screen shown in Figure 55-2, allows you to view the WSDL description of the web service. The most important part is the description of the element types for requests and responses:

```
<wsdl:types>
  <s:schema elementFormDefault="qualified" targetNamespace="http://tempuri.org/">
    <s:element name="CanWeFixIt">
      <s:complexType />
    </s:element>
    <s:element name="CanWeFixItResponse">
      <s:complexType>
        <s:sequence>
          <s:element minOccurs="0" maxOccurs="1" name="CanWeFixItResult"
                     type="s:string" />
        </s:sequence>
      </s:complexType>
    </s:element>
  </s:schema>
</wsdl:types>
```

The description also contains descriptions of the types required for requests and responses, as well as various bindings for the service, making it quite a long file.

Types Available for Web Services

Web services can be used to exchange any of the following types:

`String`	`Double`
`Char`	`Guid`
`Byte`	`Decimal`
`Boolean`	`DateTime`
`Int16`	`XmlQualifiedName`
`Int32`	`class`
`Int64`	`struct`
`UInt16`	`XmlNode`
`UInt32`	`DataSet`
`UInt64`	`enum`
`Single`	

Arrays of all these types are also allowed, as are generic collection types such as `List<string>`. Note also that only public properties and fields of `class` and `struct` types are marshalled.

Consuming Web Services

Now that you know how to create web services, in this section you look at how to use them. To do this, you need to generate a proxy class in your code that knows how to communicate with a given web service. Any calls from your code to the web service will go through this proxy, which looks identical to the web service, giving your code the illusion that you have a local copy of it. In actual fact there is a lot of HTTP communication going on, but you are shielded from the details. There are two ways of doing this. You can either use the `WSDL.exe` command-line tool or the Add Web Reference menu option in Visual Studio .NET.

Using `WSDL.exe` from the command-line generates a `.cs` file containing a proxy class, based on the WSDL description of the web service. You specify this using the URL of the web service, for example:

```
WSDL http://localhost:53679/PCSWebService1/Service.asmx?WSDL
```

This generates a proxy class for the example from the previous section in a file called `Service.cs`. The class will be named after the web service, in this case `Service`, and contain methods that call identically named methods of the service. To use this class, you simply add the `.cs` file generated to a project and use code along the lines of this:

```
Service myService = new Service();
string result = myService.CanWeFixIt();
```

By default, the class generated is placed in the root namespace, so no `using` statement is necessary, but you can specify a different namespace to use with the `/n:<namespace>` command-line option of `WSDL.exe`.

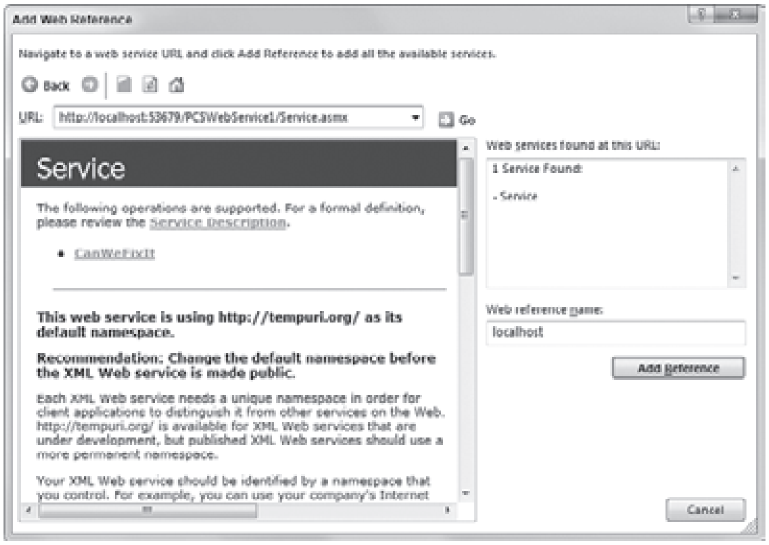
This technique works fine but can be annoying to continually redo if the service is being developed and changing continuously. Of course, it could be executed in the build options for a project to automatically update the generated proxy before each compile, but there is a better way.

This better way is illustrated by creating a client for the example in the previous section, in a new empty web site called `PCSWebClient1` (in the `C:\ProCSharp\Chapter55` directory). Create this project now, add a `Default.aspx` page, and add the following code to `Default.aspx`:

```
<form id="form1" runat="server">
  <div>
    <asp:Label Runat="server" ID="resultLabel" />
    <br />
    <asp:Button Runat="server" ID="triggerButton" Text="Invoke CanWeFixIt()" />
  </div>
</form>
```

code snippet PCSWebClient1\Default.aspx

You'll bind the button-click event handler to the web service shortly. First, you must add a reference to the web service to your project. To do this, right-click the new client project in the Solution Explorer and select the Add Web Reference... option. In the window that appears, type the URL of the web service `Service.asmx` file, or use the web services on the Local Machine link to find it automatically, as shown in Figure 55-3.



Navigate to a web service URL and click Add Reference to add all the available services.

URL: http://localhost:53679/PCSWebService1/Service.asmx

Service

The following operations are supported. For a formal definition, please review the Service Description.

- CanWeFixIt

This web service is using http://tempuri.org/ as its default namespace.

Recommendation: Change the default namespace before the XML Web service is made public.

Each XML Web service needs a unique namespace in order for client applications to distinguish it from other services on the Web. http://tempuri.org/ is available for XML Web services that are under development, but published XML Web services should use a more permanent namespace.

Your XML Web service should be identified by a namespace that you control. For example, you can use your company's Internet

Web services found at this URL:

1 Service Found:

- Service

Web reference name: localhost

FIGURE 55-3

From here you can add a reference with the Add Reference button. First, though, change the default entry for the web reference name from `localhost` to `myWebService`. Pressing the Add Reference button now adds `myWebService` to the `App_WebReferences` folder of the project in Solution Explorer. If you examine this folder in the Solution Explorer window, you can see that the files `Service.disco`, `Service.discomap`, and `Service.wsdl` have been added to the project.

The web reference name, `myWebService`, is also the namespace you need to reference to use the proxy class that has been created for you. Add the following `using` statement to your code in `Default.aspx.cs`:

```
using myWebService;
```

Now you can use the service in your class without fully qualifying its name.

Add an event handler to the button on the form by double-clicking the button in design view, and adding the following code:

```
protected void triggerButton_Click(object sender, EventArgs e)
{
   Service myService = new Service();
   resultLabel.Text = myService.CanWeFixIt();
}
```

Running the application and clicking the button displays the result of `CanWeFixIt()` in the browser window.

This web service might change later, but with this method you can simply right-click the `App_WebReference` folder in the Server Explorer and select Update Web/Service References. This generates a new proxy class for you to use.

Also, the web service may move later, perhaps when it is deployed. If you look in `web.config` for the client application you will see the following:

```
      <appSettings>
       <add key="myWebService.Service"
    value="http://localhost:53679/PCSWebService1/Service.asmx"/>
      </appSettings>
```

code snippet PCSWebClient1\web.config

This setting configures where web requests will be sent, so you must ensure that it matches the web service location, or use some other means to record this information if you prefer.

EXTENDING THE EVENT-BOOKING EXAMPLE

Now that you know the basics of creating and consuming web services, you can apply your knowledge to extending the meeting room booker application from Chapters 40, "Core ASP.NET" and 41, "ASP.NET Features." Specifically, you extract the database access aspects from the application and place them into a web service. This web service has two methods:

- ➤ `GetData()`, which returns a `DataSet` object containing all three tables in the `PCSDemoSite` database.
- ➤ `AddEvent()`, which adds an event and returns the number of rows affected so the client application can check that a change has been made.

In addition, you'll design the web service with load reduction in mind. Specifically, you'll store a `DataSet` containing the meeting room booker data at the application level in the web service application. This means that multiple requests for the data won't require additional database requests. The data in this application-level `DataSet` object will only be refreshed when new data is added to the database. This means that changes made to the database by other means, such as manual editing, will *not* be reflected in the `DataSet`. Still, as long as you know that your web service is the only application with direct access to the data, you have nothing to worry about.

The Event-Booking Web Service

Create a new web service project in Visual Studio in the `C:\ProCSharp\Chapter55` directory and call it `PCSWebService2`. The first thing to do is to copy the database file (`MeetingRoomBooker.mdf`) from `PCSDemoSite` in the code for Chapter 41 into the `App_Data` directory for the web service. Next, you need to add a `Global.asax` file to the project, then modify the code in its `Application_Start()` event handler. You want to load all the data in the `MeetingRoomBooker` database into a data set and store it. This mostly involves code that you've already seen, because getting the database into a `DataSet` is something you've already done. You'll also use a connection string stored in `web.config` as you've seen in earlier chapters. The code for the `web.config` is as follows (the connection string should be placed on a single line):

```
<?xml version="1.0" ?>
<configuration>
  ...
  <connectionStrings>
    <add name="MRBConnectionString"
      connectionString="Data Source=.\SQLExpress;Integrated
        Security=True;AttachDBFilename=|DataDirectory|MeetingRoomBooker.mdf;
        User Instance=True"
      providerName="System.Data.SqlClient"/>
  </connectionStrings>
</configuration>
```

code snippet PCSWebService2\web.config

And the code for the `Application_Start()` event handler in `Global.asax` is:

```
void Application_Start(Object sender, EventArgs e)
{
   System.Data.DataSet ds;
   System.Data.SqlClient.SqlConnection sqlConnection1;
   System.Data.SqlClient.SqlDataAdapter daAttendees;
   System.Data.SqlClient.SqlDataAdapter daRooms;
   System.Data.SqlClient.SqlDataAdapter daEvents;

    using (sqlConnection1 = new System.Data.SqlClient.SqlConnection())
   {
      sqlConnection1.ConnectionString =
         ConfigurationManager.ConnectionStrings["MRBConnectionString"]
            .ConnectionString;

      sqlConnection1.Open();

      ds = new System.Data.DataSet();
      daAttendees = new System.Data.SqlClient.SqlDataAdapter(
                       "SELECT * FROM Attendees", sqlConnection1);
      daRooms = new System.Data.SqlClient.SqlDataAdapter(
                       "SELECT * FROM Rooms", sqlConnection1);
      daEvents = new System.Data.SqlClient.SqlDataAdapter(
                       "SELECT * FROM Events", sqlConnection1);

      daAttendees.Fill(ds, "Attendees");
      daRooms.Fill(ds, "Rooms");
      daEvents.Fill(ds, "Events");
   }

   Application["ds"] = ds;
}
```

code snippet PCSWebService2\Global.asax

The important code to note here is in the last line. `Application` objects (just like `Session` objects) have a collection of name-value pairs that you can use to store data. Here you are creating a name in the `Application` store called `ds`, which takes the serialized value of `ds` containing the `Attendees`, `Rooms`, and `Events` tables from your database. This value will be accessible to all instances of the web service at any time.

This technique is very useful for read-only data because multiple threads are able to access it, reducing the load on your database. Note, however, that the `Events` table is likely to change, and you'll have to update the application-level `DataSet` class when this happens. You look at this shortly.

Next you can replace the default `Service` service with a new service, called `MRBService`. To do this, delete the existing `Service.asmx` and `Service.cs` files and add a new web service to the project called `MRBService` (make sure you check the option to place code in a separate file). You can then add the `GetData()` method to your service in `MRBService.cs`:

```
[WebMethod]
public DataSet GetData()
{
   return (DataSet)Application["ds"];
}
```

code snippet PCSWebService2\App_Code\MRBService.cs

This uses the same syntax as `Application_Load()` to access the stored `DataSet`, which you simply cast to the correct type and return.

Note that for this to work, and to make life easier in the other web method you'll be adding, you can add the following `using` statements:

```
using System;
using System.Collections.Generic;
using System.Configuration;
using System.Data;
using System.Linq;
using System.Web;
using System.Web.Services;
```

The `AddEvent()` method is slightly more complicated. Conceptually, you need to do the following:

1. Accept event data from the client
2. Create a SQL `INSERT` command using this data
3. Connect to the database and execute the SQL statement
4. Refresh the data in `Application["ds"]` if the addition is successful
5. Return a success or failure notification to the client (the client will refresh its `DataSet` if required)

Starting from the top, you'll accept all fields in their correct data types:

```
[WebMethod]
public int AddEvent(string eventName, int eventRoom,
                    string eventAttendees, DateTime eventDate)
{
   ...
}
```

Next, you declare the objects you'll need for database access, connect to the database, and execute your query, all using similar code to that in `PCSDemoSite` (remember, you need the connection string here, taken from `web.config`):

```
[WebMethod]
public int AddEvent(string eventName, int eventRoom,
                    string eventAttendees, DateTime eventDate)
{
   System.Data.SqlClient.SqlConnection sqlConnection1;
   System.Data.SqlClient.SqlDataAdapter daEvents;
   DataSet ds;

   using (sqlConnection1 = new System.Data.SqlClient.SqlConnection())
   {
      sqlConnection1.ConnectionString =
         ConfigurationManager.ConnectionStrings["MRBConnectionString"]
            .ConnectionString;

      System.Data.SqlClient.SqlCommand insertCommand =
         new System.Data.SqlClient.SqlCommand(
            "INSERT INTO [Events] (Name, Room, "
            + "AttendeeList, EventDate) VALUES  (@Name, @Room, @AttendeeList, "
            + "@EventDate)", sqlConnection1);
      insertCommand.Parameters.Add("Name", SqlDbType.VarChar, 255).Value
         = eventName;
      insertCommand.Parameters.Add("Room", SqlDbType.Int, 4).Value
         = eventRoom;
      insertCommand.Parameters.Add("AttendeeList", SqlDbType.Text, 16).Value
         = eventAttendees;
      insertCommand.Parameters.Add("EventDate", SqlDbType.DateTime, 8).Value
         = eventDate;

      sqlConnection1.Open();
```

```
            int queryResult = insertCommand.ExecuteNonQuery();
         }
      }
```

You use queryResult to store the number of rows affected by the query as before. You can check this to see whether it is 1 to gauge your success. If you are successful, you execute a new query on the database to refresh the Events table in your DataSet. It is vital to lock the application data while you perform updates to ensure that no other threads can access Application["ds"] while you update it. You can do this using the Lock() and UnLock() methods of the Application object:

```
      [WebMethod]
      public int AddEvent(string eventName, int eventRoom,
                          string eventAttendees, DateTime eventDate)
      {
            ...
            int queryResult = insertCommand.ExecuteNonQuery();
            if (queryResult == 1)
            {
               daEvents = new System.Data.SqlClient.SqlDataAdapter(
                              "SELECT * FROM Events", sqlConnection1);
               ds = (DataSet)Application["ds"];
               ds.Tables["Events"].Clear();
               daEvents.Fill(ds, "Events");
               Application.Lock();
               Application["ds"] = ds;
               Application.UnLock();
            }
         }
      }
```

Finally, you return queryResult, allowing the client to know whether the query was successful:

```
      [WebMethod]
      public int AddEvent(string eventName, int eventRoom,
                          string eventAttendees, DateTime eventDate)
      {
         ...
         return queryResult;
      }
```

And with that, you have completed your web service. As before, you can test this service simply by viewing the .asmx file in a web browser, so you can add records and look at the XML representation of the DataSet returned by GetData() without writing any client code.

Before moving on, it's worth discussing the use of DataSet objects with web services. At first glance this seems like a fantastic way of exchanging data, and indeed it is an extremely powerful technique. However, the fact that the DataSet class is so versatile does have implications. If you examine the WSDL generated for the GetData() method, you'll see the following:

```
         <s:element name="GetDataResponse">
           <s:complexType>
             <s:sequence>
               <s:element minOccurs="0" maxOccurs="1" name="GetDataResult">
                 <s:complexType>
                   <s:sequence>
                     <s:element ref="s:schema" />
                     <s:any />
                   </s:sequence>
                 </s:complexType>
               </s:element>
             </s:sequence>
           </s:complexType>
         </s:element>
```

As you can see, this is very generic code, which allows the `DataSet` object passed to contain any data specified with an inline schema. Unfortunately, this means that the WSDL does not completely describe the web service. For .NET clients this isn't a problem, and things progress as naturally as they did when passing a simple string in the earlier example, the only difference being that you exchange a `DataSet` object. However, non-.NET clients must have prior knowledge of the data that will be passed or some equivalent of a `DataSet` class to access the data. This includes script clients, such as those that use client-side ASP.NET AJAX code to process retrieved data.

A workaround to this requirement is to repackage the data into a different format — an array of structs, for example. If you were to do this, you could customize the XML produced in any way you want, and the XML could be completely described by the schema for the web service. This can also have an impact in terms of performance, because passing a `DataSet` object can result in an awful lot of XML — far more than is necessary in most cases. The overhead resulting from repackaging data is likely to be much less than that associated with sending the data over the web, and because there'll probably be less data, the serialization and deserialization is also likely to be quicker. Therefore, if performance is an issue, you probably should avoid using `DataSet` objects in this way — unless of course you make use of the additional functionality that `DataSet` objects make available to you.

For the purposes of this example, though, using a `DataSet` object is not a problem and greatly simplifies other code.

The Event-Booking Client

The client you use in this section is a development of the `PCSDemoSite` web site from Chapter 41. Call this application `PCSDemoSite2`, in the directory `C:\ProCSharp\Chapter55`, and use the code from `PCSDemoSite` as a starting point.

You'll make two major modifications to the project. First, you'll remove all direct database access from this application and use the web service instead. Second, you'll introduce an application-level store of the `DataSet` object returned from the web service that is updated only when necessary, meaning that even less of a load is placed on the database.

The first thing to do to your new web application is to add a web reference to the `PCSWebService2/MRBService.asmx` service. You can do this in the same way you saw earlier in this chapter through right-clicking the project in Server Explorer, locating the `.asmx` file, calling the web reference `MRBService`, and clicking Add Reference. You may need to start the ASP.NET Development Server before you can do this, which you can do by viewing the `.asmx` file of the web service in a browser. Because you aren't using the local database anymore, you can also delete that from the `App_Data` directory, and remove the `MRBConnectionString` entry from `web.config`. All the rest of the modifications are made to `MRB.ascx` and `MRB.ascx.cs`.

To start with, you can delete all the data sources on `MRB.ascx`, and remove the `DataSourceID` entries on all the currently data-bound controls. This is because you'll be handling the data binding yourself from the code-behind file.

Next, you'll need to add a property to `MRB.ascx.cs` to store the `DataSet` returned by the web service. This property actually uses Application state storage, in much the same way as `Global.asax` in the web service. The code is:

```
public DataSet MRBData
{
   get
   {
      if (Application["mrbData"] == null)
      {
         Application.Lock();
         MRBService.MRBService service = new MRBService.MRBService();
         service.Credentials = System.Net.CredentialCache.DefaultCredentials;
         Application["mrbData"] = service.GetData();
         Application.UnLock();
      }
      return Application["mrbData"] as DataSet;
   }
   set
   {
      Application.Lock();
      if (value == null && Application["mrbData"] != null)
      {
         Application.Remove("mrbData");
      }
      else
      {
         Application["mrbData"] = value;
      }
      Application.UnLock();
   }
}
```

code snippet PCSDemoSite2\MRB\MRB.ascx.cs

Note that you need to lock and unlock the Application state, just as in the web service. Also, note that the `Application["mrbData"]` storage is filled only when necessary, that is, when it is empty. This `DataSet` object is now available to all instances of `PCSDemoSite2`, meaning that multiple users can read data without any calls to the web service or indeed to the database. The credentials are also set here, which as noted earlier, is necessary for using web services hosted using the ASP.NET Development Server. You can comment out this line if you don't need it.

To bind to the controls on the web page, you can supply `DataView` properties that map to data stored in this property, as follows:

```
private DataView EventData
{
   get
   {
      return MRBData.Tables["Events"].DefaultView;
   }
}

private DataView RoomData
{
   get
   {
      return MRBData.Tables["Rooms"].DefaultView;
   }
}
```

```
private DataView AttendeeData
{
   get
   {
      return MRBData.Tables["Attendees"].DefaultView;
   }
}

private DataView EventDetailData
{
   get
   {
      if (EventList != null && EventList.SelectedValue != null)
      {
         return new DataView(MRBData.Tables["Events"], "ID=" +
           EventList.SelectedValue.ToString(), "",
           DataViewRowState.CurrentRows);
      }
      else
      {
         return null;
      }
   }
}
```

You can also remove the existing `EventData` field and `EventData` property.

Most of these properties are simple; it's only the last that does anything new. In this case, you are filtering the data in the `Events` table to obtain just one event — ready to display in the detail view `FormView` control.

Now that you aren't using data source controls, you have to bind data yourself. A call to the `DataBind()` method of the page will achieve this, but you also need to set the data source `DataView` properties for the various data-bound controls on the page. One good way to do this is to do it during an override of the `OnDataBinding()` event handler, as follows:

```
protected override void OnDataBinding(EventArgs e)
{
   roomList.DataSource = RoomData;
   attendeeList.DataSource = AttendeeData;
   EventList.DataSource = EventData;
   FormView1.DataSource = EventDetailData;
   base.OnDataBinding(e);
}
```

Here you are setting the `DataSource` properties of `roomList`, `attendeeList`, `EventList`, and `FormView1` to the properties defined earlier. Next, you can add the `DataBind()` call to `Page_Load()`:

```
void Page_Load(object sender, EventArgs e)
{
   if (!this.IsPostBack)
   {
      nameBox.Text = Context.User.Identity.Name;
      DateTime trialDate = DateTime.Now;
      calendar.SelectedDate = GetFreeDate(trialDate);
      DataBind();
   }
}
```

Also, you must change `submitButton_Click()` to use the web service `AddData()` method. Again, much of the code can remain unchanged; only the data addition code needs changing:

```
void submitButton_Click(object sender, EventArgs e)
{
   if (Page.IsValid)
   {
      ...
```

```
            try
            {
               MRBService.MRBService service = new MRBService.MRBService();
               if (service.AddEvent(eventBox.Text, int.Parse(roomList.SelectedValue),
                   attendees, calendar.SelectedDate) == 1)
               {
                  MRBData = null;
                  DataBind();
                  calendar.SelectedDate =
                    GetFreeDate(calendar.SelectedDate.AddDays(1));
               }
            }
            catch
            {
            }
         }
      }
```

In fact, all you've really done here is simplify things a great deal. This is often the case when using well-designed web services — you can forget about much of the inner workings and instead concentrate on the user experience.

There isn't a huge amount to comment on in this code. Continuing to make use of `queryResult` is a bonus, and locking the application is essential as already noted.

Two final modifications are required. First is `EventList_SelectedIndexChanged()`:

```
protected void EventList_SelectedIndexChanged(object sender, EventArgs e)
{
   FormView1.DataSource = EventDetailData;
   EventList.DataSource = EventData;
   EventList.DataBind();
   FormView1.DataBind();
}
```

This is simply to make sure that the data sources for the event list and detail views are refreshed properly.

You also need to add an `EventList_SelectedIndexChanging()` hander, which must be attached to the `SelectedIndexChanging` event of the `EventList` control:

```
protected void EventList_SelectedIndexChanging(object sender,
   ListViewSelectEventArgs e)
{
   EventList.SelectedIndex = e.NewSelectedIndex;
}
```

Without adding this, the code will fail as the changes you have made require a handler for this event.

The meeting room booker in the `PCSDemoSite2` web site should look and function exactly as the one in `PCSDemoSite`, but perform substantially better. You can also use the same web service very easily for other applications — simply displaying events on a page, for example, or even editing events, attendee names, and rooms if you add some more methods. Doing this won't break `PCSDemoSite2` because it simply ignores any new methods created. You will, however, have to introduce some kind of trigger mechanism to update the data cached in the event list, because modifying this data elsewhere will cause data to become out of date.

EXCHANGING DATA USING SOAP HEADERS

One final topic to look at in this chapter is using SOAP headers to exchange information, rather than including information in method parameters. The reason for covering this is that it is a very nice system to use for maintaining a user login. This section won't go into detail about setting up your server for SSL connections, or the various methods of authentication that can be configured using IIS, because these do not affect the web service code you need to get this behavior.

Say that you have a service that contains a simple authentication method with a signature as follows:

```
AuthenticationToken AuthenticateUser(string userName, string password);
```

where `AuthenticationToken` is a type you define that can be used by the user in later method calls, for example:

```
void DoSomething(AuthenticationToken token, OtherParamType param);
```

After logging in, the user has access to other methods using the token received from `AuthenticateUser()`. This technique is typical of secure web systems, although it is often implemented in a far more complex way.

You can simplify this process further by using a SOAP header to exchange tokens (or any other data). You can restrict methods so they are only called if a specified SOAP header is included in the method call. This simplifies their structure as follows:

```
void DoSomething(OtherParamType param);
```

The advantage here is that, after you have set the header on the client, it persists. After an initial bit of setting up, you can ignore authentication tokens in all further web method calls.

To see this in action, create a new web service project called `PCSWebService3` in the directory `C:\ProCSharp\Chapter55\`, and add a new class to the `App_Code` directory called `AuthenticationToken`, as follows:

```
using System;
using System.Web.Services.Protocols;

public class AuthenticationToken : SoapHeader
{
   public Guid InnerToken;
}
```

code snippet PCSWebService3\App_Code\AuthenticationToken.cs

You'll use a GUID to identify the token, a common procedure, because you can be sure that it is unique.

To declare that the web service can have a custom SOAP header, simply add a public member to the service class of your new type:

```
public class Service : System.Web.Services.WebService
{
   public AuthenticationToken AuthenticationTokenHeader;
```

code snippet PCSWebService3\App_Code\Service.cs

You will also need to use the `System.Web.Services.Protocols.SoapHeaderAttribute` attribute to mark those web methods that require the extra SOAP header to work. However, before you add such a method, you can add a very simple `Login()` method that clients can use to obtain an authentication token:

```
   [WebMethod(true)]
   public Guid Login(string userName, string password)
   {
      if ((userName == "Karli") && (password == "Cheese"))
      {
         Guid currentUser = Guid.NewGuid();
         Session["currentUser"] = currentUser;
         return currentUser;
      }
      else
      {
         Session["currentUser"] = null;
         return Guid.Empty;
      }
   }
```

If the correct username and password are used, then a new Guid object is generated, stored in a session-level variable, and returned to the user. If authentication fails, an empty Guid instance is returned and stored at the session level. The true parameter enables session state for this web method, because it is disabled by default in web services and it is required for this functionality.

Next, you have a method that accepts the header, as specified by the SoapHeaderAttribute attribute:

```
[WebMethod(true)]
[SoapHeaderAttribute("AuthenticationTokenHeader",
                     Direction = SoapHeaderDirection.In)]
public string DoSomething()
{
   if (Session["currentUser"] != null &&
       AuthenticationTokenHeader != null &&
       AuthenticationTokenHeader.InnerToken
       == (Guid)Session["currentUser"])
   {
      return "Authentication OK.";
   }
   else
   {
      return "Authentication failed.";
   }
}
```

This returns one of two strings, depending on whether the AuthenticationTokenHeader header exists, isn't an empty Guid, and matches the one stored in Session["currentUser"] (if this Session variable exists).

Next, you must create a quick client to test this service. Add a new empty web site called PCSWebClient2 to the solution, with a Default.aspx page containing the following simple code for the user interface:

```
<form id="form1" runat="server">
  <div>
    User Name:
    <asp:TextBox Runat="server" ID="userNameBox" /><br />
    Password:
    <asp:TextBox Runat="server" ID="passwordBox" /><br />
    <asp:Button Runat="server" ID="loginButton" Text="Log in" /><br />
    <asp:Label Runat="server" ID="tokenLabel" /><br />
    <asp:Button Runat="server" ID="invokeButton"
      Text="Invoke DoSomething()" /><br />
    <asp:Label Runat="server" ID="resultLabel" /><br />
  </div>
</form>
```

code snippet PCSWebClient2\Default.aspx

Add the PCSWebService3 service as a web reference (because the web service is local to the solution you can click the Web Services in This Solution link to get a reference quickly) with the name authenticateService, and add the following using statements to Default.aspx.cs:

```
using System.Net;
using authenticateService;
```

code snippet PCSWebClient2\Default.aspx.cs

You need to use the System.Net namespace because it includes the CookieContainer class. This is used to store a reference to a cookie, and you require this if you are working with web services that use session state. This is because you need some way for the web service to retrieve the correct session state across multiple calls from the client, where the proxy for the service is re-created on each postback. By retrieving the cookie used by the web service to store session state, storing it between web service calls, and then using it in later calls, you can maintain the correct session state in the web service. Without doing this, the web service would lose its session state, and therefore the login information required in this scenario.

Back to the code, where you use a protected member to store the web reference proxy, and another to store a Boolean value indicating whether the user is authenticated or not:

```
public partial class _Default : System.Web.UI.Page
{
   protected Service myService;
   protected bool authenticated;
```

`Page_Load()` starts by initializing the `myService` service, as well as preparing a `CookieContainer` instance for use with the service:

```
   protected void Page_Load(object sender, EventArgs e)
   {
      myService = new Service();
      myService.Credentials = CredentialCache.DefaultCredentials;
      CookieContainer serviceCookie;
```

Next, you check for a stored `CookieContainer` instance or create a new one. Either way you assign the `CookieContainer` to the web service proxy, ready to receive the cookie information from the web service after a call is made. The storage used here is the `ViewState` collection of the form (a useful way to persist information between postbacks, which works in a similar way to storing information at the application or session level):

```
      if (ViewState["serviceCookie"] == null)
      {
         serviceCookie = new CookieContainer();
      }
      else
      {
         serviceCookie = (CookieContainer)ViewState["serviceCookie"];
      }
      myService.CookieContainer = serviceCookie;
```

`Page_Load()` then looks to see if there is a stored header and assigns the header to the proxy accordingly (assigning the header in this way is the only step you must take for the data to be sent as a SOAP header). This way any event handlers that are being called (such as the one for the web method–invoking button) don't have to assign a header — that step has already been taken:

```
      AuthenticationToken header = new AuthenticationToken();
      if (ViewState["AuthenticationTokenHeader"] != null)
      {
         header.InnerToken = (Guid)ViewState["AuthenticationTokenHeader"];
      }
      else
      {
         header.InnerToken = Guid.Empty;
      }
      myService.AuthenticationTokenValue = header;
   }
```

Next, you add an event handler for the Login button by double-clicking it in the Designer:

```
   protected void loginButton_Click(object sender, EventArgs e)
   {
      Guid authenticationTokenHeader = myService.Login(userNameBox.Text,
                                                       passwordBox.Text);
      tokenLabel.Text = authenticationTokenHeader.ToString();
      if (ViewState["AuthenticationTokenHeader"] != null)
      {
         ViewState.Remove("AuthenticationTokenHeader");
      }
```

```
        ViewState.Add("AuthenticationTokenHeader", authenticationTokenHeader);
        if (ViewState["serviceCookie"] != null)
        {
           ViewState.Remove("serviceCookie");
        }
        ViewState.Add("serviceCookie", myService.CookieContainer);
    }
```

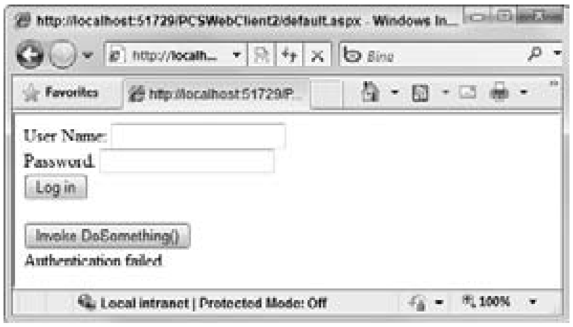
This handler uses any data entered in the two text boxes to call `Login()`, displays the `Guid` returned, and stores the `Guid` in the `ViewState` collection. It also updates the `CookieContainer` stored in the `ViewState` collection, ready for reuse.

Finally, you have to add a handler in the same way for the Invoke DoSomething() button:

```
    protected void invokeButton_Click(object sender, EventArgs e)
    {
        resultLabel.Text = myService.DoSomething();
        if (ViewState["serviceCookie"] != null)
        {
           ViewState.Remove("serviceCookie");
        }
        ViewState.Add("serviceCookie", myService.CookieContainer);
    }
```

This handler simply outputs the text returned by `DoSomething()` and updates the `CookieContainer` storage just like `loginButton_Click()`.

When you run this application, you can click the Invoke DoSomething() button straight away, because `Page_Load()` has assigned a header for you to use (if no header is assigned, an exception will be thrown because you have specified that the header is required for this method). This results in a failure message, returned from `DoSomething()`, as shown in Figure 55-4.



http://localhost:51729/PCSWebClient2/default.aspx - Windows In...
Favorites

FIGURE 55-5

You can also see a string representation of the `Guid` used for validation.

Of course, applications that use this technique of exchanging data via SOAP headers are likely to be far more complicated. You may decide to store login tokens in a more scalable way than just using session storage, perhaps in a database. For completeness you can also implement your own expiration scheme for these tokens when a certain amount of time has passed and provide the option for users to log out, which would simply mean removing the token. Session state expires after a certain amount of time (20 minutes by default), but more complicated and powerful schemes are possible. You could even validate the token against the IP address used by the user for further security. The key points here though are that the username and password of the user are only sent once, and that using a SOAP header simplifies later method calls.

SUMMARY

In this chapter, you have seen how to create and consume web services using C# and the Visual Studio .NET development platform. Doing this is perhaps surprisingly simple, but is instantly recognizable as something that could prove to be incredibly useful.

It has also been pointed out that web services may be accessed from any platform. This is the result of using the SOAP protocol, which doesn't limit you to .NET.

The main example developed in this chapter illustrates how you can create .NET-distributed applications with ease. I have assumed here that you are using a single server to test things, but there is no reason why the web service shouldn't be completely separate from the client. It may even be on a separate server from the database if an additional data tier is required.

The use of data caching throughout is another important technique to master for use in large-scale applications, which might have thousands of users connecting simultaneously.

Exchanging data via SOAP headers, introduced in the last example, is another useful technique that can be worked into your applications. The example uses the exchange of a login token, but there is no reason why more complex data shouldn't be exchanged in this way. Perhaps this could be used for simple password protection of web services, without having to resort to imposing more complex security.

Remember that web service consumers don't necessarily have to be web applications. There is no reason why you can't use web services from Windows Forms or WPF applications — which certainly seems to be an attractive option for a corporate intranet. One added bonus concerning web services in ASP.NET is the ability to call web services asynchronously, using a simple, event-driven system. This fits in perfectly with Windows Forms applications, and means that you can keep your applications responsive while complicated web services carry out hard work for you.

As a final note, it is worth mentioning that web services can be seen as a stripped down subset of the more recent WCF technology, covered in Chapter 43, "Windows Communication Foundation." This doesn't mean, though, that you should always use WCF services rather than web services — web services are much simpler to implement and the simplicity is a great thing.

56

LINQ to SQL

WHAT'S IN THIS CHAPTER?

- Working with LINQ to SQL using Visual Studio 2010
- Mapping LINQ to SQL objects to database entities
- Building LINQ to SQL operations without the O/R Designer
- Using the O/R Designer with custom objects
- Querying the SQL Server database using LINQ
- Stored procedures and LINQ to SQL

You will probably find the .NET Language Integrated Query Framework (LINQ) in C# 2010 to be one of the more exciting features the language has to offer. Basically, what LINQ provides is a lightweight façade over programmatic data integration. This is such a big deal because *data is king*.

Pretty much every application deals with data in some manner, whether that data comes from memory (in-memory data), databases, XML files, text files, or something else. Many developers find it very difficult to move from the strongly typed object-oriented world of C# to the data tier where objects are second-class citizens. The transition from one world to the next was a kludge at best and was full of error-prone actions.

In C#, programming with objects means a wonderful, strongly typed ability to work with code. You can navigate very easily through the namespaces, work with a debugger in the Visual Studio IDE, and more. However, when you have to access data, you will notice that things are dramatically different.

You end up in a world that is not strongly typed, where debugging is a pain or even non-existent, and you end up spending most of the time sending strings to the database as commands. As a developer, you also have to be aware of the underlying data and how it is structured or how all the data points relate.

LINQ provides a strongly typed interface to the underlying data stores. It provides the means for developers to stay within the coding environment that they are used to and access the underlying data as objects that work with the IDE, IntelliSense, and even debugging.

With LINQ, the queries that you create now become first-class citizens within the .NET Framework alongside everything else you are used to. When you work with queries for your data store, you quickly realize that they now work and behave as if they are types in the system. This means that you can now use any .NET-compliant language and query the underlying data store as you never have before.

Chapter 11, "Language Integrated Query," provides an introduction to LINQ.

Figure 56-1 shows LINQ's place in querying data.

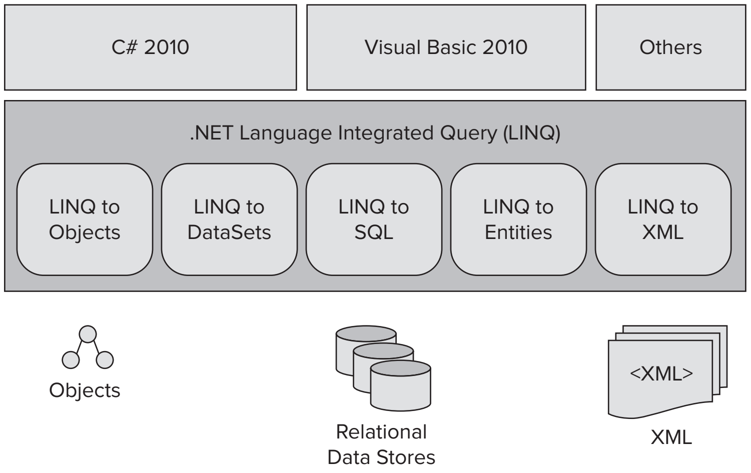

FIGURE 56-1

Looking at the figure, you can see that there are different types of LINQ capabilities, depending on the underlying data that you are going to work with in your application. From the list, you find the following LINQ technologies:

- LINQ to Objects
- LINQ to DataSets
- LINQ to SQL
- LINQ to Entities
- LINQ to XML

As a developer, you are given class libraries that provide objects that, using LINQ, can be queried as any other data store can. Objects are really nothing more than data that is stored in memory. In fact, your objects themselves might be querying data. This is where LINQ to Objects comes into play.

LINQ to SQL (the focus of this chapter), LINQ to Entities, and LINQ to DataSets provide the means to query relational data. Using LINQ, you can query directly against your database and even against the stored procedures that your database exposes. The last item from the diagram is the ability to query against your XML using LINQ to XML (this topic is covered in Chapter 33, "Manipulating XML"). The big thing that makes LINQ exciting is that it matters very little what you are querying against, because your queries will be quite similar.

LINQ TO SQL USING VISUAL STUDIO 2010

LINQ to SQL in particular is a means to have a strongly typed interface against a SQL Server database. You will find the approach that LINQ to SQL provides is by far the easiest approach to querying SQL Server available at the moment. It is not just about querying single tables within the database. For instance, if you call the `Customers` table of the Northwind database and want to pull a customer's specific orders from the `Orders` table in the same database, LINQ will use the relations of the tables and make the query on your behalf. LINQ will query the database and load up the data for you to work with from your code (again, strongly typed).

It is important to remember that LINQ to SQL is not only about querying data, but you are also able to perform the Insert/Update/Delete statements needed.

You can also interact with the entire process and customize the operations performed to add your own business logic to any of the CRUD operations (Create/Read/Update/Delete).

Visual Studio 2010 comes into strong play with LINQ to SQL in that you will find an extensive user interface that allows you to design the LINQ to SQL classes you will work with.

The next section focuses on how to set up your first LINQ to SQL instance and pull items from the `Products` table of the Northwind database.

Calling the Products Table

For an example of using LINQ to SQL, this section starts by calling a single table from the Northwind database and using it to populate results to the screen.

To start off, create a console application (using .NET Framework 4) and add the Northwind database file to this project (`Northwind.MDF`).

The following example makes use of the `Northwind.mdf` *SQL Server Express Database file. To get this database, search for "Northwind and pubs Sample Databases for SQL Server 2000." You can find this link at* `http://www.microsoft.com/downloads/details.aspx?FamilyID=06616212-0356-46A0-8DA2-EEBC53A68034&displaylang=en`. *When installed, you will find the* `Northwind.mdf` *file in the* `C:\SQL Server 2000 Sample Databases` *directory. To add this database to your application, right-click the solution you are working with and select Add Existing Item. From the provided dialog box, you are then able to browse to the location of the* `Northwind.mdf` *file that you just installed. If you are having trouble getting permissions to work with the database, make a data connection to the file from the Visual Studio Server Explorer and you will be asked to be made the appropriate user of the database. VS will make the appropriate changes on your behalf for this to occur.*

By default now, when creating many of the application types provided in .NET Framework 4 within Visual Studio 2010, you will notice that you already have the proper references in place to work with LINQ. When creating a console application, you will get the following `using` statements in your code:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Text;
```

From this, you can see that the LINQ reference required is already in place.

Adding a LINQ to SQL Class

The next step is to add a LINQ to SQL class. When working with LINQ to SQL, one of the big advantages you will find is that Visual Studio 2010 does an outstanding job of making it as easy as possible. Visual Studio provides an object-relational mapping designer, called the O/R Designer, which allows you to visually design the object to database mapping.

To start this task, right-click your solution and select Add New Item from the provided menu. From the items in the Add New Item dialog box, you will find LINQ to SQL Classes as an option. This is presented in Figure 56-2.

LINQ to SQL Classes
Type: Visual C# Items
LINQ to SQL classes mapped to relational objects.
Name: Northwind.dbml
Add
Cancel

FIGURE 56-2

Because this example is using the Northwind database, name the file `Northwind.dbml`. Click the Add button, and you will see that this operation creates a couple of files for you. Figure 56-3 presents the Solution Explorer after adding the `Northwind.dbml` file.

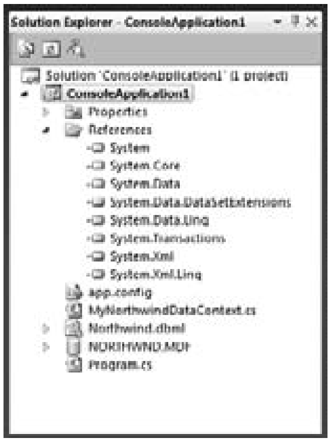

FIGURE 56-3

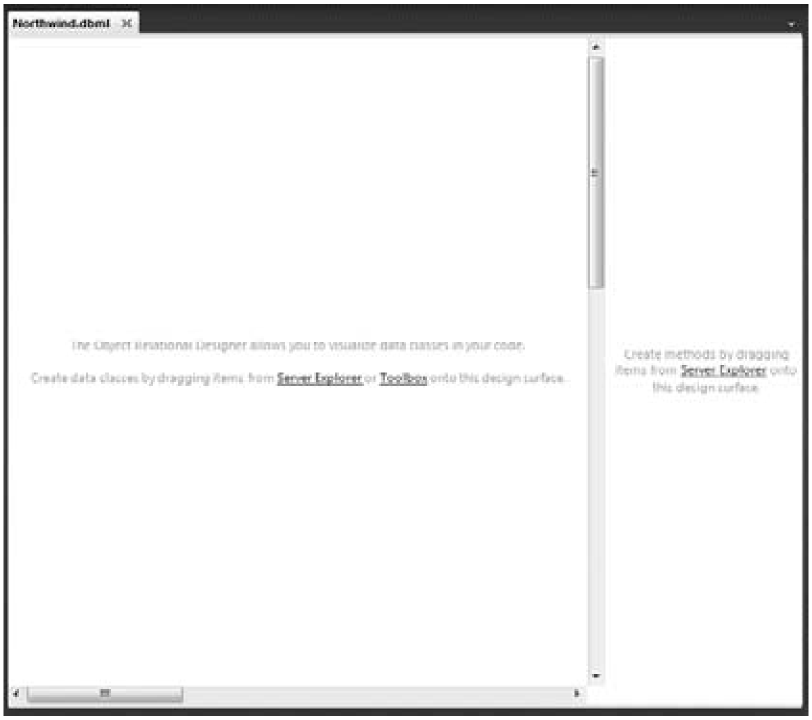
A number of things were added to your project with this action. The `Northwind.dbml` file was added and it contains two components. Because the LINQ to SQL class that was added works with LINQ, the following references were also added on your behalf: `System.Core`, `System.Data.DataSetExtensions`, `System.Data.Linq`, and `System.Xml.Linq`.

Introducing the O/R Designer

Another big addition to the IDE that appeared when you added the LINQ to SQL class to your project (the `Northwind.dbml` file), was a visual representation of the `.dbml` file. The new O/R Designer will appear as a tab within the document window directly in the IDE. Figure 56-4 shows a view of the O/R Designer when it is first initiated.



The Object Relational Designer allows you to visualize data classes in your code.

Create data classes by dragging items from Server Explorer or Toolbox onto this design surface.

Create methods by dragging items from Server Explorer onto this design surface.

FIGURE 56-4

The O/R Designer is made up of two parts. The first part is for data classes, which can be tables, classes, associations, and inheritances. Dragging such items on this design surface will give you a visual representation of the object that can be worked with. The second part (on the right) is for methods, which map to the stored procedures within a database.

When viewing your `.dbml` file within the O/R Designer, you will also have an Object Relational Designer set of controls in the Visual Studio toolbox. The toolbox is presented in Figure 56-5.

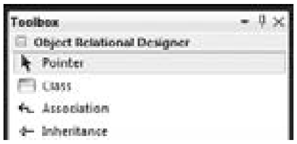


FIGURE 56-5

Creating the Product Object

For this example, you want to work with the `Products` table from the Northwind database, which means that you have to create a `Products` table that will use LINQ to SQL to map to this table. Accomplishing this task is simply a matter of opening up a view of the tables contained within the database from the Server Explorer dialog within Visual Studio and dragging and dropping the `Products` table onto the design surface of the O/R Designer. This action's results are illustrated in Figure 56-6.

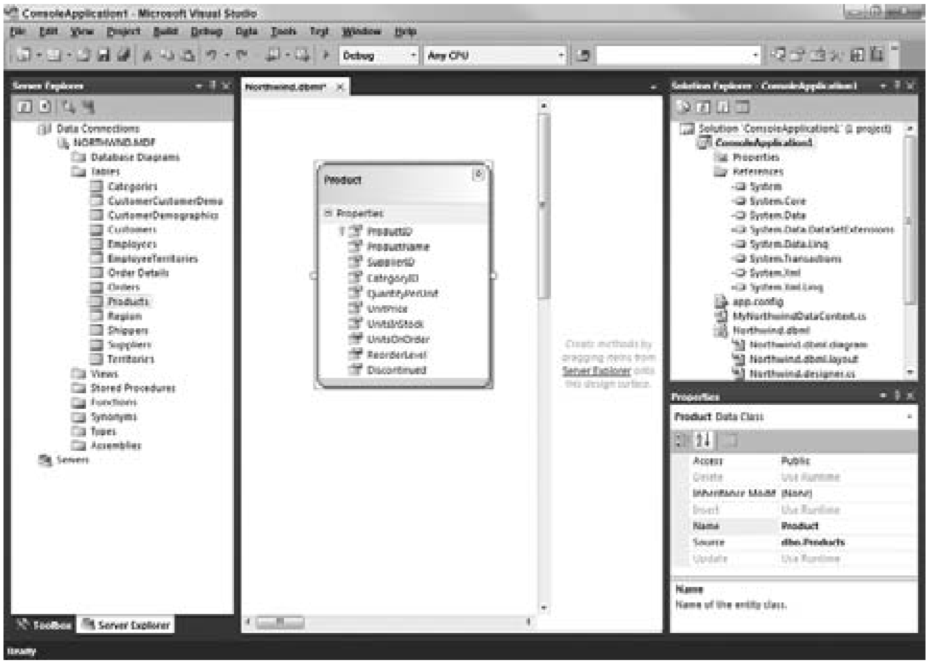

FIGURE 56-6

With this action, a bunch of code is added to the designer files of the `.dbml` file on your behalf. These classes will give you a strongly typed access to the `Products` table. For a demonstration of this, turn your attention to the console application's `Program.cs` file. The following shows the code that is required for this example:

```
using System;
using System.Linq;

namespace ConsoleApplication1
{
    class Class1
    {
        static void Main(string[] args)
        {
            NorthwindDataContext dc = new NorthwindDataContext();

            var query = dc.Products;

            foreach (Product item in query)
            {
                Console.WriteLine("{0} | {1} | {2}",
                   item.ProductID, item.ProductName, item.UnitsInStock);
            }

            Console.ReadLine();
        }
    }
}
```

code download ConsoleApplication1.sln

This bit of code does not have many lines to it, but it does query the `Products` table within the Northwind database and pulls out the data to display. It is important to step through this code starting with the first line in the `Main()` method:

```
NorthwindDataContext dc = new NorthwindDataContext();
```

The `NorthwindDataContext` object is an object of type `DataContext`. Basically, you can view this as something that maps to a `Connection` type object. This object works with the connection string and connects to the database for any required operations.

The next line is quite interesting:

```
var query = dc.Products;
```

Here, you are using the new `var` keyword, which is an implicitly typed variable. If you are unsure of the output type, you can use `var` instead of defining a type and the type will be set into place at compile time. Actually, the code `dc.Products;` returns a `System.Data.Linq.Table<ConsoleApplication1.Product>` object and this is what `var` is set to when the application is compiled. Therefore, this means that you could have also just as easily written the statement as such:

```
Table<Product> query = dc.Products;
```

This approach is actually better because programmers coming to look at the code of the application will find it easier to understand what is happening. Using the `var` keyword has so much of a hidden aspect to it that programmers might find it problematic. To use `Table<Product>`, which is basically a generic list of `Product` objects, you should make a reference to the `System.Data.Linq` namespace.

The value assigned to the `query` object is the value of the `Products` property, which is of type `Table<Product>`. From there, the next bit of code iterates through the collection of `Product` objects found in `Table<Product>`:

```
foreach (Product item in query)
{
   Console.WriteLine("{0} | {1} | {2}",
      item.ProductID, item.ProductName, item.UnitsInStock);
}
```

The iteration, in this case, pulls out the `ProductID`, `ProductName`, and `UnitsInStock` properties from the `Product` object and writes them out to the program. Because you are using only a few of the items from the table, you also have the option from the O/R Designer to delete the columns that you are not interested in pulling from the database. The results coming out from the program are presented here:

```
1 | Chai | 39
2 | Chang | 17
3 | Aniseed Syrup | 13
4 | Chef Anton's Cajun Seasoning | 53
5 | Chef Anton's Gumbo Mix | 0

** Results removed for space reasons **

73 | Röd Kaviar | 101
74 | Longlife Tofu | 4
75 | Rhönbräu Klosterbier | 125
76 | Lakkalikööri | 57
77 | Original Frankfurter grüne Soße | 32
```

From this example, you can see just how easy it is to query a SQL Server database using LINQ to SQL.

HOW OBJECTS MAP TO LINQ OBJECTS

The great thing about LINQ is that it gives you strongly typed objects to use in your code (with IntelliSense) and these objects map to existing database objects. Again, LINQ is nothing more than a thin façade over these pre-existing database objects. The following table shows the mappings that are between the database objects and the LINQ objects.

DATABASE OBJECT	LINQ OBJECT
Database	DataContext
Table	Class and Collection
View	Class and Collection
Column	Property
Relationship	Nested Collection
Stored Procedure	Method

On the left side, you are dealing with your database. The database is the entire entity — the tables, views, triggers, stored procedures — everything that makes up the database. On the LINQ side of this, you have an object called the `DataContext` object. A `DataContext` object is bound to the database. For the required interaction with the database, it contains a connection string; it will manage all the transactions that occur, it will take care of any logging, and it will manage the output of the data. The `DataContext` object completely manages the transactions with the database on your behalf.

Tables, as you saw in the console application example, are converted to classes. This means that if you have a `Products` table, you will have a `Product` class. You will notice that LINQ is name-friendly in that it changes plural tables to singular to give the proper name to the class that you are using in your code. In addition to database tables being treated as classes, you will find that database views are also treated as the same. Columns, on the other hand, are treated as properties. This gives you the ability to manage the attributes (names and type definitions) of the column directly.

Relationships are nested collections that map between these various objects. This gives you the ability to define relationships that are mapped to multiple items.

It is also important to understand the mapping of stored procedures. These actually map to methods within your code from the `DataContext` instance. The next section takes a closer look at the `DataContext` and the table objects within LINQ.

When dealing with the architecture of LINQ to SQL, you will notice that there are really three layers to this — your application, the LINQ to SQL layer, and the SQL Server database. As you saw from the previous examples, you can create a strongly typed query in your application's code:

```
dc.Products;
```

This in turn gets translated to a SQL query by the LINQ to SQL layer, which is then supplied to the database on your behalf:

```
SELECT [t0].[ProductID], [t0].[ProductName], [t0].[SupplierID],
[t0].[CategoryID], [t0].[QuantityPerUnit], [t0].[UnitPrice],
[t0].[UnitsInStock], [t0].[UnitsOnOrder], [t0].[ReorderLevel],
[t0].[Discontinued]
FROM [dbo].[Products] AS [t0]
```

In return, the LINQ to SQL layer takes the rows coming out of the database from this query and turns the returned data into a collection of strongly typed objects that you can easily work with.

The DataContext Object

Again, the `DataContext` object manages the transactions that occur with the database that you are working with when working with LINQ to SQL. There is actually a lot that you can do with the `DataContext` object.

In instantiating one of these objects, you will notice that it takes a couple of optional parameters. These options include:

- A string that represents the location of the SQL Server Express database file or the name of the SQL Server that is used
- A connection string
- Another DataContext object

The first two string options also have the option of including your own database mapping file. After you have instantiated this object, you are then able to programmatically use it for many types of operations.

Using the ExecuteQuery Method

One of the simpler things that you can accomplish with the `DataContext` object is to run quick commands that you write yourself using the `ExecuteQuery<T>()` method. For instance, if you are going to pull all the products from the `Products` table using the `ExecuteQuery<T>()` method, your code would be similar to the following:

```
using System;
using System.Collections.Generic;
using System.Data.Linq;

namespace ConsoleApplication1
{
    class Class1
    {
        static void Main(string[] args)
        {
            DataContext dc = new DataContext(@"Data Source=.\SQLEXPRESS;
               AttachDbFilename=|DataDirectory|\NORTHWND.MDF;
               Integrated Security=True;User Instance=True");

            IEnumerable<Product> myProducts =
               dc.ExecuteQuery<Product>("SELECT * FROM PRODUCTS", "");

            foreach (Product item in myProducts)
            {
              Console.WriteLine(item.ProductID + " | " + item.ProductName);
            }

            Console.ReadLine();
        }
    }
}
```

code download ConsoleApplication1.sln

In this case, the `ExecuteQuery<T>()` method is called passing in a query string and returning a collection of `Product` objects. The query utilized in the method call is a simple `Select` statement that doesn't require any additional parameters to be passed in. Because there are no parameters passed in with the query, you can either use the double quotes as the second required parameter to the method call or not even provide that parameter. If you optionally substitute any values in the query, you construct your `ExecuteQuery<T>()` call as such:

```
IEnumerable<Product> myProducts =
   dc.ExecuteQuery<Product>("SELECT * FROM PRODUCTS WHERE UnitsInStock > {0}",
   50);
```

In this case, the `{0}` is a placeholder for the substituted parameter value that you are going to pass in, and the second parameter of the `ExecuteQuery<T>()` method is the parameter that will be used in the substitution.

Using the Connection Property

The `Connection` property actually returns an instance of the `System.Data.SqlClient.SqlConnection` that is used by the `DataContext` object. This is ideal if you need to share this connection with other ADO.NET code that you might be using in your application, or if you need to get at any of the `SqlConnection` properties or methods that it exposes. For instance, getting at the connection string is a simple affair:

```
NorthwindDataContext dc = new NorthwindDataContext();

Console.WriteLine(dc.Connection.ConnectionString);
```

Using an ADO.NET Transaction

If you have an ADO.NET transaction that you can use, you are able to assign that transaction to the `DataContext` object instance using the `Transaction` property. You can also make use of transactions using the `TransactionScope` object that is from the .NET 2.0 Framework (you will need to make a reference to the `System.Transactions` assembly):

```
using System;
using System.Collections.Generic;
using System.Data.Linq;
using System.Transactions;

namespace ConsoleApplication1
{
    class Class1
    {
        static void Main(string[] args)
        {
            NorthwindDataContext dc = new NorthwindDataContext();

            using (TransactionScope myScope = new TransactionScope())
            {
               Product p1 = new Product() { ProductName = "Bill's Product" };
               dc.Products.InsertOnSubmit(p1);

               Product p2 = new Product() { ProductName = "Another Product" };
               dc.Products.InsertOnSubmit(p2);

               try
               {
                   dc.SubmitChanges();

                   Console.WriteLine(p1.ProductID);
                   Console.WriteLine(p2.ProductID);
               }
               catch (Exception ex)
               {
                   Console.WriteLine(ex.ToString());
               }

               myScope.Complete();
            }

            Console.ReadLine();
        }
    }
}
```

code download ConsoleApplication1.sln

In this case, the `TransactionScope` object is used and if one of the operations on the database fails, everything will be rolled back to the original state.

Other Methods and Properties of the DataContext Object

In addition to the items just described, a number of other methods and properties are available from the `DataContext` object. The following table shows some of the available methods from `DataContext`.

METHOD	DESCRIPTION
`CreateDatabase`	Allows you to create a database on the server.
`DatabaseExists`	Allows you to determine whether a database exists and can be opened.
`DeleteDatabase`	Deletes the associated database.
`ExecuteCommand`	Allows you to pass in a command to the database to be executed.
`ExecuteQuery`	Allows you to pass queries directly to the database.
`GetChangeSet`	The `DataContext` object keeps track of changes occurring in the database on your behalf and this method allows you access to these changes.
`GetCommand`	Gives you access to the commands that are performed.
`GetTable`	Provides access to a collection of tables from the database.
`Refresh`	Allows you to refresh your objects from the data that is stored within the database.
`SubmitChanges`	Executes your CRUD commands in the database that have been established in your code.
`Translate`	Converts an `IDataReader` to objects.

In addition to these methods, the `DataContext` object exposes some of the properties shown in the following table.

PROPERTY	DESCRIPTION
`ChangeConflicts`	Provides a collection of objects that cause concurrency conflicts when the `SubmitChanges()` method is called.
`CommandTimeout`	Allows you to set the timeout period in which a command against the database is allowed to run. You should set this to a higher value if your query needs more time to execute.
`Connection`	Allows you to work with the `System.Data.SqlClient.SqlConnection` object used by the client.
`DeferredLoadingEnabled`	Allows you to specify whether or not to delay the loading of one-to-many or one-to-one relationships.
`LoadOptions`	Allows you to specify or retrieve the value of the `DataLoadOptions` object.
`Log`	Allows you to specify the location of the output of the command that was used in the query.
`Mapping`	Provides the `MetaModel` on which the mapping is based.
`ObjectTrackingEnabled`	Specifies whether or not to track changes to the objects within the database for transactional purposes. If you are dealing with a read-only database, you should set this property to `false`.
`Transaction`	Allows you to specify the local transaction used with the database.

The Table<TEntity> Object

The `Table<TEntity>` object is a representation of the tables that you are working with from the database. For instance, you saw the use of the `Product` class, which is a `Table<Product>` instance. As you see throughout this chapter, a number of methods are available from the `Table<TEntity>` object. Some of these methods are defined in the following table.

METHOD	DESCRIPTION
`Attach`	Allows you to attach an entity to the `DataContext` instance.
`AttachAll`	Allows you to attach a collection of entities to the `DataContext` instance.
`DeleteAllOnSubmit<TSubEntity>`	Allows you to put all the pending actions into a state of being ready for deletion. Everything here is enacted when the `SubmitChanges()` method is called from the `DataContext` object.
`DeleteOnSubmit`	Allows you to put a pending action into a state of being ready for deletion. Everything here is enacted when the `SubmitChanges()` method is called from the `DataContext` object.
`GetModifiedMembers`	Provides an array of modified objects. You will be able to access their current and changed values.
`GetNewBindingList`	Provides a new list for binding to the data store.
`GetOriginalEntityState`	Provides you an instance of the object as it appeared in its original state.
`InsertAllOnSubmit<TSubEntity>`	Allows you to put all the pending actions into a state of being ready for insertion. Everything here is enacted with the `SubmitChanges()` method called off of the `DataContext` object.
`InsertOnSubmit`	Allows you to put a pending action into a state of being ready for insertion. Everything here is enacted when the `SubmitChanges()` method is called from the `DataContext` object.

WORKING WITHOUT THE O/R DESIGNER

Although the new O/R Designer in Visual Studio 2010 makes the creation of everything you need for LINQ to SQL quite easy, it is important to note that the underlying framework upon which this all rests allows you to do everything from the ground up yourself. This provides the most control over what is actually happening.

Creating Your Own Custom Object

To accomplish the same task as was accomplished earlier with the `Customer` table, you need to expose the `Customer` table yourself via a class. The first step is to create a new class in your project called `Customer.cs`. The code for this class is presented here:

```
using System.Data.Linq.Mapping;

namespace ConsoleApplication1
{
    [Table(Name = "Customers")]
    public class Customer
    {
        [Column(IsPrimaryKey = true)]
        public string CustomerID { get; set; }
        [Column]
        public string CompanyName { get; set; }
        [Column]
        public string ContactName { get; set; }
        [Column]
        public string ContactTitle { get; set; }
        [Column]
        public string Address { get; set; }
        [Column]
        public string City { get; set; }
        [Column]
        public string Region { get; set; }
        [Column]
        public string PostalCode { get; set; }
        [Column]
        public string Country { get; set; }
        [Column]
        public string Phone { get; set; }
        [Column]
        public string Fax { get; set; }
    }
}
```

code snippet Customer.cs

Here, the `Customer.cs` file defines the `Customer` object that you want to use with LINQ to SQL. The class has the `Table` attribute assigned to it to signify the table class. The `Table` class attribute includes a property called `Name`, which defines the name of the table to use within the database that is referenced with the connection string. Using the `Table` attribute also means that you need to make a reference to the `System.Data.Linq.Mapping` namespace in your code.

In addition to the `Table` attribute, each of the defined properties in the class makes use of the `Column` attribute. As stated earlier, columns from the SQL Server database will map to properties in your code.

Querying with Your Custom Object and LINQ

With only the `Customer` class in place, you are then able to query the Northwind database for the `Customers` table. The code to accomplish this task is illustrated in the following example found in the same console application:

```
using System;
using System.Data.Linq;

namespace ConsoleApplication1
{
    class Program
    {
        static void Main()
        {
            DataContext dc = new DataContext(@"Data Source=.\SQLEXPRESS;
               AttachDbFilename=|DataDirectory|\NORTHWND.MDF;
               Integrated Security=True;User Instance=True");

            dc.Log = Console.Out; // Used for outputting the SQL used

            Table<Customer> myCustomers = dc.GetTable<Customer>();

            foreach (Customer item in myCustomers)
            {
                Console.WriteLine("{0} | {1}",
                   item.CompanyName, item.Country);
            }
```

```
                Console.ReadLine();
            }
        }
    }
```

In this case, the default `DataContext` object is used and the connection string to the Northwind SQL Server Express database is passed in as a parameter. A `Table` class of type `Customer` is then populated using the `GetTable<TEntity>()` method. For this example, the `GetTable<TEntity>()` operation uses your custom-defined `Customer` class:

```
dc.GetTable<Customer>();
```

What happens is that LINQ to SQL uses the `DataContext` object to make the query to the SQL Server database on your behalf and gets the returned rows as strongly typed `Customer` objects. This allows you to then iterate through each of the `Customer` objects in the `Table` object's collection and get at the information that you need, as is done with the `Console.WriteLine()` statements here:

```
foreach (Customer item in myCustomers)
{
   Console.WriteLine("{0} | {1}",
      item.CompanyName, item.Country);
}
```

Running this code produces the following results in your console application:

```
SELECT [t0].[CustomerID], [t0].[CompanyName], [t0].[ContactName],
[t0].[ContactTitle], [t0].[Address], [t0].[City], [t0].[Region],
[t0].[PostalCode], [t0].[Country], [t0].[Phone], [t0].[Fax]
FROM [Customers] AS [t0]
--Context: SqlProvider(Sql2005) Model: AttributedMetaModel Build: 4.0.21006.1

Alfreds Futterkiste | Germany
Ana Trujillo Emparedados y helados | Mexico
Antonio Moreno Taquería | Mexico
Around the Horn | UK
Berglunds snabbköp | Sweden

// Output removed for clarity

Wartian Herkku | Finland
Wellington Importadora | Brazil
White Clover Markets | USA
Wilman Kala | Finland
Wolski  Zajazd | Poland
```

Limiting the Columns Called with the Query

You will notice that the query retrieved every single column that was specified in your `Customer` class file. If you remove the columns that you are not going to need, you can then have a new `Customer` class file as shown here:

```
using System.Data.Linq.Mapping;

namespace ConsoleApplication1
{
    [Table(Name = "Customers")]
    public class Customer
    {
        [Column(IsPrimaryKey = true)]
        public string CustomerID { get; set; }
        [Column]
        public string CompanyName { get; set; }
        [Column]
```

```
            public string Country { get; set; }
        }
    }
```

code snippet Customer.cs

In this case, I removed all the columns that are not utilized by the application. Now if you run the console application and look at the SQL query that is produced, you will see the following results:

```
SELECT [t0].[CustomerID], [t0].[CompanyName], [t0].[Country]
FROM [Customers] AS [t0]
```

You can see that only the three columns that are defined within the `Customer` class are utilized in the query to the `Customers` table.

The property `CustomerID` is interesting in that you are able to signify that this column is a primary key for the table through the use of the `IsPrimaryKey` setting in the `Column` attribute. This setting takes a `Boolean` value and in this case, it is set to `true`.

Working with Column Names

The other important point of the columns is that the name of the property you define in the `Customer` class needs to be the same name as is used in the database. For instance, if you change the name of the `CustomerID` property to `MyCustomerID`, you get the following exception when you try to run your Console application:

```
System.Data.SqlClient.SqlException was unhandled
  Message="Invalid column name 'MyCustomerID'."
  Source=".Net SqlClient Data Provider"
  ErrorCode=-2146232060
  Class=16
  LineNumber=1
  Number=207
  Procedure=""
  Server="\\\\.\\pipe\\F5E22E37-1AF9-44\\tsql\\query"
```

To get around this, you need to define the name of the column in the custom `Customer` class that you have created. You can do this by using the `Column` attribute as illustrated here:

```
[Column(IsPrimaryKey = true, Name = "CustomerID")]
public string MyCustomerID { get; set; }
```

Like the `Table` attribute, the `Column` attribute includes a `Name` property that allows you to specify the name of the column as it appears in the `Customers` table.

Doing this will generate a query as shown here:

```
SELECT [t0].[CustomerID] AS [MyCustomerID], [t0].[CompanyName], [t0].[Country]
FROM [Customers] AS [t0]
```

This also means that you need to now reference the column using the new name of `MyCustomerID` (for example, `item.MyCustomerID`).

Creating Your Own DataContext Object

Now it is probably not the best approach to use the plain-vanilla `DataContext` object, but instead, you will find that you have more control by creating your own `DataContext` class. To accomplish this task, create a new class called `MyNorthwindDataContext.cs` and have the class inherit from `DataContext`. Your class in its simplest form is illustrated here:

```
using System.Data.Linq;

namespace ConsoleApplication1
{
    public class MyNorthwindDataContext: DataContext
    {
        public Table<Customer> Customers;

        public MyNorthwindDataContext()
       : base(@"Data Source=.\SQLEXPRESS;
                     AttachDbFilename=|DataDirectory|\NORTHWND.MDF;
                     Integrated Security=True;User Instance=True")
        {
        }
    }
}
```

code snippet MyNorthwindDataContext.cs

Here, the class `MyNorthwindDataContext` inherits from `DataContext` and provides an instance of the `Table<Customer>` object from the `Customer` class that you created earlier. The constructor is the other requirement of this class. This constructor uses a base to initialize a new instance of the object referencing a file (in this case a connection to a SQL database file).

Using your own `DataContext` object now allows you to change the code in your application to the following:

```
using System;
using System.Data.Linq;

namespace ConsoleApplication1
{
    class Program
    {
        static void Main()
        {
            MyNorthwindDataContext dc = new MyNorthwindDataContext();
            Table<Customer> myCustomers = dc.Customers;

            foreach (Customer item in myCustomers)
            {
                Console.WriteLine("{0} | {1}",
                   item.CompanyName, item.Country);
            }

            Console.ReadLine();
        }
    }
}
```

code download ConsoleApplication1.sln

By creating an instance of the `MyNorthwindDataContext` object, you are now allowing the class to manage the connection to the database. You will also notice that now you have direct access to the `Customer` class through the `dc.Customers` statement.

CUSTOM OBJECTS AND THE O/R DESIGNER

In addition to building your custom object in your own `.cs` file and then tying that class to the `DataContext` that you have built, you can also use the O/R Designer in Visual Studio 2010 to build your class files. When you use Visual Studio in this manner, it will create the appropriate `.cs` file on your behalf, but by using the O/R Designer, you will also have a visual representation of the class file and any possible relationships that are established.

When viewing the Designer view of your `.dbml` file, you will notice that there are three items present in the toolbox. These items are Class, Association, and Inheritance.

For an example of this, take the Class object from the toolbox and drop it onto the design surface. You will be presented with an image of the generic class as shown in Figure 56-7.

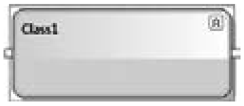

FIGURE 56-7

From here, you can now click the `Class1` name and rename this class to `Customer`. Right-clicking next to the name enables you to add properties to the class file by selecting Add Property from the provided menu. For this example, give the `Customer` class three properties — `CustomerID`, `CompanyName`, and `Country`. If you highlight the `CustomerID` property, you will be able to configure the property from the Properties dialog in Visual Studio and change the Primary Key setting from `False` to `True`. You also want to highlight the entire class and go to the Properties dialog and change the `Source` property to `Customers` because this is the name of the table from which this `Customer` object needs to work. After this is all done, you will have a visual representation of the class as shown in Figure 56-8.

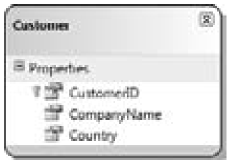

FIGURE 56-8

As you can see from this image, the `CustomerID` property is properly represented with a primary key icon next to the name. With this in place, you can expand the plus sign next to the `Northwind.dbml` file and you will find three files here — `Northwind.dbml.layout`, `Northwind.designer.cs`, and `Northwind.dbml.diagram`. The `Northwind.dbml.layout` file is an XML file that helps Visual Studio with the visual representation shown in the O/R Designer. The most important file is `Northwind.designer.cs`. This is the `Customer` class file that was created on your behalf. When you open this file, you are able to see what Visual Studio created for you.

First, you will find the `Customer` class file within the code of the page:

```
[Table(Name="Customers")]
public partial class Customer: INotifyPropertyChanging,
                               INotifyPropertyChanged
{

   // Code removed for clarity

}
```

The `Customer` class is the name of the class according to what you provided in the designer. The class comes with the `Table` attribute and provides a name value of `Customers` because this is the name of the database that this object needs to work with when connecting to the Northwind database.

Within the `Customer` class, you will find the three properties that you defined. Presented here is just one of the properties — `CustomerID`:

```
[Column(Storage="_CustomerID", CanBeNull=false, IsPrimaryKey=true)]
public string CustomerID
{
   get
   {
      return this._CustomerID;
   }
   set
   {
```

```
            if ((this._CustomerID != value))
            {
               this.OnCustomerIDChanging(value);
               this.SendPropertyChanging();
               this._CustomerID = value;
               this.SendPropertyChanged("CustomerID");
               this.OnCustomerIDChanged();
            }
         }
      }
```

code snippet Customer.cs

Similar to when you built a class for yourself from the earlier example, the properties defined use the `Column` attribute and some of the properties available to this attribute. You can see that the primary key setting is set using the `IsPrimaryKey` item.

In addition to the `Customer` class, you will find that a class inheriting from the `DataContext` object is also within the created file:

```
[System.Data.Linq.Mapping.DatabaseAttribute(Name="NORTHWND")]
public partial class NorthwindDataContext: System.Data.Linq.DataContext
{

   // Code removed for clarity

}
```

The `DataContext` object, `NorthwindDataContext`, allows you to connect to the Northwind database and the `Customers` table, as was accomplished in the previous examples.

You will find that using the O/R Designer is a process that can make the creation of your database object class files simple and straightforward. However, at the same time, if you want complete control, you can code up everything yourself and get the results you are after.

QUERYING THE DATABASE

As you've seen, there are a number of ways in which you can query the database from the code of your application. In some of the simplest forms, your queries looked like the following:

```
Table<Product> query = dc.Products;
```

This command was pulling down the entire `Products` table to your `query` object instance.

Using Query Expressions

In addition to pulling a table straight out of the database using `dc.Products`, you also can use a query expression directly in your code that is strongly typed. An example of this is shown in the following code:

```
using System;
using System.Linq;

namespace ConsoleApplication1
{
    class Class1
    {
        static void Main(string[] args)
        {
            NorthwindDataContext dc = new NorthwindDataContext();

            var query = from p in dc.Products
                        select p;
```

```
                foreach (Product item in query)
                {
                    Console.WriteLine(item.ProductID + " | " + item.ProductName);
                }

                Console.ReadLine();
            }
        }
    }
```

code download ConsoleApplication1.sln

In this case, a `query` object (again, a `Table<Product>` object) is populated with the query value of `from p in dc.Products select p;`. This command, though shown on two lines for readability purposes, can also be presented on a single line if you wish.

Query Expressions in Detail

You will find that there are a number of query expressions that you can use from your code. The previous example is a simple select statement that returns the entire table. The following list of items are some of the other query expressions that you have at your disposal.

SEGMENTATION	SYNTAX
`Project`	select <*expression*>
`Filter`	where <*expression*>, distinct
`Test`	any(<*expression*>), all(<*expression*>)
`Join`	<*expression*> join <*expression*> on <*expression*> equals <*expression*>
`Group`	group by <*expression*>, into <*expression*>, <*expression*> group join <*decision*> on <*expression*> equals <*expression*> into <*expression*>
`Aggregate`	count([<*expression*>]), sum(<*expression*>), min(<*expression*>), max(<*expression*>), avg(<*expression*>)
`Partition`	skip [while] <*expression*>, take [while] <*expression*>
`Set`	union, intersect, except
`Order`	order by <*expression*>, <*expression*> [ascending | descending]

Filtering Using Expressions

In addition to straight queries for the entire table, you can filter items using the `where` and `distinct` options. The following provides an example of querying the `Products` table for a specific type of record:

```
var query = from p in dc.Products
            where p.ProductName.StartsWith("L")
            select p;
```

In this case, this query is selecting all the records from the `Products` table that start with the letter `L`. This is done via the `where p.ProductName.StartsWith("L")` expression. You will find a large selection of methods available from the `ProductName` property that allows you to fine-tune the filtering you need. This operation produces the following results:

```
65 | Louisiana Fiery Hot Pepper Sauce
66 | Louisiana Hot Spiced Okra
67 | Laughing Lumberjack Lager
74 | Longlife Tofu
76 | Lakkalikööri
```

You can also add as many of these expressions to the list as you need. For instance, here is an example of adding two `where` statements to your query:

```
var query = from p in dc.Products
            where p.ProductName.StartsWith("L")
            where p.ProductName.EndsWith("i")
            select p;
```

In this case, there is a filter expression that looks for items with a product name starting with the letter `L` and then a second expression is done to make sure the second criteria is also applied, which states that the items must also end with the letter `i`. This would give you the following results:

```
76 | Lakkalikööri
```

Performing Joins

In addition to working with one table, you can work with multiple tables and perform joins with your queries. If you drag and drop both the `Customers` table and the `Orders` table onto the `Northwind.dbml` design surface, you will get the result presented in Figure 56-9.

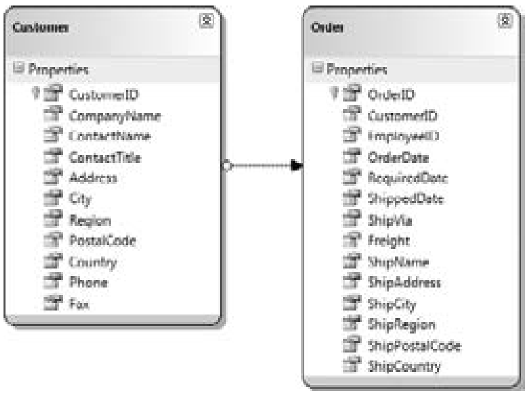

FIGURE 56-9

From this figure, you can see that after you drag and drop both of these elements onto the design surface, Visual Studio will know that there is a relationship between these items and will create this relationship for you in the code and represent it with the black arrow.

From here, you can use a `join` statement in your query to work with both of the tables as presented in the following example:

```
using System;
using System.Linq;

namespace ConsoleApplication1
{
    class Class1
    {
        static void Main(string[] args)
        {
            NorthwindDataContext dc = new NorthwindDataContext();
            dc.Log = Console.Out;

            var query = from c in dc.Customers
                  join o in dc.Orders on c.CustomerID equals o.CustomerID
                  orderby c.CustomerID
                  select new { c.CustomerID, c.CompanyName,
                     c.Country, o.OrderID, o.OrderDate };

            foreach (var item in query)
            {
                Console.WriteLine(item.CustomerID + " | " + item.CompanyName
                     + " | " + item.Country  + " | " + item.OrderID
                      + " | " + item.OrderDate);
            }

            Console.ReadLine();
        }
    }
}
```

code download ConsoleApplication1.sln

This example is pulling from the `Customers` table and joining on the `Orders` table where the `CustomerID` columns match. This is done through the `join` statement:

```
join o in dc.Orders on c.CustomerID equals o.CustomerID
```

From here, a new object is created with the `select new` statement and this new object comprises of the `CustomerID`, `CompanyName`, and `Country` columns from the `Customer` table as well as the `OrderID` and `OrderDate` columns from the `Orders` table.

When it comes to iterating through the collection of this new object, the interesting part is that the `foreach` statement also uses the `var` keyword because the type is not known at this point in time:

```
foreach (var item in query)
{
   Console.WriteLine(item.CustomerID + " | " + item.CompanyName
      + " | " + item.Country  + " | " + item.OrderID
      + " | " + item.OrderDate);
}
```

Regardless, the `item` object here has access to all the properties that you specified. When you run this example, you will get results similar to what is presented in this partial result:

```
WILMK | Wilman Kala | Finland | 10695 | 10/7/1997 12:00:00 AM
WILMK | Wilman Kala | Finland | 10615 | 7/30/1997 12:00:00 AM
WILMK | Wilman Kala | Finland | 10673 | 9/18/1997 12:00:00 AM
WILMK | Wilman Kala | Finland | 11005 | 4/7/1998 12:00:00 AM
WILMK | Wilman Kala | Finland | 10879 | 2/10/1998 12:00:00 AM
WILMK | Wilman Kala | Finland | 10873 | 2/6/1998 12:00:00 AM
WILMK | Wilman Kala | Finland | 10910 | 2/26/1998 12:00:00 AM
```

Grouping Items

You are also easily able to group items with your queries. In the `Northwind.dbml` example that you are working with, drag and drop the `Categories` table onto the design surface and you will see that there is a relation with this table and the `Products` table from earlier. The following example shows you how to group products by categories:

```
using System;
using System.Linq;

namespace ConsoleApplication1
{
    class Class1
    {
        static void Main(string[] args)
        {
            NorthwindDataContext dc = new NorthwindDataContext();

            var query = from p in dc.Products
                        orderby p.Category.CategoryName ascending
                        group p by p.Category.CategoryName into g
                        select new { Category = g.Key, Products = g};

            foreach (var item in query)
            {
                    Console.WriteLine(item.Category);

                    foreach (var innerItem in item.Products)
                    {
                        Console.WriteLine("      " + innerItem.ProductName);
                    }

                    Console.WriteLine();
                }

                Console.ReadLine();
            }
        }

    }
```

code download ConsoleApplication1.sln

This example creates a new object, which is a group of categories, and packages the entire `Product` table into this new table called `g`. Before that, the categories are ordered by name using the `orderby` statement because the order provided is in `ascending` order (the other option being `descending`). The output is the `Category` (passed in through the `Key` property) and the `Product` instance. The iteration with the `foreach` statements is done once for the categories and once for each of the products that are found in the category.

A partial output of this program is presented here:

```
Beverages
      Chai
      Chang
      Guaraná Fantástica
      Sasquatch Ale
      Steeleye Stout
      Côte de Blaye
      Chartreuse verte
      Ipoh Coffee
      Laughing Lumberjack Lager
      Outback Lager
      Rhönbräu Klosterbier
      Lakkalikööri

Condiments
      Aniseed Syrup
      Chef Anton's Cajun Seasoning
      Chef Anton's Gumbo Mix
      Grandma's Boysenberry Spread
      Northwoods Cranberry Sauce
      Genen Shouyu
      Gula Malacca
      Sirop d'érable
      Vegie-spread
      Louisiana Fiery Hot Pepper Sauce
      Louisiana Hot Spiced Okra
      Original Frankfurter grüne Soße
```

You will find that there a lot more commands and expressions available to you beyond what are presented in this short chapter.

STORED PROCEDURES

So far, you have been querying the tables directly and leaving it up to LINQ to create the appropriate SQL statement for the operation. When working with pre-existing databases that make heavy use of stored procedures and for those that want to follow the best practice of using stored procedures within a database, you will find that LINQ is still a viable option.

LINQ to SQL treats working with stored procedures as a method call. As you saw in Figure 56-4, there is a design surface called the O/R Designer that allows you to drag and drop tables onto it so that you can then programmatically work with the table. On the right side of the O/R Designer, you will find a spot where you are able to drag and drop stored procedures.

Any stored procedures that you drag and drop onto this part of the O/R Designer will now become available methods to you from the `DataContext` object. For this example, drag and drop the `TenMostExpensiveProducts` stored procedure onto this part of the O/R Designer.

The following example shows how you would call this stored procedure within the Northwind database:

```
using System;
using System.Collections.Generic;
using System.Data.Linq;
using System.Linq;

namespace ConsoleApplication1
{
    class Class1
    {
        static void Main(string[] args)
        {
            NorthwindDataContext dc = new NorthwindDataContext();

            ISingleResult<Ten_Most_Expensive_ProductsResult> result =
                dc.Ten_Most_Expensive_Products();

            foreach (Ten_Most_Expensive_ProductsResult item in result)
            {
                Console.WriteLine(item.TenMostExpensiveProducts + " | " +
                   item.UnitPrice);
            }

            Console.ReadLine();
        }
    }
}
```

code download ConsoleApplication1.sln

From this example, you can see that the rows coming out of the stored procedure are collected into an `ISingleResult<Ten_Most_Expensive_ProductsResult>` object. From here, iteration through this object is as simple as all the rest.

As you can see from this example, calling your stored procedures is a simple process.

SUMMARY

One of the more exciting features of the .NET Framework 4 release is the LINQ capabilities that the platform provides. This chapter focused on using LINQ to SQL and some of the options available to you in querying your SQL Server databases.

Using LINQ to SQL enables you to have a strongly typed set of operations for performing CRUD operations against your database. With that said, though, you are still able to use pre-existing access capabilities whether that is interacting with ADO.NET or working with your stored procedures.

➤

➤ Built-in activities

➤ Creating custom activities

➤ Workflow Services

➤ Integration with WCF

➤ Hosting Workflows

➤ Tips for migrating to Workflow Foundation 4

This chapter presents an overview of the Windows Workflow Foundation 3.0 (known as WF throughout the rest of this chapter), which provides a model to define and execute processes using a set of building blocks called *activities*. WF provides a Designer that, by default, is hosted within Visual Studio, and that allows you to drag and drop activities from the toolbox onto the design surface to create a workflow template.

This template can then be executed by creating a `WorkflowInstance` and then running that instance. The code that executes a workflow is known as the `WorkflowRuntime`, and this object can also host a number of services that the running workflows can access. At any time, there may be several workflow instances executing, and the runtime deals with scheduling these instances and saving and restoring state; it can also record the behavior of each workflow instance as it executes.

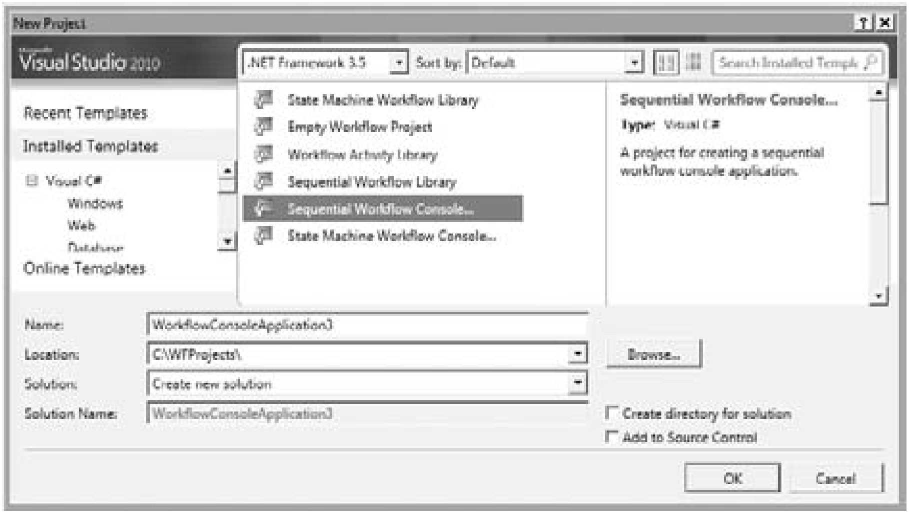
A workflow is constructed from a number of activities, and these activities are executed by the runtime. An activity might send an e-mail, update a row in a database, or execute a transaction on a back-end system. There are a number of built-in activities that can be used for general-purpose work, and you can also create your own custom activities and plug these into the workflow as necessary.

Note that with Visual Studio 2010 there is a new version of Windows Workflow which is not backward compatible. This chapter describes the older version of workflow; however, for new projects I recommend using the WF 4 version. Refer to Chapter 44, “Windows Workflow Foundation 4,” for further details. At the end of this chapter, I have also included a set of suggestions to make upgrading easier.

We begin with the canonical example that everyone uses when faced with a new technology — "Hello World" — and also describe what you need to get workflows running on your development machine.

HELLO WORLD

Visual Studio 2010 contains built-in support for creating workflows, and when you open the New Project dialog, you see a list of workflow project types, as shown in Figure 57-1.



.NET Framework 3.5 · Sort by: Default · Search Installed Templates

Sequential Workflow Console...
Type: Visual C#
A project for creating a sequential workflow console application.

Name: WorkflowConsoleApplication3
Location: C:\WFProjects\
Solution: Create new solution
Solution Name: WorkflowConsoleApplication3
☐ Create directory for solution
☐ Add to Source Control

FIGURE 57-1

Select Sequential Workflow Console Application from the available templates (that will create a console application that hosts the workflow runtime) and a default workflow onto which you can then drag and drop activities.

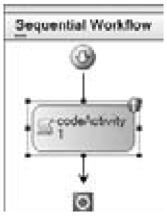

FIGURE 57-2

Next, drag a `Code` activity from the toolbox onto the design surface so that you have a workflow that looks like the one shown in Figure 57-2.

The exclamation mark glyph on the top right of the activity indicates that a mandatory property of that activity has not been defined — in this case, it is the `ExecuteCode` property, which indicates the method that will be called when the activity executes. You learn how to mark your own properties as mandatory in the section on activity validation. If you double-click the code activity, a method will be created for you in the code-behind class, and here you can use `Console.WriteLine` to output the "Hello World" string, as shown in the following code snippet:

```
private void codeActivity1_ExecuteCode(object sender, EventArgs e)
{
    Console.WriteLine("Hello World");
}
```

If you then build and run the program, you will see the output text on the console. When the program executes, an instance of the `WorkflowRuntime` is created, and then an instance of your workflow is constructed and executed. When the code activity executes, it calls the method defined and that outputs the string to the console. The section entitled "The Workflow Runtime" later in the chapter describes in detail how to host the runtime. The code for the preceding example is available in the `01 HelloWorkflow World` folder.

ACTIVITIES

Everything in a workflow is an activity, including the workflow itself. The workflow is a specific type of activity that typically allows other activities to be defined within it — this is known as a composite activity, and you see other composite activities later in this chapter. An activity is just a class that ultimately derives from the `Activity` class.

The `Activity` class defines a number of overridable methods, and arguably the most important of these is the `Execute` method, shown in the following snippet:

```
protected override ActivityExecutionStatus Execute
  ( ActivityExecutionContext executionContext )
{
    return ActivityExecutionStatus.Closed;
}
```

When the runtime schedules an activity for execution, the `Execute` method is ultimately called, and that is where you have the opportunity to write custom code to provide the behavior of the activity. In the simple example in the previous section, when the workflow runtime calls `Execute` on the `CodeActivity`, the implementation of this method on the code activity will execute the method defined in the code-behind class, and that displays the message on the console.

The `Execute` method is passed a context parameter of type `ActivityExecutionContext`. You will see more about this as the chapter progresses. The method has a return value of type `ActivityExecutionStatus`, and this is used by the runtime to determine whether the activity has completed successfully, is still processing, or is in one of several other potential states that can describe to the workflow runtime what state the activity is in. Returning `ActivityExecutionStatus.Closed` from this method indicates that the activity has completed its work and can be disposed of.

Numerous standard activities are provided with WF, and the following sections provide examples of some of these together with scenarios in which you might use these activities. The naming convention for activities is to append `Activity` to the name; so for example, the code activity previously shown in Figure 57-2 is defined by the `CodeActivity` class.

All of the standard activities are defined within the `System.Workflow.Activities` namespace, which in turn forms part of the `System.Workflow.Activities.dll` assembly. There are two other assemblies that make up WF — these are `System.Workflow.ComponentModel.dll` and `System.Workflow.Runtime.dll`.

IfElseActivity

As its name implies, this activity acts like an `If-Else` statement in C#.

When you drop an `IfElseActivity` onto the design surface, you will see an activity as displayed in Figure 57-3. The `IfElseActivity` is a composite activity in that it constructs two branches (which themselves are types of activity, in this case `IfElseBranchActivity`). Each branch is also a composite activity that derives from `SequenceActivity` — this class executes each activity in turn from top to bottom. The Designer adds the "Drop Activities Here" text to indicate where child activities can be added.

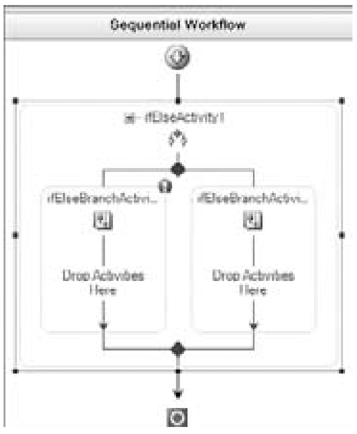

FIGURE 57-3

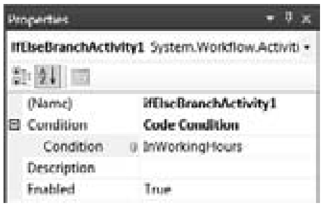
The first branch, as shown in Figure 57-3, includes a glyph indicating that the `Condition` property needs to be defined. A condition derives from `ActivityCondition` and is used to determine whether that branch should be executed.

When the `IfElseActivity` is executed, it evaluates the condition of the first branch, and if the condition evaluates to `true` the branch is executed. If the condition evaluates to `false`, the `IfElseActivity` then tries the next branch, and so on until the last branch in the activity. It is worth noting that the `IfElseActivity` can have any number of branches, each with its own condition. The last branch needs no condition because it is in effect the `else` part of the `If-Else` statement. To add a new branch, you can display the context menu for the activity and select Add Branch from that menu — this is also available from the Workflow menu within Visual Studio. As you add branches, each will have a mandatory condition except for the last one.

Two standard condition types are defined in WF — the `CodeCondition` and the `RuleConditionReference`. The `CodeCondition` class executes a method on your code-behind class, which can return `true` or `false` as appropriate. To create a `CodeCondition`, display the property grid for the `IfElseActivity` and set the condition to Code Condition, then type in a name for the code to be executed, as shown in Figure 57-4.



Properties

ifElseBranchActivity1 System.Workflow.Activiti

(Name)	ifElseBranchActivity1
⊟ Condition	Code Condition
Condition	InWorkingHours
Description	
Enabled	True

FIGURE 57-4

When you have typed the method name into the property grid, the Designer will construct a method on your code-behind class, as shown in the following snippet:

```
private void InWorkingHours(object sender, ConditionalEventArgs e)
{
    int hour = DateTime.Now.Hour;

    e.Result = ((hour >= 9) && (hour <= 17));
}
```

This code sets the `Result` property of the passed `ConditionalEventArgs` to `true` if the current hour is between 9 AM and 5 PM. Conditions can be defined in code as shown here, but another option is to define a condition based on a rule that is evaluated in a similar manner. The Workflow Designer contains a rule editor, which can be used to declare conditions and statements (much like the `If-Else` statement shown previously). These rules are evaluated at runtime based on the current state of the workflow.

ParallelActivity

This activity permits you to define a set of activities that execute in parallel — or rather in a pseudo-parallel manner. When the workflow runtime schedules an activity, it does so on a single thread. This thread executes the first activity, then the second, and so on until all activities have completed (or until an activity is waiting on some form of input). When the `ParallelActivity` executes, it iterates through each branch and schedules execution of each branch in turn. The workflow runtime maintains a queue of scheduled activities for each workflow instance, and typically executes these in a FIFO (first in, first out) manner.

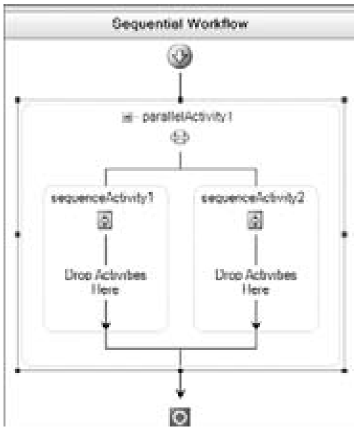


FIGURE 57-5

Assuming that you have a `ParallelActivity`, as shown in Figure 57-5, this will schedule execution of `sequenceActivity1` and then `sequenceActivity2`. The `SequenceActivity` type works by scheduling execution of its first activity with the runtime, and when this activity completes, it then schedules the second activity. This schedule/wait-for-completion method is used to traverse through all child activities of the sequence, until all child activities have executed, at which time the sequence activity can complete.

Given that the `SequenceActivity` schedules execution of one activity at a time, it means that the queue maintained by the `WorkflowRuntime` is continually updated with schedulable activities. Assuming that we have a parallel activity P1, which contains two sequences, S1 and S2, each with two code activities, C1 and C2, this would produce entries in the scheduler queue, as shown in the following table.

WORKFLOW QUEUE	INITIALLY THERE ARE NO ACTIVITIES IN THE QUEUE
P1	Parallel is executed when the workflow runs
S1, S2	Added to the queue when P1 executes
S2, S1.C1	S1 executes and adds S1.C1 to the queue
S1.C1, S2.C1	S2 executes and adds S2.C1 to the queue
S2.C1, S1.C2	S1.C1 completes, so S1.C2 is queued
S1.C2, S2.C2	S2.C1 completes, so S2.C2 is queued
S2.C2	The last entry in the queue

Here, the queue processes the first entry (the parallel activity P1), and this adds the sequence activities S1 and S2 to the workflow queue. As the sequence activity S1 executes, it pushes its first child activity (S1.C1) to the end of the queue, and when this activity is scheduled and completes, it then adds the second child activity to the queue.

As can be seen from the preceding example, execution of the `ParallelActivity` is not truly parallel — it effectively interleaves execution between the two sequential branches. From this, you could infer that it's best that an activity execute in a minimal amount of time because, given that there is only one thread servicing the scheduler queue for each workflow, a long-running activity could hamper the execution of other activities in the queue. That said, often, an activity needs to execute for an arbitrary amount of time, so there must be some way to mark an activity as "long-running" so that other activities get a chance to execute. You can do this by returning `ActivityExecutionStatus.Executing` from the `Execute` method, which lets the runtime know that you will call it back later when the activity has finished. An example of this type of activity is the `DelayActivity`.

CallExternalMethodActivity

A workflow will typically need to call methods outside of the workflow, and this activity allows you to define an interface and a method to call on that interface. The `WorkflowRuntime` maintains a list of services (keyed on a `System.Type` value) that can be accessed by using the `ActivityExecutionContext` parameter passed to the `Execute` method.

You can define your own services to add to this collection and then access these services from within your own activities. You could, for example, construct a data access layer exposed as a service interface and then provide different implementations of this service for SQL Server and Oracle. Because the activities simply call interface methods, the swap from SQL Server to Oracle would be opaque to the activities.

When you add a `CallExternalMethodActivity` to your workflow, you then define the two mandatory properties of `InterfaceType` and `MethodName`. The interface type defines which runtime service will be used when the activity executes, and the method name defines which method of that interface will be called.

When this activity executes, it looks up the service with the defined interface by querying the execution context for that service type, and it then calls the appropriate method on that interface. You can also pass parameters to the method from within the workflow — this is discussed later in the section titled "Binding Parameters to Activities."

DelayActivity

Business processes often need to wait for a period of time before completing. Consider using a workflow for expense approval. Your workflow might send an e-mail to your immediate manager asking him or her to approve your expense claim. The workflow then enters a waiting state, where it either waits for approval (or, horror of horrors, rejection), but it would also be nice to define a timeout so that if no response is returned within, say, one day, the expense claim is then routed to the next manager up the chain of command.

The `DelayActivity` can form part of this scenario (the other part is the `ListenActivity`, defined later). Its job is to wait for a predefined time before continuing execution of the workflow. There are two ways to define the duration of the delay — you can either set the `TimeoutDuration` property of the delay to a string, such as “1.00:00:00” (1 day, no hours, minutes, or seconds), or you can provide a method that is called when the activity is executed that sets the duration to a value from code. To do this, you need to define a value for the `InitializeTimeoutDuration` property of the delay activity. This creates a method in the code-behind, as shown in the following snippet:

```
private void DefineTimeout(object sender, EventArgs e)
{
    DelayActivity delay = sender as DelayActivity;

    if (null != delay)
     {
        delay.TimeoutDuration = new TimeSpan(1, 0, 0, 0);
     }
}
```

Here, the `DefineTimeout` method casts the sender to a `DelayActivity` and then sets the `TimeoutDuration` property in code to a `TimeSpan`. Even though the value is hard-coded here, it is more likely that you would construct this from some other data — maybe a parameter passed into the workflow or a value read from the configuration file. Workflow parameters are discussed in the section “Workflows” later in the chapter.

ListenActivity

A common programming construct is to wait for one of a set of possible events — one example of this is the `WaitAny` method of the `System.Threading.WaitHandle` class. The `ListenActivity` is the way to do this in a workflow, because it can define any number of branches, each with an event-based activity as that branch’s first activity.

An event activity is one that implements the `IEventActivity` interface defined in the `System.Workflow.Activities` namespace. There are currently three such activities defined as standard in WF — `DelayActivity`, `HandleExternalEventActivity`, and the `WebServiceInputActivity`. Figure 57-6 shows a workflow that is waiting for either external input or a delay — this is an example of the expense approval workflow discussed earlier.

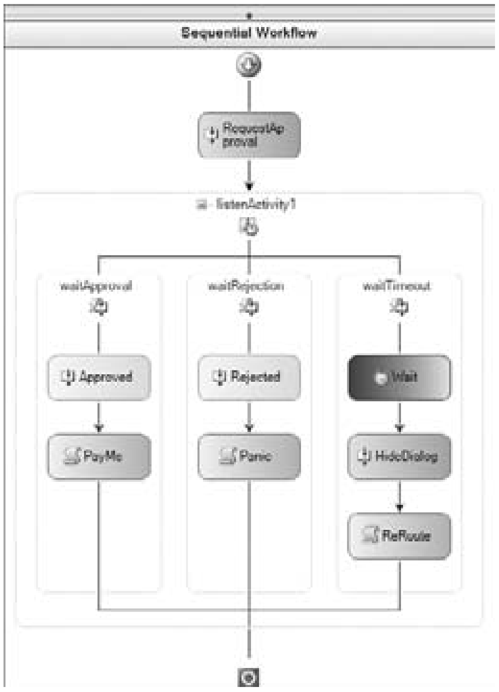

FIGURE 57-6

In the example, the `CallExternalMethodActivity` is used as the first activity in the workflow. This calls a method defined on a service interface that would prompt the manager for approval or rejection. Because this is an external service, this prompt could be an e-mail, an IM message, or any other manner of notifying your manager that an expense claim needs to be processed. The workflow then executes the `ListenActivity`, which awaits input from this external service (either an approval or a rejection), and also waits on a delay.

When the listen executes, it effectively queues a wait on the first activity in each branch, and when one event is triggered, this cancels all other waiting events and then processes the rest of the branch where the event was raised. So, in the instance where the expense report is approved, the `Approved` event is raised and the `PayMe` activity is then scheduled. If, however, your manager rejects the claim, the `Rejected` event is raised, and in the example you then `Panic`.

Last, if neither the `Approved` nor `Rejected` event is raised, the `DelayActivity` ultimately completes after its delay expires, and the expense report could then be routed to another manager — potentially looking up that person in Active Directory. In the example, a dialog is displayed to the user when the `RequestApproval` activity is executed, so if the delay executes, you also need to close the dialog, which is the purpose of the activity named `HideDialog` in Figure 57-6.

The code for this example is available in the `02 Listen` directory. Some concepts used in that example have not been covered yet — such as how a workflow instance is identified and how events are raised back into the workflow runtime and ultimately delivered to the right workflow instance. These concepts are covered in the section titled "Workflows."

Activity Execution Model

So far, this chapter has discussed the execution of an activity only by the runtime calling the `Execute` method. However, an activity may go through a number of states while it executes — these are presented in Figure 57-7.

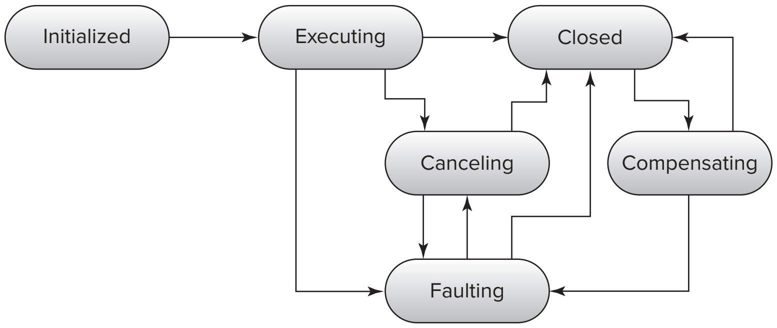

FIGURE 57-7

An activity is first initialized by the `WorkflowRuntime` when the runtime calls the activity's `Initialize` method. This method is passed an `IServiceProvider` instance, which maps to the services available within the runtime. These services are discussed in the "Workflow Services" section later in the chapter. Most activities do nothing in this method, but the method is there for you to do any setup necessary.

The runtime then calls the `Execute` method, and the activity can return any one of the values from the `ActivityExecutionStatus` enum. Typically, you will return `Closed` from your `Execute` method, which indicates that your activity has finished processing; however, if you return one of the other status values, the runtime will use this to determine what state your activity is in.

You can return `Executing` from this method to indicate to the runtime that you have extra work to do — a typical example of this is when you have a composite activity that needs to execute its children. In this case, your activity can schedule each child for execution and then wait for all children to complete before notifying the runtime that your activity has completed.

CUSTOM ACTIVITIES

So far, you have used activities that are defined within the `System.Workflow.Activities` namespace. In this section, you learn how to create custom activities and extend these activities to provide a good user experience at both design time and runtime.

To begin, you create a `WriteLineActivity` that can be used to output a line of text to the console. Although this is a trivial example, it will be expanded to show the full gamut of options available for custom activities using this example. When creating custom activities, you can simply construct a class within a workflow project; however, it is preferable to construct your custom activities inside a separate assembly, because the Visual Studio design time environment (and specifically workflow projects) will load activities from your assemblies and can lock the assembly that you are trying to update. For this reason, you should create a simple class library project to construct your custom activities within.

A simple activity such as the `WriteLineActivity` will be derived directly from the `Activity` base class. The following code shows a constructed activity class and defines a `Message` property that is displayed when the `Execute` method is called:

```
using System;
using System.ComponentModel;
using System.Workflow.ComponentModel;

namespace SimpleActivity
{
  /// <summary>
  /// A simple activity that displays a message to the console when it executes
  /// </summary>
  public class WriteLineActivity: Activity
  {
    /// <summary>
    /// Execute the activity – display the message on screen
    /// </summary>
    /// <param name="executionContext"></param>
    /// <returns></returns>
    protected override ActivityExecutionStatus Execute
     (ActivityExecutionContext executionContext)
    {
      Console.WriteLine(Message);

      return ActivityExecutionStatus.Closed;
    }

    /// <summary>
    /// Get/Set the message displayed to the user
    /// </summary>
    [Description("The message to display")]
    [Category("Parameters")]
    public string Message
    {
      get { return _message; }
      set { _message = value; }
    }

    /// <summary>
    /// Store the message displayed to the user
    /// </summary>
    private string _message;
  }
}
```

Within the `Execute` method, you can write the message to the console and then return a status of `Closed` to notify the runtime that the activity has completed.

You can also define attributes on the `Message` property so that a description and category are defined for that property. This is used in the property grid within Visual Studio, as shown in Figure 57-8.

The code for the activities created in this section is in the `03 CustomActivities` solution. If you compile that solution, you can then add the custom activities to the toolbox within Visual Studio by choosing the Choose Items menu item from the context menu on the toolbox and navigating to the folder where the assembly containing the activities resides. All activities within the assembly will be added to the toolbox.

As it stands, the activity is perfectly usable; however, there are several areas that should be addressed to make this more user-friendly. As you saw with the `CodeActivity` earlier in the chapter, it has some mandatory properties that, when not defined, produce an error glyph on the design surface. To get the same behavior from your activity, you need to construct a class that derives from `ActivityValidator` and associate this class with your activity.

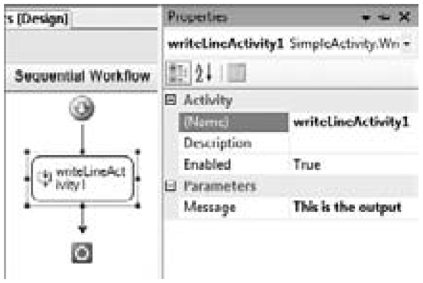

FIGURE 57-8

Activity Validation

When an activity is placed onto the design surface, the Workflow Designer looks for an attribute on that activity that defines a class that performs validation on that activity. To validate your activity, you need to check if the `Message` property has been set.

A custom validator is passed the activity instance, and from this you can then determine which mandatory properties (if any) have not been defined and add an error to the `ValidationErrorCollection` used by the Designer. This collection is then read by the Workflow Designer, and any errors found in the collection will cause a glyph to be added to the activity and optionally link each error to the property that needs attention.

```
using System;
using System.Workflow.ComponentModel.Compiler;

namespace SimpleActivity
{
  public class WriteLineValidator: ActivityValidator
  {
    public override ValidationErrorCollection Validate
      (ValidationManager manager, object obj)
    {
      if (null == manager)
        throw new ArgumentNullException("manager");
      if (null == obj)
        throw new ArgumentNullException("obj");

      ValidationErrorCollection errors = base.Validate(manager, obj);

      // Coerce to a WriteLineActivity
      WriteLineActivity act = obj as WriteLineActivity;

      if (null != act)
      {
        if (null != act.Parent)
        {
          // Check the Message property
          if (string.IsNullOrEmpty(act.Message))
            errors.Add(ValidationError.GetNotSetValidationError("Message"));
        }
      }

      return errors;
    }
  }
}
```

The `Validate` method is called by the Designer when any part of the activity is updated and also when the activity is dropped onto the design surface. The Designer calls the `Validate` method and passes through the activity as the untyped `obj` parameter.

In this method, first validate the arguments passed in, and then call the base class `Validate` method to obtain a `ValidationErrorCollection`. Although this is not strictly necessary here, if you are deriving from an activity that has a number of properties that also need to be validated, calling the base class method will ensure that these are also checked.

The code then coerces the passed `obj` parameter into a `WriteLineActivity` instance, and also checks if the activity has a parent. This test is necessary because the `Validate` function is called during compilation of the activity (if the activity is within a workflow project or activity library), and, at this point, no parent activity has been defined. Without this check, you cannot actually build the assembly that contains the activity and the validator. This extra step is not needed if the project type is class library.

The last step is to check that the `Message` property has been set to a value other than an empty string. This uses a static method of the `ValidationError` class, which constructs an error that specifies that the property has not been defined.

To add validation support to your `WriteLineActivity`, the last step is to add the `ActivityValidation` attribute to the activity, as shown in the following snippet:

```
 [ActivityValidator(typeof(WriteLineValidator))]
public class WriteLineActivity: Activity
{
  .
}
```

If you compile the application and then drop a `WriteLineActivity` onto the workflow, you should see a validation error, as shown in Figure 57-9; clicking this error will take you to that property within the property grid.

If you enter some text for the `Message` property, the validation error will be removed, and you can then compile and run the application.

Now that you have completed the activity validation, the next thing to do is to change the rendering behavior of the activity to add a fill color to that activity. To do this, you need to define both an `ActivityDesigner` class and an `ActivityDesignerTheme` class, as described in the next section.

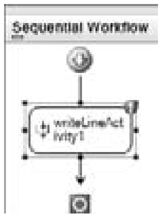

FIGURE 57-9

Themes and Designers

The onscreen rendering of an activity is performed by using an `ActivityDesigner` class, and this can also use an `ActivityDesignerTheme`.

The theme class is used to make simple changes to the rendering behavior of the activity within the Workflow Designer:

```
public class WriteLineTheme: ActivityDesignerTheme
{
  /// <summary>
  /// Construct the theme and set some defaults
  /// </summary>
  /// <param name="theme"></param>
  public WriteLineTheme(WorkflowTheme theme)
  : base(theme)
  {
    this.BackColorStart = Color.Yellow;
    this.BackColorEnd = Color.Orange;
    this.BackgroundStyle = LinearGradientMode.ForwardDiagonal;
  }
}
```

A theme is derived from `ActivityDesignerTheme`, which has a constructor that is passed a `WorkflowTheme` argument. Within the constructor, set the start and end colors for the activity, and then define a linear gradient brush, which is used when painting the background.

The `Designer` class is used to override the rendering behavior of the activity. In this case, no override is necessary, so the following code will suffice:

```
 [ActivityDesignerTheme(typeof(WriteLineTheme))]
public class WriteLineDesigner: ActivityDesigner
{
}
```

Note that the theme has been associated with the Designer by using the `ActivityDesignerTheme` attribute.

The last step is to adorn the activity with the `Designer` attribute:

```
 [ActivityValidator(typeof(WriteLineValidator))]
[Designer(typeof(WriteLineDesigner))]
public class WriteLineActivity: Activity
{
  .
}
```

With this in place, the activity is rendered as shown in Figure 57-10.

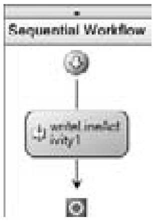

FIGURE 57-10

With the addition of the Designer and the theme, the activity now looks much more professional. A number of other properties are available on the theme — such as the pen used to render the border, the color of the border, and the border style.

By overriding the `OnPaint` method of the `ActivityDesigner` class, you can have complete control over the rendering of the activity. Be sure to exercise restraint here, because you could get carried away and create an activity that doesn't resemble any of the other activities in the toolbox.

One other useful override on the `ActivityDesigner` class is the `Verbs` property. This allows you to add menu items on the context menu for the activity. It is used by the Designer of the `ParallelActivity` to insert the Add Branch menu item into the activities context menu and also the Workflow menu. You can also alter the list of properties exposed for an activity by overriding the `PreFilterProperties` method of the Designer — this is how the method parameters for the `CallExternalMethodActivity` are surfaced into the property grid. If you need to do this type of extension to your Designer, you should run Red Gate's Reflector (available from `http://reflector.red-gate.com`) and load the workflow assemblies into it to see how Microsoft has defined some of these extended properties.

This activity is nearly done, but now you need to define the icon used when rendering the activity and also the toolbox item to associate with the activity.

ActivityToolboxItem and Icons

To complete your custom activity, you need to add an icon. You can optionally create a class deriving from `ActivityToolboxItem` that is used when displaying the activity in the toolbox within Visual Studio.

To define an icon for an activity, create a 16×16 pixel image and include it in your project. When it has been included, set the build action for the image to `Embedded Resource`. This will include the image in the manifest resources for the assembly. You can add a folder to your project called Resources, as shown in Figure 57-11.

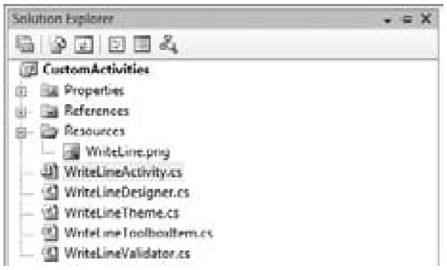

FIGURE 57-11

Once you have added the image file and set its build action to `Embedded Resource`, you can then attribute the activity as shown in the following snippet:

```
 [ActivityValidator(typeof(WriteLineValidator))]
[Designer(typeof(WriteLineDesigner))]
[ToolboxBitmap(typeof(WriteLineActivity),"Resources.WriteLine.png")]
public class WriteLineActivity: Activity
{
  .
}
```

The `ToolboxBitmap` attribute has a number of constructors defined, and the one being used here takes a type defined in the activity assembly and the name of the resource. When you add a resource to a folder, its name is constructed from the namespace of the assembly and the name of the folder that the image resides within — so the fully qualified name for the resource here is `CustomActivities.Resources.WriteLine.png`. The constructor used with the `ToolboxBitmap` attribute appends the namespace that the type parameter resides within to the string passed as the second argument, so this will resolve to the appropriate resource when loaded by Visual Studio.

The last class you need to create is derived from `ActivityToolboxItem`. This class is used when the activity is loaded into the Visual Studio toolbox. A typical use of this class is to change the displayed name of the activity on the toolbox — all of the built-in activities have their names changed to remove the word "Activity" from the type. In your class, you can do the same by setting the `DisplayName` property to "WriteLine."

```
 [Serializable]
public class WriteLineToolboxItem: ActivityToolboxItem
{
    /// <summary>
    /// Set the display name to WriteLine — i.e. trim off
    /// the 'Activity' string
    /// </summary>
    /// <param name="t"></param>
    public WriteLineToolboxItem(Type t)
      : base(t)
    {
        base.DisplayName = "WriteLine";
    }

    /// <summary>
    /// Necessary for the Visual Studio design time environment
    /// </summary>
    /// <param name="info"></param>
    /// <param name="context"></param>
    private WriteLineToolboxItem(SerializationInfo info,
                                 StreamingContext context)
    {
        this.Deserialize(info, context);
    }
}
```

The class is derived from `ActivityToolboxItem` and overrides the constructor to change the display name; it also provides a serialization constructor that is used by the toolbox when the item is loaded into the toolbox. Without this constructor, you will receive an error when you attempt to add the activity to the toolbox. Note that the class is also marked as `[Serializable]`.

The toolbox item is added to the activity by using the `ToolboxItem` attribute as shown:

```
 [ActivityValidator(typeof(WriteLineValidator))]
[Designer(typeof(WriteLineDesigner))]
[ToolboxBitmap(typeof(WriteLineActivity),"Resources.WriteLine.png")]
[ToolboxItem(typeof(WriteLineToolboxItem))]
public class WriteLineActivity: Activity
{
  .
}
```

With all of these changes in place, you can compile the assembly and then create a new workflow project. To add the activity to the toolbox, open a workflow and then display the context menu for the toolbox and click Choose Items.

You can then browse for the assembly containing your activity, and once you have added it to the toolbox, it will look something like Figure 57-12. The icon is somewhat less than perfect, but it's close enough.

FIGURE 57-12

You revisit the `ActivityToolboxItem` in the next section on custom composite activities, because there are some extra facilities available with that class that are necessary only when adding composite activities to the design surface.

To recap, you've created a custom `WriteLineActivity`, added validation logic by creating the `WriteLineValidator`, created a designer and a theme with the `WriteLineDesigner` and `WriteLineTheme` classes, created a bitmap for the activity, and lastly created the `WriteLineToolboxItem` class to alter the display name of the activity.

Custom Composite Activities

There are two main types of activity. Activities that derive from `Activity` can be thought of as callable functions from the workflow. Activities that derive from `CompositeActivity` (such as `ParallelActivity`, `IfElseActivity`, and the `ListenActivity`) are containers for other activities. Their design-time behavior is considerably different from simple activities in that they present an area on the Designer where child activities can be dropped.

In this section, you create an activity that you can call the `DaysOfWeekActivity`. This activity can be used to execute different parts of a workflow based on the current date. You might, for instance, need to execute a different path in the workflow for orders that arrive over the weekend than for those that arrive during the week. In this example, you learn about a number of advanced workflow topics, and by the end of this section, you should have a good understanding of how to extend the system with your own composite activities. The code for this example is also available in the `03 CustomActivities` solution.

To begin, you create a custom activity that has a property that will default to the current date/time. You will allow that property to be set to another value that could come from another activity in the workflow or a parameter that is passed to the workflow when it executes. This composite activity will contain a number of branches — these will be user defined. Each of these branches will contain an enumerated constant that defines which day(s) that branch will execute. The following example defines the activity and two branches:

```
DaysOfWeekActivity
  SequenceActivty: Monday, Tuesday, Wednesday, Thursday, Friday
    <other activites as appropriate>
  SequenceActivity: Saturday, Sunday
    <other activites as appropriate>
```

For this example, you need an enumeration that defines the days of the week — this will include the `[Flags]` attribute (so you can't use the built-in `DayOfWeek` enum defined within the `System` namespace, because this doesn't include the `[Flags]` attribute).

```
 [Flags]
[Editor(typeof(FlagsEnumEditor), typeof(UITypeEditor))]
public enum WeekdayEnum: byte
{
    None = 0x00,
    Sunday = 0x01,
    Monday = 0x02,
    Tuesday = 0x04,
    Wednesday = 0x08,
    Thursday = 0x10,
    Friday = 0x20,
    Saturday = 0x40
}
```

Also included is a custom editor for this type, which will allow you to choose enum values based on check boxes. This code is available in the download.

With the enumerated type defined, you can take an initial stab at the activity itself. Custom composite activities are typically derived from the `CompositeActivity` class, because this defines, among other things, an `Activities` property, which is a collection of all subordinate activities.

```
public class DaysOfWeekActivity: CompositeActivity
{
    /// <summary>
    /// Get/Set the day of week property
    /// </summary>
    [Browsable(true)]
    [Category("Behavior")]
    [Description("Bind to a DateTime property, set a specific date time,
                  or leave blank for DateTime.Now")]
    [DefaultValue(typeof(DateTime),"")]
    public DateTime Date
    {
        get { return (DateTime)
                base.GetValue(DaysOfWeekActivity.DateProperty); }
        set { base.SetValue(DaysOfWeekActivity.DateProperty, value); }
    }

    /// <summary>
    /// Register the DayOfWeek property
    /// </summary>
    public static DependencyProperty DateProperty =
        DependencyProperty.Register("Date", typeof(DateTime),
            typeof(DaysOfWeekActivity));
}
```

The `Date` property provides the regular getter and setter, and we've also added a number of standard attributes so that it displays correctly within the property browser. The code, though, looks somewhat different from a normal .NET property, because the getter and setter are not using a standard field to store their values, but instead are using what's called a `DependencyProperty`.

The `Activity` class (and therefore this class, because it's ultimately derived from `Activity`) is derived from the `DependencyObject` class, and this defines a dictionary of values keyed on a `DependencyProperty`. This indirection of getting/setting property values is used by WF to support binding; that is, linking a property of one activity to a property of another. As an example, it is common to pass parameters around in code, sometimes by value, sometimes by reference. WF uses binding to link property values together — so in this example, you might have a `DateTime` property defined on the workflow, and this activity might need to be bound to that value at runtime. You see an example of binding later in the chapter.

If you build this activity, it won't do much; indeed it will not even allow child activities to be dropped into it, because you haven't defined a `Designer` class for the activity.

Adding a Designer

As you saw with the `WriteLineActivity` earlier in the chapter, each activity can have an associated `Designer` class, which is used to change the design-time behavior of that activity. You saw a blank `Designer` in the `WriteLineActivity`, but for the composite activity you need to override a couple of methods to add some special case processing:

```
public class DaysOfWeekDesigner: ParallelActivityDesigner
{
    public override bool CanInsertActivities
        (HitTestInfo insertLocation, ReadOnlyCollection<Activity> activities)
    {
        foreach (Activity act in activities)
```

```
            {
                if (!(act is SequenceActivity))
                    return false;
            }

            return base.CanInsertActivities(insertLocation, activitiesToInsert);
        }

        protected override CompositeActivity OnCreateNewBranch()
        {
            return new SequenceActivity();
        }
    }
```

This `Designer` derives from `ParallalActivityDesigner`, which provides you with good design-time behavior when adding child activities. You will need to override `CanInsertActivities` to return `false` if any of the dropped activities is not a `SequenceActivity`. If all activities are of the appropriate type, you can call the base class method, which makes some further checks on the activity types permitted within your custom activity.

You should also override the `OnCreateNewBranch` method that is called when the user chooses the Add Branch menu item. The `Designer` is associated with the activity by using the `[Designer]` attribute, as shown here:

```
     [Designer(typeof(DaysOfWeekDesigner))]
    public class DaysOfWeekActivity: CompositeActivity
    {
    }
```

The design-time behavior is nearly complete; however, you also need to add a class that is derived from `ActivityToolboxItem` to this activity, because that defines what happens when an instance of that activity is dragged from the toolbox. The default behavior is simply to construct a new activity; however, in the example you also want to create two default branches. The following code shows the toolbox item class in its entirety:

```
     [Serializable]
    public class DaysOfWeekToolboxItem: ActivityToolboxItem
    {
        public DaysOfWeekToolboxItem(Type t)
          : base(t)
        {
            this.DisplayName = "DaysOfWeek";
        }

        private DaysOfWeekToolboxItem(SerializationInfo info,
                                      StreamingContext context)
        {
            this.Deserialize(info, context);
        }

        protected override IComponent[] CreateComponentsCore(IDesignerHost host)
        {
            CompositeActivity parent = new DaysOfWeekActivity();
            parent.Activities.Add(new SequenceActivity());
            parent.Activities.Add(new SequenceActivity());

            return new IComponent[] { parent };
        }
    }
```

As shown in the code, the display name of the activity was changed, a serialization constructor was implemented, and the `CreateComponentsCore` method was overridden.

This method is called at the end of the drag-and-drop operation, and it is where you construct an instance of the `DaysOfWeekActivity`. In the code, you are also constructing two child sequence activities, because this gives the user of the activity a better design-time experience. Several of the built-in activities do this, too — when you drop an `IfElseActivity` onto the design surface, its toolbox item class adds two branches. A similar thing happens when you add a `ParallelActivity` to your workflow.

The serialization constructor and the `[Serializable]` attribute are necessary for all classes derived from `ActivityToolboxItem`.

The last thing to do is associate this toolbox item class with the activity:

```
 [Designer(typeof(DaysOfWeekDesigner))]
[ToolboxItem(typeof(DaysOfWeekToolboxItem))]
public class DaysOfWeekActivity: CompositeActivity
{
}
```

With that in place, the UI of your activity is almost complete, as you can see in Figure 57-13.

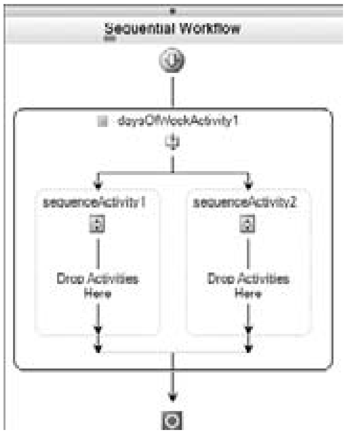

FIGURE 57-13

Now, you need to define a property on each of the sequence activities shown in Figure 57-13, so that the user can define which day(s) the branch will execute. There are two ways to do this in Windows Workflow: you can create a subclass of `SequenceActivity` and define it there, or you can use another feature of dependency properties called Attached Properties.

You will use the latter method, because this means that you don't have to subclass but instead can effectively extend the sequence activity without needing the source code of that activity.

Attached Properties

When registering dependency properties, you can call the `RegisterAttached` method to create an attached property. An attached property is one that is defined on one class but is displayed on another. So here, you define a property on the `DaysOfWeekActivity`, but that property is actually displayed in the UI as attached to a sequential activity.

The code in the following snippet shows a property called `Weekday` of type `WeekdayEnum`, which will be added to the sequence activities that reside within your composite activity:

```
public static DependencyProperty WeekdayProperty =
    DependencyProperty.RegisterAttached("Weekday",
        typeof(WeekdayEnum), typeof(DaysOfWeekActivity),
        new PropertyMetadata(DependencyPropertyOptions.Metadata));
```

The final line allows you to specify extra information about a property. In this instance, it is specifying that it is a `Metadata` property.

Metadata properties differ from normal properties in that they are effectively read only at runtime. You can think of a `Metadata` property as similar to a constant declaration within C#. You cannot alter constants while the program is executing, and you cannot change `Metadata` properties while a workflow is executing.

In this example, you wish to define the days that the activity will execute, so you could in the Designer set this field to "Saturday, Sunday". In the code emitted for the workflow, you would see a declaration as follows (I have reformatted the code to fit the confines of the page):

```
this.sequenceActivity1.SetValue
  (DaysOfWeekActivity.WeekdayProperty,
  ((WeekdayEnum)((WeekdayEnum.Sunday | WeekdayEnum.Saturday))));
```

In addition to defining the dependency property, you will need methods to get and set this value on an arbitrary activity. These are typically defined as static methods on the composite activity and are shown in the following code:

```
public static void SetWeekday(Activity activity, object value)
{
    if (null == activity)
        throw new ArgumentNullException("activity");
    if (null == value)
        throw new ArgumentNullException("value");

    activity.SetValue(DaysOfWeekActivity.WeekdayProperty, value);
}

public static object GetWeekday(Activity activity)
{
    if (null == activity)
        throw new ArgumentNullException("activity");

    return activity.GetValue(DaysOfWeekActivity.WeekdayProperty);
}
```

You need to make two other changes in order for this extra property to show up attached to a `SequenceActivity`. The first is to create an *extender provider,* which tells Visual Studio to include the extra property in the sequence activity. The second is to register this provider, which is done by overriding the `Initialize` method of the Activity Designer and adding the following code to it:

```
protected override void Initialize(Activity activity)
{
    base.Initialize(activity);

    IExtenderListService iels = base.GetService(typeof(IExtenderListService))
        as IExtenderListService;

    if (null != iels)
    {
        bool extenderExists = false;

        foreach (IExtenderProvider provider in iels.GetExtenderProviders())
        {
            if (provider.GetType() == typeof(WeekdayExtenderProvider))
            {
                extenderExists = true;
                break;
            }
        }
        if (!extenderExists)
        {
            IExtenderProviderService ieps =
                base.GetService(typeof(IExtenderProviderService))
                    as IExtenderProviderService;
            if (null != ieps)
                ieps.AddExtenderProvider(new WeekdayExtenderProvider());
        }
    }
}
```

The calls to `GetService` in the preceding code allow the custom Designer to query for services proffered by the host (in this case Visual Studio). You query Visual Studio for the `IExtenderListService`, which provides a way to enumerate all available extender providers, and if no instance of the `WeekdayExtenderProvider` service is found, then query for the `IExtenderProviderService` and add a new provider.

The code for the extender provider is shown here:

```
 [ProvideProperty("Weekday", typeof(SequenceActivity))]
public class WeekdayExtenderProvider: IExtenderProvider
{
    bool IExtenderProvider.CanExtend(object extendee)
    {
        bool canExtend = false;

        if ((this != extendee) && (extendee is SequenceActivity))
        {
            Activity parent = ((Activity)extendee).Parent;

            if (null != parent)
                canExtend = parent is DaysOfWeekActivity;
        }

        return canExtend;
    }

    public WeekdayEnum GetWeekday(Activity activity)
    {
        WeekdayEnum weekday = WeekdayEnum.None;

        Activity parent = activity.Parent;

        if ((null != parent) && (parent is DaysOfWeekActivity))
            weekday = (WeekdayEnum)DaysOfWeekActivity.GetWeekday(activity);

        return weekday;
    }

    public void SetWeekday(Activity activity, WeekdayEnum weekday)
    {
        Activity parent = activity.Parent;

        if ((null != parent) && (parent is DaysOfWeekActivity))
            DaysOfWeekActivity.SetWeekday(activity, weekday);

    }
}
```

An extender provider is attributed with the properties that it provides, and for each of these properties it must provide a public `Get<Property>` and `Set<Property>` method. The names of these methods must match the name of the property with the appropriate *Get* or *Set* prefix.

With the preceding changes made to the Designer and the addition of the extender provider, when you add a sequence activity within the Designer (shown here as sequenceActivity1), you will see the properties in Figure 57-14 within Visual Studio.

Extender providers are used for other features in .NET. One common one is to add tooltips to controls in a Windows Forms project — this registers an extender and adds a `Tooltip` property to each control on the form.

FIGURE 57-14

WORKFLOWS

Up to this point, the chapter has concentrated on activities but has not discussed workflows. A workflow is simply a list of activities, and indeed a workflow itself is just another type of activity. Using this model simplifies the runtime engine, because the engine just needs to know how to execute one type of object — that being anything derived from the `Activity` class.

Each workflow instance is uniquely identified by its `InstanceId` property — this is a `Guid` that can be assigned by the runtime, or this `Guid` can be provided to the runtime by your code. A common use of this is to correlate a running workflow instance with some other data maintained outside of the workflow, such as a row in a database. You can access the specific workflow instance by using the `GetWorkflow(Guid)` method of the `WorkflowRuntime` class.

Two types of workflows are available with WF — sequential and state machine.

Sequential Workflows

The root activity in a sequential workflow is the `SequentialWorkflowActivity`. This class is derived from `SequenceActivity`, which you have already seen, and it defines two events that you can attach handlers to as necessary. These are the `Initialized` and `Completed` events.

A sequential workflow starts executing the first child activity within it, and typically continues until all other activities have executed. There are a couple of instances when a workflow will not continue through all activities — one is if an exception is raised while executing the workflow, and the other is if a `TerminateActivity` exists within the workflow.

A workflow may not be executing at all times. For example, when a `DelayActivity` is encountered, the workflow will enter a wait state and can be removed from memory if a workflow persistence service is defined. Persistence of workflows is covered in “The Persistence Service” section later in this chapter.

State Machine Workflows

A state machine workflow is useful when you have a process that may be in one of several states, and transitions from one state to another can be made by passing data into the workflow.

One example is when a workflow is used for access control to a building. In this case, you may model a door class that can be closed or open, and a lock class that can be locked or unlocked. Initially when you boot up the system (or building!), you start at a known state — for sake of argument, assume that all doors are closed and locked, so the state of a given door is *closed locked*.

When an employee enters his or her building access code at the front door, an event is sent to the workflow, which includes details such as the code entered and possibly the user ID. You might then need to access a database to retrieve details such as whether that person is permitted to open the selected door at that time of day, and assuming that access is granted, the workflow would change from its initial state to the *closed unlocked* state.

From this state, there are two potential outcomes — the employee opens the door (you know this because the door also has an open/closed sensor), or the employee decides not to enter because he has left something in his car, and so after a delay you relock the door. The door could revert to its *closed locked* state or move to the *open unlocked* state.

From here, assume that the employee enters the building and then closes the door. Again, you would then like to transition from the *open unlocked* state to *closed unlocked,* and again, after a delay, would then transition to the *closed locked* state. You might also want to raise an alarm if the door was *open unlocked* for a long period.

Modeling this scenario within Windows Workflow is fairly simple. You need to define the states that the system can be in, and then define events that can transition the workflow from one state to the next. The following table describes the states of the system and provides details of the transitions that are possible from each known state and the inputs (either external or internal) that change the states.

STATE	TRANSITIONS
Closed Locked	This is the initial state of the system. In response to the user swiping her card (and a successful access check), the state changes to closed unlocked, and the door lock is electronically opened.
Closed Unlocked	One of two events can occur when the door is in this state: The user opens the door — you transition to the open unlocked state. A timer expires, and the door reverts to the closed locked state.
Open Unlocked	From this state, the workflow can only transition to closed unlocked.
Fire Alarm	This is the final state for the workflow and can be transitioned to from any of the other states.

One other feature you might want to add to the system is the capability to respond to a fire alarm. When the fire alarm goes off, you would want to unlock all of the doors so that anyone can exit the building, and the fire service can enter the building unimpeded. You might want to model this as the final state of the doors workflow, because from this state the full system would be reset once the fire alarm had been canceled.

The workflow in Figure 57-15 defines this state machine and shows the states that the workflow can be in. The lines denote the state transitions that are possible within the system.

The initial state of the workflow is modeled by the `ClosedLocked` activity. This consists of some initialization code (which locks the door) and then an event-based activity that awaits an external event — in this case, the employee entering his building access code. Each of the activities shown within the state shapes consist of sequential workflows, so we have defined a workflow for the initialization of the system (`CLInitialize`) and a workflow that responds to the external event raised when the employee enters her PIN (`RequestEntry`). If you look at the `RequestEntry` workflow, it is defined as shown in Figure 57-16.

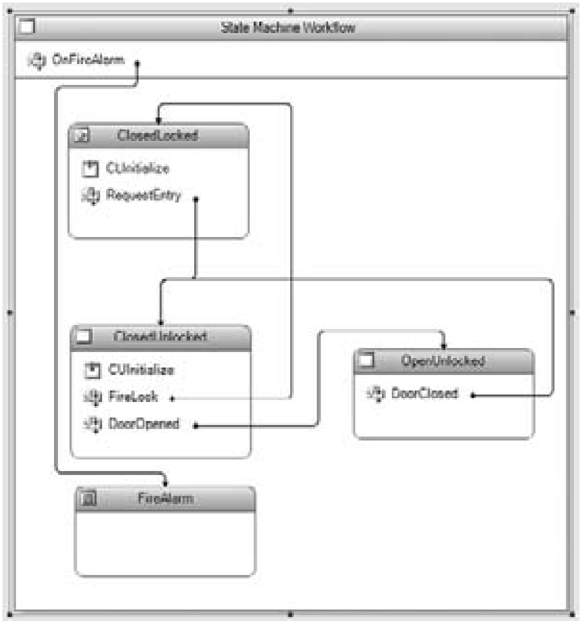

FIGURE 57-15

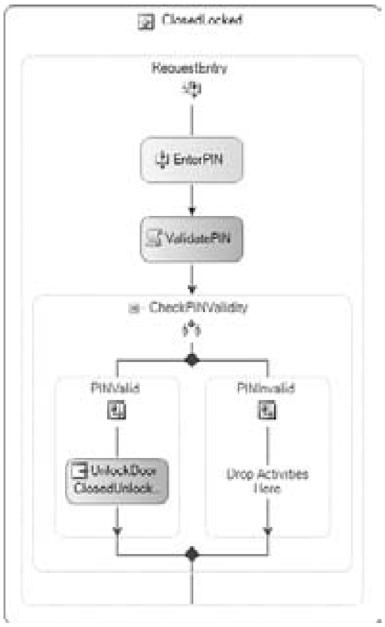

FIGURE 57-16

Each state consists of a number of subworkflows, each of which has an event-driven activity at the start and then any number of other activities that form the processing code within the state. In Figure 57-16, there is a `HandleExternalEventActivity` at the start that awaits the entry of the PIN. This is then checked, and if it is valid, the workflow transitions to the `ClosedUnlocked` state.

The `ClosedUnlocked` state consists of two workflows — one that responds to the door open event, which transitions the workflow to the `OpenUnlocked` state, and another that contains a delay activity that is used to change the state to `ClosedLocked`. A state-driven activity works in a similar manner to the `ListenActivity` shown earlier in the chapter — the state consists of a number of event-driven workflows, and on arrival of an event, just one of the workflows will execute.

To support the workflow, you need to be able to raise events in the system to affect the state changes. This is done by using an interface and an implementation of that interface; this pair of objects is termed an *external service*. The interface used for this state machine is described later in the chapter.

The code for the state machine example is available in the `04 StateMachine` solution. This also includes a user interface in which you can enter a PIN and gain access to the building through one of two doors.

Passing Parameters to a Workflow

A typical workflow requires some data in order to execute. This could be an order ID for an order-processing workflow, a customer account ID for a payment-processing workflow, or any other items of data necessary.

The parameter-passing mechanism for workflows is somewhat different from that of standard .NET classes, in which you typically pass parameters in a method call. For a workflow, you pass parameters by storing those parameters in a dictionary of name-value pairs, and when you construct the workflow, you pass through this dictionary.

When WF schedules the workflow for execution, it uses these name-value pairs to set public properties on the workflow instance. Each parameter name is checked against the public properties of the workflow, and if a match is found, the property setter is called and the value of the parameter is passed to this setter. If you add a name-value pair to the dictionary where the name does not correspond to a property on the workflow, an exception will be thrown when you try to construct that workflow.

As an example, consider the following workflow, which defines the `OrderID` property as an integer:

```
public class OrderProcessingWorkflow: SequentialWorkflowActivity
{
    public int OrderID
    {
        get { return _orderID; }
        set { _orderID = value; }
    }

    private int _orderID;
}
```

The following snippet shows how you can pass the order ID parameter into an instance of this workflow:

```
WorkflowRuntime runtime = new WorkflowRuntime ();

Dictionary<string,object> parms = new Dictionary<string,object>();
parms.Add("OrderID", 12345);

WorkflowInstance instance = runtime.CreateWorkflow(typeof(OrderProcessingWorkflow), parms);

instance.Start();

. Other code
```

In the example code, you construct a `Dictionary<string, object>` that will contain the parameters you wish to pass to the workflow and then use this when the workflow is constructed. The preceding code includes the `WorkflowRuntime` and `WorkflowInstance` classes, which haven't been described yet but are discussed in the "Hosting Workflows" section later in the chapter.

Returning Results from a Workflow

Another common requirement of a workflow is to return output parameters, which might then be used to record data within a database or other persistent storage.

Because a workflow is executed by the workflow runtime, you can't just call a workflow using a standard method invocation — you need to create a workflow instance, start that instance, and then await the completion of that instance. When a workflow completes, the workflow runtime raises the `WorkflowCompleted` event. This is passed contextual information about the workflow that has just completed and contains the output data from that workflow.

So, to harvest the output parameters from a workflow, you need to attach an event handler to the `WorkflowCompleted` event, and the handler can then retrieve the output parameters from the workflow. The following code shows an example of how this can be done:

```
using(WorkflowRuntime workflowRuntime = new WorkflowRuntime())
{
    AutoResetEvent waitHandle = new AutoResetEvent(false);
    workflowRuntime.WorkflowCompleted +=
        delegate(object sender, WorkflowCompletedEventArgs e)
        {
            waitHandle.Set();
            foreach (KeyValuePair<string, object> parm in e.OutputParameters)
            {
                Console.WriteLine("{0} = {1}", parm.Key, parm.Value);
            }
        };

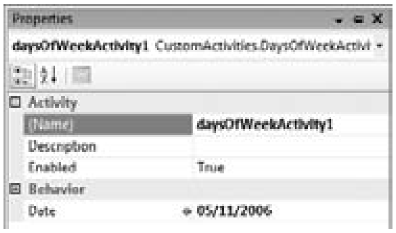
    WorkflowInstance instance =
        workflowRuntime.CreateWorkflow(typeof(Workflow1));
    instance.Start();

    waitHandle.WaitOne();
}
```

You have attached a delegate to the `WorkflowCompleted` event, and within this you iterate through the `OutputParameters` collection of the `WorkflowCompletedEventArgs` class passed to the delegate and display the output parameters on the console. This collection contains all public properties of the workflow. There is actually no notion of specific output parameters for a workflow.

Binding Parameters to Activities

Now that you know how to pass parameters into a workflow, you also need to know how to link these parameters to activities. This is done via a mechanism called binding. In the `DaysOfWeekActivity` defined earlier, there was a `Date` property that could be hard-coded or bound to another value within the workflow. A bindable property is displayed in the property grid within Visual Studio, as shown in Figure 57-17. In the image the `Date` property is bindable, as indicated by the small icon to the right of the property name.



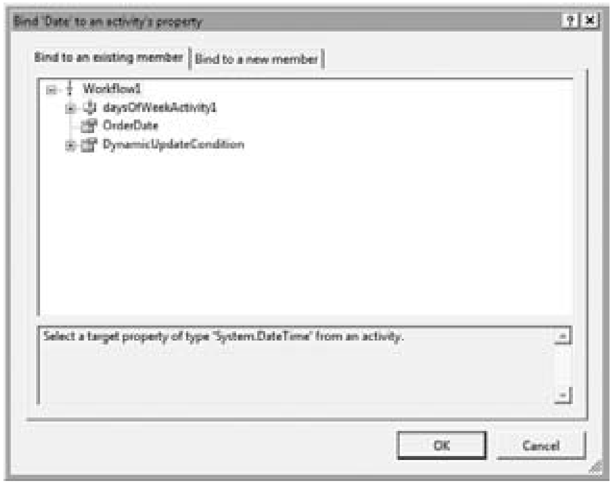
daysOfWeekActivity1 CustomActivities.DaysOfWeekActivi

Activity	
(Name)	daysOfWeekActivity1
Description	
Enabled	True
Behavior	
Date	05/11/2006

FIGURE 57-17

Double-clicking the bind icon will display the dialog shown in Figure 57-18. This dialog allows you to select an appropriate property to link to the `Date` property.

In Figure 57-18, we have selected the `OrderDate` property of a workflow (`OrderDate` is defined as a regular .NET property on the workflow). Any bindable property can be bound to either a property of the workflow that the activity is defined within or a property of any activity that resides in the workflow above the current activity. Note that the data type of the property being bound must match the data type of the property you are binding to — the dialog will not permit you to bind nonmatching types.



Select a target property of type 'System.DateTime' from an activity.

FIGURE 57-18

The code for the `Date` property is shown here to show how binding works and is explained in the following paragraphs:

```
public DateTime Date
{
    get { return (DateTime)base.GetValue(DaysOfWeekActivity.DateProperty); }
    set { base.SetValue(DaysOfWeekActivity.DateProperty, value); }
}
```

When you bind a property in the workflow, an object of type `ActivityBind` is constructed behind the scenes, and it is this "value" that is stored within the dependency property. So, the property setter will be passed an object of type `ActivityBind`, and this is stored within the dictionary of properties on this activity. This `ActivityBind` object consists of data that describes the activity being bound to and the property of that activity that is to be used at runtime.

When reading the value of the property, the `GetValue` method of the `DependencyObject` is called, and this method checks the underlying property value to see if it is an `ActivityBind` object. If so, it resolves the activity to which this binding is linked and then reads the real property value from that activity. If, however, the bound value is another type, it simply returns that object from the `GetValue` method.

THE WORKFLOW RUNTIME

In order to start a workflow, it is necessary to create an instance of the `WorkflowRuntime` class. This is typically done once within your application, and this object is usually defined as a static member of the application so that it can be accessed anywhere within the application.

When you start the runtime, it can then reload any workflow instances that were executing the last time the application was executed by reading these instances from the persistence store. This uses a service called the *persistence service*, which is defined in the following section.

The runtime contains six various `CreateWorkflow` methods that can be used to construct workflow instances. The runtime also contains methods for reloading a workflow instance and enumerating all running instances.

The runtime also has a number of events that are raised while workflows are executing — such as `WorkflowCreated` (raised when a new workflow instance is constructed), `WorkflowIdled` (raised when a workflow is awaiting input such as in the expense-processing example shown earlier), and `WorkflowCompleted` (raised when a workflow has finished).

WORKFLOW SERVICES

A workflow doesn't exist on its own. As described in the previous section, a workflow is executed within the `WorkflowRuntime`, and this runtime provides *services* to running workflows.

A service is any class that may be needed while executing the workflow. Some standard services are provided to your workflow by the runtime, and you can optionally construct your own services to be consumed by running workflows.

This section describes two of the standard services provided by the runtime. It then shows how you can create your own services and some instances of when this is necessary.

When an activity runs, it is passed some contextual information via the `ActivityExecutionStatus` parameter of the `Execute` method:

```
protected override ActivityExecutionStatus Execute
    (ActivityExecutionContext executionContext)
{
    .
}
```

One of the methods available on this context parameter is the `GetService<T>` method. This can be used as shown in the following code to access a service attached to the workflow runtime:

```
protected override ActivityExecutionStatus Execute
    (ActivityExecutionContext executionContext)
{
    ICustomService myService = executionContext.GetService<ICustomService>();
    . Do something with the service
}
```

The services hosted by the runtime are added to the runtime prior to calling the `StartRuntime` method. An exception is raised if you attempt to add a service to the runtime once it has been started.

Two methods are available for adding services to the runtime. You can construct the services in code and then add them to the runtime by calling the `AddService` method. Or, you can define services within the application configuration file, and these will be constructed for you and added to the runtime.

The following code snippet shows how to add services to the runtime in code — the services added are those described later in this section:

```
using(WorkflowRuntime workflowRuntime = new WorkflowRuntime())
{
    workflowRuntime.AddService(
        new SqlWorkflowPersistenceService(conn, true, new TimeSpan(1,0,0),
                                          new TimeSpan(0,10,0)));
    workflowRuntime.AddService(new SqlTrackingService(conn));
    .
}
```

Here are constructed instances of the `SqlWorkflowPersistenceService`, which is used by the runtime to store workflow state, and an instance of the `SqlTrackingService`, which records the execution events of a workflow while it runs.

To create services using an application configuration file, you need to add a section handler for the workflow runtime and then add services to this section as shown here:

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <configSections>
    <section name="WF"
      type="System.Workflow.Runtime.Configuration.WorkflowRuntimeSection,
      System.Workflow.Runtime, Version=3.0.00000.0, Culture=neutral,
      PublicKeyToken=31bf3856ad364e35" />
  </configSections>

  <WF Name="Hosting">
    <CommonParameters/>
      <Services>
        <add type="System.Workflow.Runtime.Hosting.SqlWorkflowPersistenceService,
                   System.Workflow.Runtime, Version=3.0.00000.0, Culture=neutral,
                   PublicKeyToken=31bf3856ad364e35"
          connectionString="Initial Catalog=WF;Data Source=.;
                            Integrated Security=SSPI;"
          UnloadOnIdle="true"
          LoadIntervalSeconds="2"/>
        <add type="System.Workflow.Runtime.Tracking.SqlTrackingService,
                   System.Workflow.Runtime, Version=3.0.00000.0, Culture=neutral,
                   PublicKeyToken=31bf3856ad364e35"
          connectionString="Initial Catalog=WF;Data Source=.;
                            Integrated Security=SSPI;"
          UseDefaultProfile="true"/>
      </Services>
  </WF>
</configuration>
```

Within the configuration file, you have added the `WF` section handler (the name is unimportant but must match the name given to the later configuration section) and then created the appropriate entries for this section. The `<Services>` element can contain an arbitrary list of entries that consist of a .NET type and then parameters that will be passed to that service when constructed by the runtime.

To read the configuration settings from the application configuration file, you call another constructor on the runtime, as shown here:

```
using(WorkflowRuntime workflowRuntime = new WorkflowRuntime("WF"))
{
    .
}
```

This constructor will instantiate each service defined within the configuration file and add these to the services collection on the runtime.

The following sections describe some of the standard services available with WF.

The Persistence Service

When a workflow executes, it may reach a wait state. This can occur when a delay activity executes or when you are waiting for external input within a `ListenActivity`. At this point, the workflow is said to be *idle* and as such is a candidate for persistence.

Let's assume that you begin execution of 1,000 workflows on your server, and each of these instances becomes idle. At this point, it is unnecessary to maintain data for each of these instances in memory, so it would be ideal if you could unload a workflow and free up the resources in use. The persistence service is designed to accomplish this.

When a workflow becomes idle, the workflow runtime checks for the existence of a service that derives from the `WorkflowPersistenceService` class. If this service exists, it is passed the workflow instance, and the service can then capture the current state of the workflow and store it in a persistent storage medium. You could store the workflow state on disk in a file, or store this data within a database such as SQL Server.

The workflow libraries contain an implementation of the persistence service, which stores data within a SQL Server database — this is the `SqlWorkflowPersistenceService`. In order to use this service, you need to run two scripts against your SQL Server instance. One of these constructs the schema, and the other creates the stored procedures used by the persistence service. These scripts are, by default, located in the `C:\Windows\Microsoft.NET\Framework\v3.5\Windows Workflow Foundation\SQL\EN` directory.

The scripts to execute against the database are `SqlPersistenceProviderSchema.sql` and `SqlPersistenceProviderLogic.sql`. These need to be executed in order, with the schema file first and then the logic file. The schema for the SQL persistence service contains two tables: `InstanceState` and `CompletedScope`. These are essentially opaque tables, and they are not intended for use outside the SQL persistence service.

When a workflow idles, its state is serialized using binary serialization, and this data is then inserted into the `InstanceState` table. When a workflow is reactivated, the state is read from this row and used to reconstruct the workflow instance. The row is keyed on the workflow instance ID and is deleted from the database once the workflow has completed.

The SQL persistence service can be used by multiple runtimes at the same time — it implements a locking mechanism so that a workflow is accessible by only one instance of the workflow runtime at a time. When you have multiple servers all running workflows using the same persistence store, this locking behavior becomes invaluable.

To see what is added to the persistence store, construct a new workflow project and add an instance of the `SqlWorkflowPersistenceService` to the runtime. The following code shows an example using declarative code:

```
using(WorkflowRuntime workflowRuntime = new WorkflowRuntime())
{
    workflowRuntime.AddService(
        new SqlWorkflowPersistenceService(conn, true, new TimeSpan(1,0,0),
                                          new TimeSpan(0,10,0)));
    // Execute a workflow here.
}
```

If you then construct a workflow that contains a `DelayActivity` and set the delay to something like 10 seconds, you can then view the data stored within the `InstanceState` table. The `05 WorkflowPersistence` example contains the preceding code and executes a delay within a 20-second period.

The parameters passed to the constructor of the persistence service are shown in the following table.

PARAMETER	DESCRIPTION	DEFAULT
`ConnectionString`	The database connection string used by the persistence service.	None
`UnloadOnIdle`	Determines whether a workflow is unloaded when it idles. This should always be set to true; otherwise no persistence will occur.	False
`InstanceOwnershipDuration`	This defines the length of time that the workflow instance will be owned by the runtime that has loaded that workflow.	None
`LoadingInterval`	The interval used when polling the database for updated persistence records.	2 Minutes

These values can also be defined within the configuration file.

The Tracking Service

When a workflow executes, it might be necessary to record which activities have run, and in the case of composite activities such as the `IfElseActivity` or the `ListenActivity`, which branch was executed. This data could be used as a form of audit trail for a workflow instance, which could then be viewed at a later date to prove which activities executed and what data was used within the workflow. The tracking service can be used for this type of recording and can be configured to log as little or as much information about a running workflow instance as is necessary.

As is common with WF, the tracking service is implemented as an abstract class called `TrackingService`, so it is easy to replace the standard tracking implementation with one of your own. There is one concrete implementation of the tracking service available within the workflow assemblies — this is the `SqlTrackingService`.

To record data about the state of a workflow, it is necessary to define a `TrackingProfile`. This defines which events should be recorded, so you could, for example, record just the start and end of a workflow and omit all other data about the running instance. More typically, you will record all events for the workflow and each activity in that workflow to provide a complete picture of the execution profile of the workflow.

When a workflow is scheduled by the runtime engine, the engine checks for the existence of a workflow tracking service. If one is found, it asks the service for a tracking profile for the workflow being executed, and then uses this to record workflow and activity data. You can, in addition, define user tracking data and store this within the tracking data store without needing to change the schema.

The tracking profile class is shown in Figure 57-19. The class includes collection properties for activity, user, and workflow *track points*. A track point is an object (such as `WorkflowTrackPoint`) that typically defines a *match location* and some extra data to record when this track point is hit. The match location defines where this track point is valid — so for example, you could define a `WorkflowTrackPoint`, which will record some data when the workflow is created, and another to record some data when the workflow is completed.

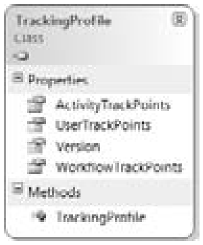


FIGURE 57-19

Once this data has been recorded, it may be necessary to display the execution path of a workflow, as in Figure 57-20. This shows the workflow that was executed, and each activity that ran includes a glyph to show that it executed. This data is read from the tracking store for that workflow instance.

To read the data stored by the `SqlTrackingService`, you could execute queries against the SQL database directly; however, Microsoft has provided the `SqlTrackingQuery` class defined within the `System.Workflow.Runtime.Tracking` namespace for this purpose. The following example code shows how to retrieve a list of all workflows tracked between two dates:

```
public IList<SqlTrackingWorkflowInstance> GetWorkflows
  (DateTime startDate, DateTime endDate, string connectionString)
{
  SqlTrackingQuery query = new SqlTrackingQuery (connectionString);

  SqlTrackingQueryOptions queryOptions = new SqlTrackingQueryOptions();
  query.StatusMinDateTime = startDate;
  query.StatusMaxDateTime = endDate;

  return (query.GetWorkflows (queryOptions));
}
```

This uses the `SqlTrackingQueryOptions` class, which defines the query parameters. You can define other properties of this class to further constrain the workflows retrieved.

In Figure 57-20 you can see that all activities have executed. This might not be the case if the workflow were still running or if there were some decisions made within the workflow so that different paths were taken during execution. The tracking data contains details such as which activities have executed, and this data can be correlated with the activities to produce the image in Figure 57-20. It is also possible to extract data from the workflow as it executes, which could be used to form an audit trail of the execution flow of the workflow.

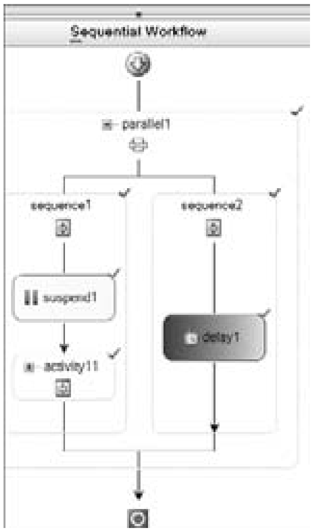

FIGURE 57-20

Custom Services

In addition to built-in services such as the persistence service and the tracking service, you can add your own objects to the services collection maintained by the `WorkflowRuntime`. These services are typically defined using an interface and an implementation, so that you can replace the service without recoding the workflow.

The state machine presented earlier in the chapter uses the following interface:

```
 [ExternalDataExchange]
public interface IDoorService
{
    void LockDoor();
    void UnlockDoor();

    event EventHandler<ExternalDataEventArgs> RequestEntry;
    event EventHandler<ExternalDataEventArgs> OpenDoor;
    event EventHandler<ExternalDataEventArgs> CloseDoor;
    event EventHandler<ExternalDataEventArgs> FireAlarm;

    void OnRequestEntry(Guid id);
    void OnOpenDoor(Guid id);
    void OnCloseDoor(Guid id);
    void OnFireAlarm();
}
```

The interface consists of methods that are used by the workflow to call the service and events raised by the service that are consumed by the workflow. The use of the `ExternalDataExchange` attribute indicates to the workflow runtime that this interface is used for communication between a running workflow and the service implementation.

Within the state machine, there are a number of instances of the `CallExternalMethodActivity` that are used to call methods on this external interface. One example is when the door is locked or unlocked — the workflow needs to execute a method call to the `UnlockDoor` or `LockDoor` methods, and the service responds by sending a command to the door lock to unlock or lock the door.

When the service needs to communicate with the workflow, this is done by using an event, because the workflow runtime also contains a service called the `ExternalDataExchangeService`, which acts as a proxy for these events. This proxy is used when the event is raised, because the workflow may not be loaded in memory at the time the event is delivered. So the event is first routed to the external data exchange service, which checks to see if the workflow is loaded, and, if not, rehydrates it from the persistence store and then passes the event on into the workflow.

The code used to construct the `ExternalDataExchangeService` and to construct proxies for the events defined by the service is shown here:

```
WorkflowRuntime runtime = new WorkflowRuntime();
ExternalDataExchangeService edes = new ExternalDataExchangeService();

runtime.AddService(edes);
DoorService service = new DoorService();
edes.AddService(service);
```

This constructs an instance of the external data exchange service and adds it to the runtime. It then creates an instance of the `DoorService` (which itself implements `IDoorService`) and adds this to the external data exchange service.

The `ExternalDataExchangeService.Add` method constructs a proxy for each event defined by the custom service so that a persisted workflow can be loaded prior to delivery of the event. If you don't host your service within the external data exchange service, when you raise events there will be nothing listening to these events, so they will not be delivered to the correct workflow.

Events use the `ExternalDataEventArgs` class, because this includes the workflow instance ID that the event is to be delivered to. If there are other values that need to be passed from an external event to a workflow, you should derive a class from `ExternalDataEventArgs` and add these values as properties to that class.

INTEGRATION WITH WINDOWS COMMUNICATION FOUNDATION

Two activities are available starting with .NET 3.5 that support integration between workflows and WCF. These are the `SendActivity` and the `ReceiveActivity`. The `SendActivity` could more aptly be called the `CallActivity`, because what it does is issue a request to a WCF service and can optionally surface the results as parameters that can be bound within the calling workflow.

Somewhat more interesting, however, is the `ReceiveActivity`. This allows a workflow to become the implementation of a WCF service, so now the workflow is the service. The following example exposes a service using a workflow and also uses the new service test host tool to test the service without having to write a separate test harness.

From the New Project menu in Visual Studio 2010, choose the WCF node and then the Sequential Workflow Service Library entry as shown in Figure 57-21.

FIGURE 57-21

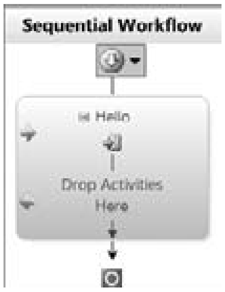

FIGURE 57-22

This will create a library that contains a workflow, as shown in Figure 57-22, an application configuration file, and a service interface. The code for this example is available in the `06 ExposeWFService` subdirectory.

The workflow exposes the Hello operation of the contract and also defines properties for the arguments passed to this operation, and the return value of the operation. Then, all you need to do is to add code that provides the execution behavior of the service, and your service is complete.

To do this for the example, drag a `CodeActivity` onto the `ReceiveActivity`, as shown in Figure 57-23, and then double-click that activity to supply the service implementation.

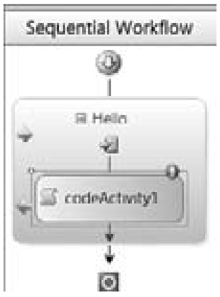

FIGURE 57-23

The code shown in the following snippet is all that there is to this service implementation:

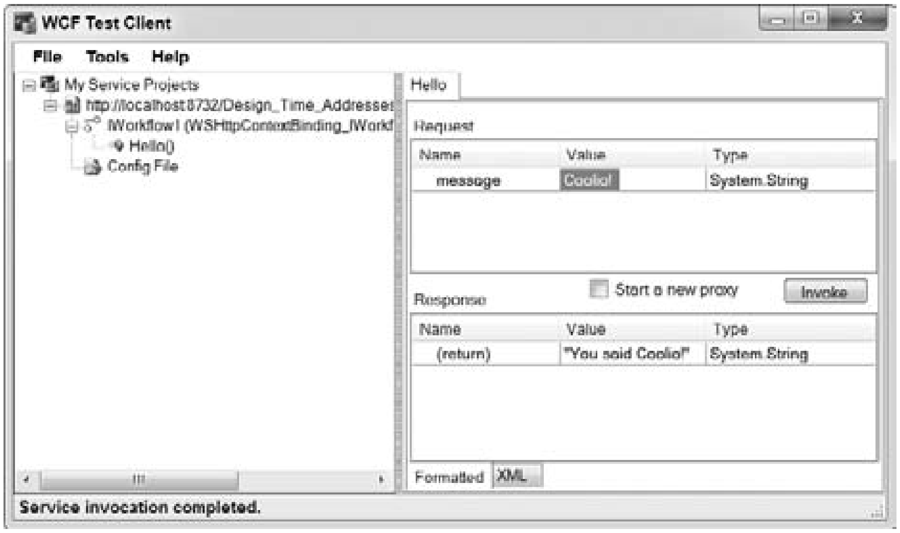
```
public sealed partial class Workflow1: SequentialWorkflowActivity
{
    public Workflow1()
    {
        InitializeComponent();
    }

    public String returnValue = default(System.String);
    public String inputMessage = default(System.String);

    private void codeActivity1_ExecuteCode(object sender, EventArgs e)
    {
        this.returnValue = string.Format("You said {0}", inputMessage);
    }
}
```

Because the service contract for the Hello operation includes both a parameter (`inputMessage`) and a return value, these have been exposed to the workflow as public fields. Within the code, we have set the `returnValue` to a string value, and this is what is returned from a call to the WCF service.

If you compile this service and hit F5, you will notice a feature of Visual Studio 2010 — the WCF Test Client application, as shown in Figure 57-24.



Name	Value	Type
message	Coolio!	System.String

Name	Value	Type
(return)	"You said Coolio!"	System.String

Service invocation completed.

FIGURE 57-24

Here you can browse for the operations that the service exposes, and by double-clicking an operation, the right-hand side of the window is displayed, which lists the parameters used by that service and any return value(s) exposed.

To test the service, enter a value for the message property and click the Invoke button. This will then make a request over WCF to the service, which will construct and execute the workflow, call the code activity, which then runs the code-behind, and ultimately return to the WCF Test Client the result from the workflow.

If you wish to manually host workflows as services, you can use the new `WorkflowServiceHost` class defined within the `System.WorkflowServices` assembly. The following snippet shows a minimal host implementation:

```
using (WorkflowServiceHost host = new WorkflowServiceHost
                                    (typeof(YourWorkflow)))
{
  host.Open();
  Console.WriteLine ( "Press [Enter] to exit" );
  Console.ReadLine();
}
```

Here we have constructed an instance of `WorkflowServiceHost` and passed it the workflow that will be executed. This is similar to how you would use the `ServiceHost` class when hosting WCF services. It will read the configuration file to determine which endpoints the service will listen on and then await service requests.

The next section describes some other options you have for hosting workflows.

HOSTING WORKFLOWS

The code to host the `WorkflowRuntime` in a process will vary based on the application itself.

For a Windows Forms application or a Windows Service, it is typical to construct the runtime at the start of the application and store this in a property of the main application class.

In response to some input in the application (such as the user clicking a button on the user interface), you might then construct an instance of a workflow and execute this instance locally. The workflow may well need to communicate with the user — so, for example, you might define an external service that prompts the user for confirmation before posting an order to a back-end server.

When hosting workflows within ASP.NET, you would not normally prompt the user with a message box but instead navigate to a different page on the site that requested the confirmation and then present a confirmation page. When hosting the runtime within ASP.NET, it is typical to override the `Application_Start` event and construct an instance of the workflow runtime there so that it is accessible within all other parts of the site. You can store the runtime instance in a static property, but it is more usual to store this in application state and provide an accessor method that will retrieve the workflow runtime from application state so that it can be used elsewhere in the application.

In either scenario — Windows Forms or ASP.NET — you will construct an instance of the workflow runtime and add services to it as shown here:

```
WorkflowRuntime workflowRuntime = new WorkflowRuntime();

workflowRuntime.AddService(
    new SqlWorkflowPersistenceService(conn, true, new TimeSpan(1,0,0),
                                      new TimeSpan(0,10,0)));
// Execute a workflow here.
```

To execute a workflow, you need to create an instance of that workflow using the `CreateInstance` method of the runtime. There are a number of overrides of this method that can be used to construct an instance of a code-based workflow or a workflow defined in XML.

Up to this point in the chapter, you have considered workflows as .NET classes — and indeed that is one representation of a workflow. You can, however, define a workflow using XML, and the runtime will construct an in-memory representation of the workflow and then execute it when you call the `Start` method of the `WorkflowInstance`.

Within Visual Studio, you can create an XML-based workflow by choosing the Sequential Workflow (with code separation) or the State Machine Workflow (with code separation) items from the Add New Item dialog. This will create an XML file with the extension `.xoml` and load it into the Designer.

When you add activities to the Designer, these activities are persisted into the XML, and the structure of elements defines the parent/child relationships between the activities. The following XML shows a simple sequential workflow that contains an `IfElseAcvtivity` and two code activities, one on each branch of the `IfElseActivity`:

```
<SequentialWorkflowActivity x:Class="DoorsWorkflow.Workflow1" x:Name="Workflow1"
  xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
  xmlns="http://schemas.microsoft.com/winfx/2006/xaml/workflow">
  <IfElseActivity x:Name="ifElseActivity1">
    <IfElseBranchActivity x:Name="ifElseBranchActivity1">
      <IfElseBranchActivity.Condition>
        <CodeCondition Condition="Test" />
      </IfElseBranchActivity.Condition>
      <CodeActivity x:Name="codeActivity1" ExecuteCode="DoSomething" />
    </IfElseBranchActivity>
    <IfElseBranchActivity x:Name="ifElseBranchActivity2">
      <CodeActivity x:Name="codeActivity2" ExecuteCode="DoSomethingElse" />
    </IfElseBranchActivity>
  </IfElseActivity>
</SequentialWorkflowActivity>
```

The properties defined on the activities are persisted into the XML as attributes, and each activity is persisted as an element. As you can see from the XML, the structure defines the relationship between parent activities (such as the `SequentialWorkflowActivity` and the `IfElseActivity`) and the child activities.

Executing an XML-based workflow is no different from executing a code-based workflow — you simply use an override of the `CreateWorkflow` method that takes an `XmlReader` instance, and then start that instance by calling the `Start` method.

One benefit of using XML-based workflows over code-based workflows is that you can then easily store the workflow definition within a database. You can load up this XML at runtime and execute the workflow, and you can very easily make changes to the workflow definition without having to recompile any code.

Changing a workflow at runtime is also supported whether the workflow is defined in XML or code. You construct a `WorkflowChanges` object, which contains all of the new activities to be added to the workflow, and then call the `ApplyWorkflowChanges` method defined on the `WorkflowInstance` class to persist these changes. This is exceptionally useful, because business needs often change and, for example, you might want to apply changes to an insurance policy workflow so that you send an e-mail to the customers a month prior to the renewal date to let them know their policy is due for renewal. Changes are made on an instance-by-instance basis, so if you had 100 policy workflows in the system, you would need to make these changes to each individual workflow.

THE WORKFLOW DESIGNER

To complete this chapter, we've left the best until last. The Workflow Designer that you use to design workflows isn't tied to Visual Studio — you can rehost this Designer within your own application as necessary.

This means that you could deliver a system containing workflows and permit end users to customize the system without requiring them to have a copy of Visual Studio. Hosting the Designer is, however, fairly complex, and we could devote several chapters to this one topic, but we are out of space. A number of examples of rehosting are available on the Web — we recommend reading the MSDN article on hosting the Designer available at `http://msdn2.microsoft.com/en-us/library/aa480213.aspx` for more information.

The traditional way of allowing users to customize a system is by defining an interface and then allowing the customer to implement this interface to extend processing as required.

With Windows Workflow that extension becomes a whole lot more graphic, because you can present users with a blank workflow as a template and provide a toolbox that contains custom activities that are appropriate for your application. They can then author their workflows and add in your activities or custom activities they have written themselves.

MOVING FROM WF 3.X TO WF 4

With .NET 4 and Visual Studio .NET 2010 there is a new version of WF, and this new version is not backwards compatible with 3.*x*. The concepts are much the same; however the implementation is completely different. One upside of this is that you can continue to run 3.x workflows without any modification; however, if you want to take advantage of the new features then you will have to migrate your applications. In this section I cover the main points of that migration process, and provide some suggestions for simplifying the process.

For more detail on WF 4, see Chapter 44, "Windows Workflow Foundation 4."

Extract Activity Code into Services

The class hierarchy for WF 4 is significantly different from that of WF 3.*x*; however, the activity class is much the same, so to simplify an upgrade I would recommend removing inline code from an activity and instead moving that into a set of services (such as simple .NET classes that contain static methods).

The nature of data bindings has changed considerably in WF 4, so whereas in WF 3.*x* you might use dependency properties and/or standard .NET properties, in WF 4 you'll need to use argument objects. The simplest way to migrate your code is to move all processing from within the activity and out into a separate class. As a trivial example, consider the snippet for a WriteLine activity:

```
public class WriteLineActivity : Activity
{
    public string Message { get; set; }

    public override ActivityExecutionStatus Execute
    ( ActivityExecutionContext context )
    {
        Console.WriteLine ( Message ) ;
        return ActivityExecutionStatus.Closed;
    }
}
```

If you wished to convert this to a WF 4 activity, you might wish to create a class as follows:

```
public static class WriteLineService
{
    public static void WriteLine ( string message )
    {
        Console.WriteLine ( message ) ;
    }
}
```

You could then use this inside the current activity (and also unit test it in isolation), and when you upgrade to WF 4 there will be less code to write. While this is a trivial example, it shows how to simplify an upgrade.

Remove Code Activities

Workflow 4 does not include the same code-behind style of activity that existed in 3.*x* and, therefore, if you have any code in a code-behind file, you should use the previous suggestion to port this into a library in order to be able to use it in WF 4.

Run 3.x and 4 Side by Side

If at all possible, strive to run 3.*x* workflows alongside 4 workflows until no more 3.*x* workflows exist. The persistence store and tracking store are different for 4, so a combined system is the easiest way to go. If you have no long-running workflows, then the issue is moot; however, where you do have long-running workflows, it's easiest to leave the old workflows unchanged and ensure that any new workflows created are on 4.

When your application starts a workflow, is it possible to replace this code easily with something that will start a WF 4 workflow? If not, I would recommend adding in a version-aware execution policy into your code, so that you don't have to alter the class calling the workflow in order to schedule a new workflow instance.

Consider Moving State Machines to Flowcharts

Workflow 4 currently does not support state machines — or rather there is no built-in support for state machines as yet. The underlying activity model can handle state machines (and indeed any workflow processing model you could think up); however, in the initial WF 4 release, there is no state machine activity or any design support.

The closest match to the 3.*x* state machine is the 4 flowchart. It's not an exact match by any means, but it does permit a workflow to jump back to an earlier phase of processing, which is what state machine workflows typically do.

SUMMARY

Windows Workflow will produce a radical change in the way that applications are constructed. You can now surface complex parts of an application as activities, and permit users to alter the processing of the system simply by dragging and dropping activities into a workflow.

There is almost no application that you could not apply workflow to — from the simplest command-line tool to the most complex system containing many hundreds of modules. Although the new communication capabilities of WCF and the new UI capabilities of Windows Presentation Foundation are a great step forward for applications in general, the advent of Windows Workflow will produce a seismic change in the way that applications are developed and configured.

Workflow 3.*x* is largely superseded by WF 4 in Visual Studio 2010, and this chapter provides some guidance on simplifying the upgrade. If you are planning on using workflow for the first time I recommend starting with version 4 and bypassing the 3.*x* version entirely.

Start using the new features of C# 4 and .NET 4 right away

The new C# 4 language version is indispensable for writing code in Visual Studio® 2010. This essential guide emphasizes that C# is the language of choice for your .NET 4 applications. The unparalleled author team of experts begins with a refresher of C# basics and quickly moves on to provide detailed coverage of all the recently added language and Framework features so that you can start writing Windows applications and ASP.NET web applications immediately.

- Reviews the .NET architecture, objects, generics, inheritance, arrays, operators, casts, delegates, events, Lambda expressions, and more
- Details integration with dynamic objects in C#, named and optional parameters, COM-specific interop features, and type-safe variance
- Provides coverage of new features of .NET 4, Workflow Foundation 4, ADO.NET Data Services, MEF, the Parallel Task Library, and PLINQ
- Has deep coverage of great technologies including LINQ, WCF, WPF, flow and fixed documents, and Silverlight™
- Reviews ASP.NET programming and goes into new features such as ASP.NET MVC and ASP.NET Dynamic Data
- Discusses communication with WCF, MSMQ, peer-to-peer, and syndication

Christian Nagel is a Microsoft Regional Director, software architect, and author of many .NET books. He founded CN innovation and is an associate of thinktecture.

Bill Evjen is Global Head of Platform Architecture for Thomson Reuters, Lipper. He is also a Microsoft Regional Director and the founder of INETA.

Jay Glynn is the Principle Architect at PureSafety, a leading provider of results-driven software and information solutions for workforce safety and health.

Karli Watson is a freelance author and a consultant for Infusion Development.

Morgan Skinner works in premier support for developers at Microsoft.
